         5.2.1.7 Magnetic resonance imaging 19

6. DISEASE MANAGEMENT IN MALES 21
   6.1 Conservative options 21
      6.1.1 Observation 21
      6.1.2 Suprapubic catheter 22
   6.2 Endoluminal treatment of anterior urethral strictures in males 22
      6.2.1 Direct vision internal urethrotomy 22
         6.2.1.1 Indications of “cold knife” direct vision internal urethrotomy 22
            6.2.1.1.1 Direct vision internal urethrotomy for primary stricture treatment 22
            6.2.1.1.2 Direct vision internal urethrotomy for recurrent strictures and as salvage treatment after failed urethroplasty 23
            6.2.1.1.3 Predictors of failure of “cold knife” direct vision internal urethrotomy 24
         6.2.1.2 Indications of “hot-knife” direct vision internal urethrotomy 25
            6.2.1.2.1 Laser urethrotomy 25
            6.2.1.2.2 Plasmakinetic (bipolar) urethrotomy 25
         6.2.1.3 Complications of direct vision internal urethrotomy 25
6.2.1.3.1 Complications of “cold knife” direct vision internal urethrotomy 25
6.2.1.3.2 Complications of “hot knife” direct vision internal urethrotomy 26
6.2.1.3.3 Complications of “cold knife” vs. “hot knife” direct vision internal urethrotomy 26
6.2.1.3.4 Complications of direct vision internal urethrotomy vs. dilatation 26
6.2.1.3.5 Complications of “cold knife” direct vision internal urethrotomy vs. urethroplasty 26

6.2.2 Single dilatation 27
6.2.2.1 Modalities of dilatation and results 27
6.2.2.2 Effectiveness of dilatation compared with direct vision internal urethrotomy 28

6.2.3 Post-dilatation/direct vision internal urethrotomy strategies 28
6.2.3.1 Intermittent self-dilatation 28
6.2.3.1.1 Results 28
6.2.3.1.2 Complications 29
6.2.3.1.3 Intermittent self-dilatation combined with intra-urethral corticosteroids 29

6.2.3.2 Intralvesional injections 29
6.2.3.2.1 Steroids 30
6.2.3.2.2 Mitomycin C 30
6.2.3.2.3 Platelet rich plasma 30

6.2.3.3 Urethral stents 30
6.2.3.3.1 Results 30

6.2.3.4 Drug-coated balloon dilatation 31
6.2.3.4.1 Treatment of stent failure 31

6.3 Open repairs (urethroplasty): site and aetiology (clinical scenario) treatment options 33
6.3.1 The role of urethroplasty in the management of penile urethral strictures 33
6.3.1.1 Staged augmentation urethroplasty 33
6.3.1.2 Single-stage augmentation urethroplasty 33
6.3.1.3 Anastomotic urethroplasty in men with penile urethral strictures 34
6.3.1.4 Specific considerations for failed hypospadias repair-related strictures 34
6.3.1.5 Specific considerations for lichen sclerosus-related penile urethral strictures 35
6.3.1.6 Distal urethral strictures (meatal stenosis, fossa navicularis strictures) 36

6.3.2 Urethroplasty for bulbar strictures 37
6.3.2.1 “Short” bulbar strictures 37
6.3.2.1.1 Excision and primary anastomosis 37
6.3.2.1.1.1 Excision and primary anastomosis with transection of corpus spongiosum (transecting EPA) 37
6.3.2.1.1.2 Non-transecting excision and primary anastomosis 38
6.3.2.1.1.2.1 Patency rates 38
6.3.2.1.1.2.2 Complications 38

6.3.2.1.2 Free graft urethroplasty 38
6.3.2.2 “Longer” bulbar strictures 39
6.3.2.2.1 Free graft urethroplasty 39
6.3.2.2.2 Augmented anastomotic repair 39
6.3.2.2.3 Location of the graft during urethroplasty for bulbar strictures 39

6.3.3 Staged urethroplasty for bulbar urethral strictures 40
6.3.3.1 Indications 40
6.3.3.2 Outcomes 40
6.3.3.3 Risk factors 41
6.3.2.3.4 Risk factors for adverse outcomes 41
6.3.2.4 Management of recurrence after bulbar urethroplasty 42
6.3.3 Urethroplasty for penobulbar or panurethral strictures 42
6.3.4 Perineal urethrostomy 43
  6.3.4.1 Indications 43
  6.3.4.2 Types of perineal urethrostomy 43
  6.3.4.3 Outcomes 44
    6.3.4.3.1 Patency rates 44
    6.3.4.3.2 Complications 44
    6.3.4.3.3 Patient reported outcomes 44
    6.3.4.3.4 Risk factors for patency failure of the perineal urethrostomy 44
6.3.5 Posterior urethra 45
  6.3.5.1 Non-traumatic posterior urethral stenosis 45
    6.3.5.1.1 Treatment of non-traumatic posterior urethral stenosis 45
    6.3.5.1.2 Endoluminal management of non-traumatic posterior urethral stenosis 45
      6.3.5.1.2.1 Dilatation of non-traumatic posterior urethral stenosis 45
      6.3.5.1.2.2 Endoscopic incision/resection of non-traumatic posterior urethral stenosis (Table 6.8) 45
    6.3.5.1.2.3 Post-dilatation/direct vision internal urethrotomy strategies for non-traumatic posterior urethral stenosis 47
      6.3.5.1.2.3.1 Intermittent self-dilatation for non-traumatic posterior urethral stenosis 47
      6.3.5.1.2.3.2 Intraluminal injections for non-traumatic posterior urethral stenosis 47
      6.3.5.1.2.3.3 Urethral stent for non-traumatic posterior urethral stenosis 47
    6.3.5.1.3 Lower urinary tract reconstruction for non-traumatic posterior urethral stenosis 48
      6.3.5.1.3.1 Redo vesico-urethral anastomosis for vesico-urethral anastomotic stenosis after radical prostatectomy 49
      6.3.5.1.3.2 Posterior stenosis after surgery for benign prostatic obstruction 50
        6.3.5.1.3.2.1 Bladder neck reconstruction for bladder neck stenosis after surgery for benign prostatic obstruction 50
        6.3.5.1.3.2.2 Bulbomembranous strictures after surgery for benign prostatic obstruction 50
      6.3.5.1.3.3 Radiation/high-energy induced posterior strictures 51
        6.3.5.1.3.3.1 Bulbomembranous strictures secondary to radiation/high energy sources 51
        6.3.5.1.3.3.2 Prostatic strictures secondary to radiation/high energy sources 51
    6.3.5.1.4 Extirpative surgery and urinary diversion for non-traumatic posterior urethral stenosis 52
6.3.5.2 Post-traumatic posterior stenosis
6.3.5.2.1 Endoluminal treatment for post-traumatic posterior stenosis
  6.3.5.2.1.1 Endoluminal treatment as primary treatment for post-traumatic posterior stenosis
  6.3.5.2.1.2 Endoluminal treatment after failed urethroplasty for post-traumatic posterior stenosis
6.3.5.2.2 Urethroplasty for post-traumatic posterior stenosis
  6.3.5.2.2.1 First urethroplasty for post-traumatic posterior stenosis
    6.3.5.2.2.1.1 Indication and technique of urethroplasty for post-traumatic posterior stenosis
    6.3.5.2.2.1.2 Patency rate after urethroplasty for post-traumatic posterior stenosis
    6.3.5.2.2.1.3 Sexual function, urinary continence, and rectal injury after urethroplasty for post-traumatic posterior stenosis
  6.3.5.2.2.2 ReDo-urethroplasty for post-traumatic posterior stenosis

7. DISEASE MANAGEMENT IN FEMALES 56
7.1 Signs and symptoms of female urethral strictures
7.2 Diagnosis of female urethral strictures
7.3 Treatment of female urethral strictures
  7.3.1 Minimally invasive techniques for treatment of female urethral strictures
    7.3.1.1 Urethrotomy for treatment of female urethral strictures
    7.3.1.2 Urethral dilatation for treatment of female urethral strictures
    7.3.1.3 Meatoplasty for treatment of female urethral strictures
  7.3.2 Urethroplasty for treatment of female urethral strictures
    7.3.2.1 Vaginal graft augmentation urethroplasty for treatment of female urethral strictures
    7.3.2.2 Vaginal flap augmentation urethroplasty for treatment of female urethral strictures
    7.3.2.3 Labial/vestibular graft augmentation urethroplasty for treatment of female urethral strictures
    7.3.2.4 Labial/vestibular flap urethroplasty for treatment of female urethral strictures
    7.3.2.5 Buccal and lingual mucosal graft augmentation urethroplasty for treatment of female urethral strictures
    7.3.2.6 Anastomotic urethroplasty

8. DISEASE MANAGEMENT IN TRANSGENDER PATIENTS 60
8.1 Treatment of strictures in trans men
  8.1.1 Management of strictures early after neophallic reconstruction
  8.1.2 Treatment of meatal stenosis in trans men
  8.1.3 Treatment of strictures at the neophallic urethra
  8.1.4 Treatment of strictures at the anastomosis neophallic urethra-fixed part of the urethra
  8.1.5 Treatment of strictures at the fixed part of the urethra
  8.1.6 Definitive perineostomy in trans men
8.2 Peri-operative care after treatment of strictures in trans men
8.3 Strictures in trans women
9. TISSUE TRANSFER
  9.1 Comparison of grafts with flaps
  9.2 Comparison of different types of flaps
  9.3 Comparison of different types of grafts
  9.4 Tissue engineered grafts
    9.4.1 Cell-free tissue engineered grafts
    9.4.2 Autologous tissue engineered oral mucosa grafts
  9.5 Management of oral cavity after buccal mucosa harvesting

10. PERI-OPERATIVE CARE OF URETHRAL SURGERY
    10.1 Urethral rest
    10.2 Antibiotics
    10.3 Catheter management

11. FOLLOW-UP
    11.1 Rationale for follow-up after urethral surgery
    11.2 Definition of success after urethroplasty surgery
    11.3 Follow-up tools after urethral surgery
      11.3.1 Diagnostic tools for follow-up after urethral surgery
        11.3.1.1 Calibration during follow-up after urethral surgery
        11.3.1.2 Urethrocystoscopy during follow-up after urethral surgery
        11.3.1.3 Retrograde urethrogram and voiding cystourethrogram during follow-up after urethral surgery
        11.3.1.4 Urethral ultrasound – Sonourethrography during follow-up after urethral surgery
      11.3.2 Screening tools for follow-up after urethral surgery
        11.3.2.1 Flow-rate analysis during follow-up after urethral surgery
        11.3.2.2 Post-void residual ultrasound measure during follow-up after urethral surgery
        11.3.2.3 3 Symptom questionnaires during follow-up after urethral surgery
      11.3.3 Quality of life assessment, including disease specific questionnaires during follow-up after urethral surgery
    11.4 Ideal follow-up interval after urethral surgery
    11.5 Length of follow-up after urethral surgery
    11.6 Risk-stratified proposals during follow-up after urethral surgery
    11.7 Follow-up protocol proposal after urethroplasty
      11.7.1 Surgeries with low risk of recurrence
      11.7.2 Surgical management options with standard risk of recurrence

13. CONFLICT OF INTEREST

14. CITATION INFORMATION
1. INTRODUCTION

1.1 Aims and scope
The European Association of Urology (EAU) Urethral Strictures Guidelines aim to provide a comprehensive overview of urethral strictures in male, female, and transgender patients. The Panel is aware of the geographical variations in healthcare provision.

It must be emphasised that guidelines present the best evidence available to the experts; however, following guideline recommendations will not necessarily result in the best outcome. Guidelines can never replace clinical expertise when making treatment decisions for individual patients, but rather help to focus decisions - also taking personal values and preferences/individual circumstances of patients into account. Guidelines are not mandates and do not purport to be a legal standard of care.

1.2 Panel composition
The EAU Urethral Strictures Guidelines panel consists of an international multidisciplinary group of clinicians with particular expertise in this area. All experts involved in the production of this document have submitted potential conflict of interest statements which can be viewed on the EAU website: http://www.uroweb.org/guideline/urethral-strictures/.

1.3 Available publications
Alongside the full text version, a quick reference document (Pocket Guidelines) is available in print and as an app for iOS and Android devices. These are abridged versions which may require consultation together with the full text version. All documents can be viewed through the EAU website: http://www.uroweb.org/guideline/urethral-strictures/. A list of supplementary tables supporting this text can also be found online, along with an appendix of abbreviations specific to this text: https://uroweb.org/guideline/urethralstrictures/?type=appendices-publications.

1.4 Publication history
This Guideline was first published in 2021. Additional information can be found in the general Methodology section of this print, and online at the EAU website: http://www.uroweb.org/guideline/. A list of associations endorsing the EAU Guidelines can also be viewed online at the above address.

2. METHODOLOGY

2.1 Methods
For the 2021 Urethral Strictures Guidelines, new and relevant evidence was identified, collated, and appraised through a structured assessment of the literature. A broad and comprehensive literature search, covering all sections of the Guidelines was performed. Databases searched included Medline, EMBASE, and the Cochrane Libraries, covering a time frame between 2008 and 2019 and restricted to English language publications. The panel defined by consensus inclusion and exclusion criteria for each topic before the scope search. Detailed search strategies are available online: https://uroweb.org/guideline/urethral-strictures/.

For each recommendation within the guidelines there is an accompanying online strength rating form which includes the assessment of the benefit to harms ratio and patients’ preferences for each recommendation. The strength rating forms draws on the guiding principles of the GRADE methodology but do not purport to be GRADE [1, 2].

Each strength rating form addresses a number of key elements namely:

1. the overall quality of the evidence which exists for the recommendation, references used in this text are graded according to a classification system modified from the Oxford Centre for Evidence-Based Medicine Levels of Evidence [3];
2. the magnitude of the effect (individual or combined effects);
3. the certainty of the results (precision, consistency, heterogeneity and other statistical or study related factors);
4. the balance between desirable and undesirable outcomes;
5. the impact of patient values and preferences on the intervention;
6. the certainty of those patient values and preferences.
These key elements are the basis which panels use to define the strength rating of each recommendation. The strength of each recommendation is represented by the words ‘strong’ or ‘weak’ [4]. The strength of each recommendation is determined by the balance between desirable and undesirable consequences of alternatives.

The Panel wants to highlight that “success” in urethral stricture treatment is poorly defined and subjective. “Success” is usually defined as urethral patency, either subjective by the absence of voiding symptoms or objective by imaging or urethral calibration. Despite urethral patency, the patient themselves might not consider the treatment as successful because of functional consequences (e.g., post-void dribbling, erectile/ejaculatory dysfunction, altered genital appearance). In this Guideline, the Panel agreed to avoid the term “success”. Instead, the term “patency rate” or “stricture recurrence rate” will be used to clarify that only stricture recurrence was taken into consideration (as assessed by the authors).

The Panel would like to stress that patency after urethral surgery is dependent on the general principles of wound healing. These principles have stood the test of time and need to be respected [5]. Some examples:

- An anastomosis should be made between healthy urethral ends and without any tension.
- A graft requires a well-vascularised graft bed with a close contact between the graft and graft bed to promote imbibition and inosculation.
- If the full circumference of the urethral mucosa is destroyed, spontaneous regeneration will not take place.
- Contraction and fibrosis in a wound only stops after it is covered by its epithelium.

The Panel conducted two systematic reviews (SR) to support guideline recommendations, which were published in 2021:

- What is the role of single-stage oral mucosa graft urethroplasty in the surgical management of Lichen Sclerosus-related stricture disease in men? A systematic review [6];
- Free Graft Augmentation Urethroplasty for Bulbar Urethral Strictures: Which Technique Is Best? A Systematic Review [7].

The results of these reviews are included in the 2023 Urethral stricture guidelines.

In addition, the panel drafted three summary papers of the guidelines which were published in European Urology and European Urology Focus:

- EAU guidelines on urethral stricture disease (part 1): management of male urethral stricture disease [8];
- EAU Guidelines on urethral stricture disease (part 2): diagnosis, perioperative management, and follow-up in males [9];
- EAU guidelines on urethral stricture disease (part 3): management of strictures in females and transgender patients [10].

2.2 Review

The Urethral Strictures Guidelines were peer reviewed prior to initial publication in 2021.

3. DEFINITION, EPIDEMIOLOGY, AETIOLOGY AND PREVENTION

3.1 Definitions

In males, a urethral stricture refers to a narrowed segment of the anterior urethra due to a process of fibrosis and cicatrisation of the urethral mucosa and surrounding spongious tissue (“spongiofibrosis”) [11, 12]. In the male posterior urethra, there is no spongious tissue and at this location the terms stenosis is preferred [11, 12]. The definition of meatal stenosis is generally accepted as a short distal narrowing at the meatus, without involvement of the fossa navicularis [12].

There is no universal definition for what constitutes a female urethral stricture (FUS). Female urethral stricture is defined by most authors as a ‘fixed anatomical narrowing’ causing reduced urethral calibre [13, 14]. This reduced urethral calibre is variously defined as between < 10 Fr to < 20 Fr [15, 16] with the majority of series defining < 14 Fr as diagnostic, compared with a ‘normal’ urethral calibre of 18-30 Fr.
In transgender patients, the term stricture is also used to define a narrowing of the reconstructed urethra despite the absence of surrounding spongious tissue.

3.2 Epidemiology

In males, a sharp increase in incidence is observed after the age of 55 years, with a mean age of 45.1 [17, 18]. Overall, the incidence is estimated to be 229-627 per 100,000 males [17]. The anterior urethra is most frequently affected (92.2%), in particular the bulbar urethra (46.9%) [18].

In females, 2-29% of patients presenting with refractory lower urinary tract symptoms (LUTS) have bladder outflow obstruction (BOO) [19-22] of whom 4-20% will have a urethral stricture [21-23]. True FUS therefore occurs in 0.08-5.4% of women with refractory LUTS. There is a markedly increased incidence in women over 64 years of age [24].

After hypospadias repair, meatal stenosis and urethral strictures are reported in 1.3-20% of cases, depending on the severity of the hypospadias and the technique used [25]. There is a significantly higher incidence of this type of strictures in well-resourced countries due to a higher surgical repair rate [26].

Up to 18% of all urethral strictures have been reported to involve the meatus or fossa navicularis, usually due to failed hypospadias repair (FHR), lichen sclerosus (LS), trauma/instrumentation or idiopathic causes [27-30]. Meatal stenosis post-circumcision has been reported in less than 0.2% of children undergoing circumcision as neonates [17].

In female-to-male (FtM) transgender patients (“transmen”), 2-56% will suffer a urethral stricture. Strictures almost exclusively arise at the neomeatus in male-to-female (MtF) transgender patients (“transwomen”) and occur in 4-40% of cases [31].

3.3 Aetiology and prevention

Stricture aetiology differs significantly throughout different regions in the world, due to differences in healthcare quality and environmental and practice patterns [26]. Regardless of geography, urethral stricture disease adversely impacts physical health and quality of life (QoL) [32, 33], notwithstanding costs associated with the treatment of primary and recurrent disease [34, 35]. The rationale for preventing urethral strictures is to avoid morbidity to the individual and costs to society. Prevention of urethral strictures encompasses reducing the causes of stricture (e.g., infection, trauma, iatrogenic injury) and where this is not possible, mitigating the risk.

3.3.1 Aetiology and prevention in males

a. Sexually transmitted infection

Urethritis due to sexually transmitted infection (STI), in particular gonorrhoea, was previously a major cause of urethral strictures in well-resourced countries accounting for 40% of all cases [36]. The wide-scale promotion of safe sexual practices and easier access to sexual health services, resulting in timely treatment with antimicrobials, is thought to have led to the considerable reduction in the problem [36]. Infective urethritis now accounts for 0.9% to 4.6% of cases in contemporary series from well-resourced countries [36, 37] but continues to be the major cause of strictures in low-resourced countries comprising 41.6% of all strictures [38].

b. Inflammation

Lichen sclerosus involves the urethra in 20% of cases [39] and is the most common cause of panurethral stricture disease (48.6%) [18]. The aetiology of LS has not been fully elucidated but is thought to have an autoimmune origin [40]. Lichen sclerosus may be associated with environmental factors and non-autoimmune comorbidities. Uncircumcised men are far more likely to suffer LS than circumcised men (age-adjusted odds ratio [OR] of 53.55; 95% confidence interval [CI]: 7.24-395.88) [41]. Lichen sclerosus is also associated with higher mean body mass index (BMI), diabetes mellitus, coronary artery disease, tobacco usage, hyperlipidaemia, and hypertension [42-44].
c. **External urethral trauma**

External trauma to the urethra is the second most common cause of stricture formation in adults [36]. The urethra is vulnerable to trauma during certain activities including sport, driving a vehicle, sexual intercourse and during combat. The bulbar urethra is the site most frequently affected by blunt trauma [12], usually as a result of straddle injuries or kicks to the perineum. Penile fracture is associated with a urethral injury in 15% of cases [45]. Motor vehicle accidents are the main cause of blunt injuries to the posterior urethra associated with pelvic fractures [46]. Penetrating injuries of the urethra are uncommon during non-combat situations [47].

d. **Iatrogenic urethral injury**

Iatrogenic injury to the urethra is one of the most common causes of strictures in well-resourced countries [18, 36] accounting for 32-79% of all strictures [36, 48]. Preventing iatrogenic urethral injury represents the main way in which urologists can prevent urethral strictures. Iatrogenic urethral injury most commonly results from urethral instrumentation (e.g., catheterisation, cystoscopy), surgery for benign prostatic obstruction (BPO), surgery for prostate cancer, or radiotherapy [37].

d.1 **Urethral catheterisation**

Urethral strictures are a recognised complication of urethral catheterisation accounting for 11.2-16.3% of all strictures [18, 36]. In a meta-analysis by Hollingsworth et al., the pooled percentage of patients who developed urethral stricture or erosion after short-term catheterisation (< 3 weeks) in higher-quality studies was 3.4% (CI: 1-7%) [49]. In studies comprised mainly of men with spinal cord injury with indwelling urethral catheters, the pooled estimate of urethral stricture or erosion was 8.7% (CI: 0.0-18.7%) [49].

Urethral strictures following catheterisation may arise as a consequence of injury during attempts at insertion or during the period a catheter remains in situ. During insertion, the urethra may be injured by formation of a false passage by the catheter tip (29.7%) or inflation of the balloon within its lumen (70.3%) [50]. The rate of urethral injuries due to catheterisation was found to be 3.2 per 1,000 inpatients [51]. A six-month prospective multicentre study found that of 37 patients with catheter-related urethral trauma referred to urologists, 24% continued to perform ISD once weekly and 11% required at least one urethral dilation for urethral stricture [52]. In another follow-up study of 37 patients with catheter-related urethral trauma, 78% of patients developed urethral stricture [50]. The most common locations of trauma are the bulbar and posterior urethra [53].

Catheter-related trauma can be prevented through several measures [54]. Studies have indicated around 25% of all indwelling catheterisations in hospitals were unnecessary and inappropriate [55, 56]. Implementation of guidelines [57, 58] and specific criteria [59] have been shown to reduce catheterisation rates. Several studies have identified deficits in the knowledge of urethral catheterisation amongst resident doctors [60, 61]. This is postulated to be a factor in catheter-related trauma [61]. A targeted training program on urethral catheterisation for nursing staff was shown to be effective in reducing iatrogenic urethral injuries in a prospective single institution study [62].

In addition to guidance and education, another approach to safer catheterisation is modification of the standard Foley catheter. A novel catheter balloon pressure safety system was developed to prevent balloon inflation injury though this has not been assessed in comparative studies [63, 64]. Bugajta et al., studied the use of urethral catheterisation device (UCD) incorporating a guidewire, in prospective observational cohort study that included 174 patients. The incidence of adverse events was 7% with standard Foley catheterisation vs. 0% with the UCD (no statistical analysis was performed) [65]. A further prospective observational study found that Seldinger technique catheterisation could be used successfully by non-urology trained doctors [66]. These technologies need to be further assessed in prospective randomised controlled trials (RCTs), incorporating cost-benefit analysis.

Catheter diameter is suggested as a possible contributing factor to urethral stricture due to a pressure effect on the urethral wall [67]. Decreasing the catheter size from 22 Fr to 18 Fr significantly decreased the risk of fossa navicularis strictures (6.9% vs. 0.9%, p=0.02) after radical prostatectomy (RP) [68]. Catheter material may also have an influence on the occurrence of stricture. In the 1970s/80s several comparative studies in patients undergoing cardiac surgery demonstrated that non-coated latex catheters were associated with a greater incidence of urethritis and more stricture formation than silicone catheters [69-71]. Other studies showed no difference [72-74]. Modern latex catheters have polymeric coatings [75] due to the concern with regards to stricture alongside the risk of hypersensitivity and the demonstrable in vitro toxicity of latex. Prolonged urethral catheterisation has also been implicated in the aetiology of stricture (e.g., poly-trauma, burns patients) [48].
A significant proportion of catheter insertions in hospitalised patients were considered unnecessary.  

Education programs can reduce the incidence of catheter-related urethral injury.  

Larger catheter size was associated with a greater risk of navicular fossa strictures.  

Non-coated latex catheters are associated with a greater degree of urethritis and possibly a greater risk of urethral strictures than non-latex catheters or coated latex catheters.

Recommendations

**d.2 Transurethral prostate surgery**

Urethral stricture following transurethral prostate surgery occurs in between 4.5-13% of patients [76], whereas bladder neck stenosis (BNS) occurs in between 0.3-9.7% [77]. Transurethral surgery is the most common cause of iatrogenic urethral stricture accounting for 41% of all causes [48]. The most common location for urethral stricture is the bulbomembranous urethra, followed by the fossa navicularis and penile urethra [78, 79]. Postulated mechanisms include friction at the penoscrotal junction, lack of adequate lubrication, repetitive ‘in and out’ movement of the resectoscope, breach of mucosal integrity leading to urine extravasation and monopolar current leak due to inadequate resectoscope insulation [80]. Bladder neck stenosis may be related to excessive and/or circumferential resection and the use of relatively large resection loops which may generate excessive heat in small intraurethral adenomas leading to scarring [77, 81]. Stenoses of the posterior urethra may also be due to a prolonged period of post-operative inability to void [82].

**d.2.1 Risk factors for development of urethral stricture and bladder neck stenosis**

Several risk factors for the development of urethral stricture and BNS following transurethral prostate surgery have been identified. Both prostatic inflammation (OR: 4.31) and operative time > 60 min (OR: 4.27) were found to be independent predictors of stricture after monopolar transurethral resection of prostate (TURP) [83]. In terms of bipolar TURP, slower resection rate (OR: 0.003), intraoperative urethral mucosa rupture (OR: 2.44) and post-operative infection were shown to be independent predictors (OR: 1.49) [84, 85]. A larger-calibre endoscopic sheath (26 Fr vs. 24 Fr) was associated with a greater risk of bulbar urethral stricture following monopolar TURP (11.4% vs. 2.9%, p=0.018) [86]. Room temperature irrigation solution was associated with a greater risk of urethral stricture following combined transurethral resection and vapourisation of the prostate compared to body temperature irrigation (21.3% vs. 6.3%, p=0.002) [87].

Bladder neck stenosis is known to occur more frequently in smaller prostate glands after both monopolar and bipolar TURP [88, 89]. Lee et al., found that adenoma weight was an independent risk factor for BNS after monopolar TURP [89]. Meanwhile, Tao et al., found total prostate volume (< 46.2 g) (OR: 1.5), but not resected gland weight, to be an independent risk factor [84].

**d.2.2 Incidence of urethral stricture and bladder neck stenosis with different energy modalities**

A SR and meta-analysis by Cornu et al., showed no significant differences in urethral stricture and BNS rates by energy modality (monopolar, bipolar, holmium laser enucleation, photoselective vapourisation) [76]. In another meta-analysis assessing outcomes of thulium (Tm:Yag) laser and bipolar TURP, no difference in urethral stricture and BNS rates were found between the two modalities [90]. The presence of potentially confounding factors such as endoscopic sheath diameter, energy setting used, procedural length and length of follow-up make inter-study comparisons between energy modalities problematic. Overall, there is no strong evidence that any single modality is associated with a clinically significant higher incidence of urethral stricture and BNS than others. Selection of modality should be based on a comprehensive evaluation of clinical safety and efficacy. A summary of incidences of urethral stricture and BNS with different modalities is presented in Table 3.1.

A systematic review analysing different techniques used for BPH surgery, showed the lowest incidence of urethral strictures in enucleation procedures, followed by B-TURP and ablation, and M-TURP. However, after twelve months of follow-up there were no significant differences in stricture rate [91].

d.2.3 Interventions to prevent urethral stricture and bladder neck stenosis

Sciara and colleagues conducted a single-blind RCT (n=96) to assess the use of rofecoxib for stricture prevention following TURP. At twelve months follow-up a urethral stricture was found in 17% and 0% of cases in the placebo and rofecoxib groups, respectively (p=0.0039) [92]. Chung et al., conducted a single blinded RCT (n=180) evaluating the effect of urethral instillation of hyaluronic acid (HA) and carboxymethylcellulose (CMC). Urethral stricture on urethrography was diagnosed in 1.25% and 8.64% of patients in the treatment and placebo group respectively (p=0.031). Further RCTs are needed to confirm these findings and the safety of the pharmacological interventions.

Several earlier comparative studies assessed whether routine preliminary urethrotomy with an Otis urethrotome prevented the incidence of stricture following TURP [93-96]. Only one of these reported at least twelve month follow-up, finding no significant difference in stricture rate in patients undergoing TURP alone vs. Otis urethrotomy followed by TURP (21% vs. 14%) [97]. Others have suggested performing internal urethrotomy where there are pre-existent meatal or urethral strictures [98].

Adjunctive transurethral incision of the prostate (TUIP) at the end of TURP to reduce the rates of BNS was studied by Lee et al. [89]. A total of 1,135 patients of whom 667 underwent TURP and 468 underwent TURP plus TUIP were retrospectively studied. At median follow-up of 38 months, the incidence of BNS was 12.3% for the TURP group vs. 6.0% for the TURP plus TUIP group (p < 0.001). In glands < 30 g, the incidence of BNS in the TURP vs. the TURP plus TUIP group was 19.3% and 7.7%, respectively (p < 0.05). The clinical efficacy and safety of additional surgical interventions to prevent urethral stricture and BNS need to be confirmed in larger prospective RCTs before their use can be recommended.

Summary of evidence

An RCT with more than twelve months follow-up failed to demonstrate a significant reduction in stricture rate using routine urethrotomy prior to TURP. LE 1b

Recommendation

Do not routinely perform urethrotomy when there is no pre-existent urethral stricture. Strength rating Strong

d.3 Radical prostatectomy

Radical prostatectomy has been associated with vesico-urethral anastomosis stricture (VUAS) in 0.5-30% of patients [77], though most modern series report it in the range of 1-3% [99]. The risk of stricture formation after salvage RP is notably higher (22-40%) [100]. Most VUAS develop within the first two years [100, 101]. A 2012 meta-analysis by Tewari et al., showed no significant difference in VUAS between open-, laparoscopic and robotic RP [102]. In contrast, a more recent analysis of a national cohort in the UK found that VUAS rate after robotic RP was 3.3%, which is significantly lower than following laparoscopic (5.7%) or open RP (6.9%) [103]. These findings are consistent with an earlier similar study conducted in the USA [104]. The difference in VUAS rates may be explained by the level of experience and surgical volume of surgeons [105]. The cohort studies represent “real world” data, including all levels of surgical experience and surgical volumes whereas the meta-analysis is based on clinical studies. Thus, the better outcomes for robotic RP in the population studies may be related to the shorter learning curve [106].

d.3.1 Risk factors for development of vesicourethral anastomosis strictures

These include higher grade cancer, more advanced stage, higher prostate volume, coronary artery disease, obesity, hypertension, diabetes mellitus, previous bladder outlet surgery and older age [99, 107, 108]. Surgical factors include the use of non-nerve-sparing technique, anastomotic urine leak, increased operative time and increased estimated blood loss [99, 107, 108]. In addition, low-volume surgeons (< 40/year) were shown to have higher VUAS rates, 27.7%, compared to high-volume surgeons (> 40/year), 22% [109].
d.3.2 Interventions to prevent vesicourethral anastomosis strictures

Srougi et al., studied bladder neck mucosal eversion in a prospective RCT of 95 patients. No significant difference was found in rates of VUAS at twelve months follow-up [110]. A meta-analysis by Kowelewski et al., comparing interrupted vs. continuous vesico-urethral anastomosis suturing found no difference in VUAS rates [111]. Another SR by Bai et al., compared barbed sutures to conventional sutures, and although heterogeneity across studies precluded meta-analysis, no patients developed VUAS with either approach [112].

d.4 Prostate radiation and ablative treatments

Urethral strictures occur in 1.5% of patients undergoing external beam radiation therapy (EBRT), 1.9% having brachytherapy (BT) and 4.9% who receive combination EBRT-BT at around four years follow-up [113]. These strictures typically occur in the bulbomembranous urethra [114]. As opposed to RP, stricture incidence after irradiation increases with time [100, 113]. For the ablative treatments, the stricture incidence after cryotherapy and high-intensity focused ultrasound (HIFU) is 1.1-3.3% and 10.3%, respectively [100, 115]. The use of these modalities in the salvage setting is associated with increased risk of stricture formation: 3-10% after salvage EBRT, 5-12% after salvage cryotherapy and 15-30% after salvage HIFU [100]. Due to the increasing utilisation of prostate irradiation (EBRT, BT) and ablative treatments (cryotherapy, HIFU), an increasing number of respectively radiation-induced and ablative treatment-induced strictures are expected [116].

d.4.1 Risk factors for the development of radiation strictures

Awad et al., performed a multivariate meta-regression analysis including 46 studies, finding combining ERBT + BT and length of follow-up to be significant predictors of urethral stricture following prostate radiation [113]. Factors not shown to predict urethral stricture included biochemical equivalent dose, age, and androgen deprivation therapy [113]. Previous TURP was not included in the analysis, but has been found to be an independent predictor of stricture (HR: 2.81) in a previous multivariate analysis from a single institution [117] as well as PSA level < 10 ng/ml (HR: 0.47) [118].

d.4.2 Interventions to prevent radiation induced urethral strictures

Delaying adjuvant or salvage EBRT by nine months is associated with lower rates of urethral stricture (HR: 0.6) [119]. This has to be balanced with risk of delaying treatment in terms of cancer control [77]. In BT, it has been reported that downward movement of needle applicators occurs between fractions [120]. This may explain why strictures occur below the prostatic apex [118] in the so called “hot spot” [121]. Several measures taken together are thought to have contributed to a reduction in urethral stricture formation with BT including reduction of dose to the “hot spot”, more careful needle placement, avoiding midline insertion and the introduction of plastic needles rather than steel [113].

e. Failed hypospadias repair

Although urethral strictures after hypospadias repair are sometimes considered as iatrogenic [36], they are a very specific subtype and should be considered as a separate entity. The main reasons for this are the absence of spongosus tissue at different levels within the penile urethral segment, and the lack of high-quality local tissues for urethral reconstruction [122].

f. Congenital

The diagnosis of a congenital urethral stricture can only be made in the absence of other possible aetiology, such as iatrogenic, inflammatory, and traumatic causes [123]. Congenital strictures are thought to be consequent to incomplete or incorrect fusion of the urethra formed from the urogenital sinus with the urethra formed following closure of the urethral folds. They typically have a deep bulbar location and are usually short. In general, congenital strictures are diagnosed at a young age (Moorman’s ring or Cobb’s collar).

g. Idiopathic

Idiopathic strictures are seen in 34% of all penile strictures and in 63% of all bulbar strictures [124]. Unrecognised trauma is thought to be a possible aetiology of idiopathic urethral strictures [26].

3.3.2 Aetiology in females

The cause of FUS was idiopathic in 48.5%, iatrogenic in 24.1%, resulting from prior urethral dilations, difficult/traumatic catheterisation with subsequent fibrosis, urethral surgeries (mainly diverticulum surgery, fistula repair and anti-incontinence procedures) and trauma (mainly following pelvic fracture) in 16.4% [125-137]. Radiation therapy and infections are rare causes of FUS [138]. The most common segment of urethra affected is the midor mid-to-distal (58%). Panurethral strictures are rare (4%) [15, 125, 127, 128, 130-132, 137, 139].

For further information see online supplementary Tables S3.1 and S3.2.
4. **CLASSIFICATIONS**

4.1 **According to stricture location**

Classification according to stricture location is important as this will affect further management.

4.1.1 **In males**

4.1.1.1 **Anterior urethra**

The anterior urethra runs from the meatus to the urogenital diaphragm and is surrounded in its entire length by the corpus spongiosum [11, 140]. Further subdivision is made in three different areas (from distal to proximal) [12]:

Meatal strictures: these strictures are located at the external urethral meatus and may extend into the fossa navicularis of the glans.

Penile strictures: these are located in the segment between the fossa navicularis and the bulbar urethra. Externally, the penile urethra begins approximately at the balanopreputial sulcus and continues to the penoscrotal junction. The whole penile urethral segment lies in the groove ventral to corpora cavernosa and is surrounded by a thin layer of corpus spongiosum.

Bulbar strictures: the bulbar urethra starts at the penoscrotal junction and is surrounded by the bulbospongious muscle. It ends in the membranous urethra proximally at the level of the urogenital diaphragm. The bulbar urethra can be subdivided into a proximal and distal part. The proximal bulbar urethra is defined as the segment within 5 cm of the membranous urethra; the urethra lies eccentrically in this part with abundant ventral spongious tissue. The distal bulbar urethra is defined as the adjoining segment extending to the penoscrotal junction [141]. Strictures extending towards the membranous urethra are termed bulbomembranous strictures (BMS).

Penobulbar strictures: these extend from the penile urethra into the bulbar segment, compromising long segments of urethra.

The difference between penobulbar strictures and multifocal strictures should be noted. The latter are defined by two or more narrowed segments, either in the same or different subdivision of the urethra but preserving healthy lengths of urethra between them (e.g., iatrogenic strictures related to TUR procedures which typically affect the fossa navicularis and the penoscrotal junction with healthy urethra in between).

4.1.1.2 **Posterior urethra**

The posterior urethra is approximately 5 cm long, with three different segments [12]:

- The membranous urethra is the area of the urethra traversing the urogenital diaphragm, between the proximal bulbar and the distal verumontanum.
- The prostatic urethra runs through the prostatic gland, starting at the proximal membranous urethra and extending to the bladder neck.
- The bladder neck is surrounded by the internal urinary sphincter and is the junction between the prostatic urethra and the bladder. Stenosis (or contracture) of the bladder neck implies a prostate in situ (i.e., after TURP or simple prostatectomies). If the narrowing or obliteration appears at this level but after a RP, the correct term is VUAS [12].

4.1.2 **In females**

The female urethra is approximately 4 cm long and arbitrarily divided in an upper, mid, and lower part [15, 125, 127, 128, 130-132, 137, 139].

4.2 **According to stricture tightness**

Several classifications systems have been proposed over the years [142]. The definition of low- vs. high-grade strictures remains debatable [143-145]. A urethral plate less than 3 mm is considered a high-grade or tight stricture [146]. It has been demonstrated with a normally functioning bladder that flow rate will not diminish until the urethral lumen has a diameter below 10 Fr [144].

Table 4.1 presents a suggested classification for male patients with a normal functioning bladder. This classification was developed by the EAU Urethral Stricture Panel based on a consensus process.

4.3 Strictures in transgender men and woman

4.3.1 Trans women

After MtF gender confirming surgery, the penile urethra has been resected. Meatal strictures are defined as strictures occurring at the neomeatus, which is formed between the junction of the distal bulbar urethra and the neovagina. The other segments (bulbar and posterior) are the same as in a biological man.

4.3.2 Trans men

Four different areas can be identified in the urethra after FtM gender confirming surgeries [147]:

- The native urethra is the female urethral segment which remains preserved during surgery. It goes from the bladder neck to the original external meatus.
- The fixed part (pars fixa) or perineal urethra follows the native urethra, starting at the original external meatus. This segment is reconstructed using local tissues, typically vestibular mucosa, or anterior vaginal mucosa. Its course is similar to the bulbar urethral segment in males, but without being covered by spongiosal tissue.
- The anastomotic part is the area where the pars fixa joins the neophallus.
- The phallic urethra is the segment located within the neophallus or the metoidioplasty and is usually made of skin tube. Its course is similar to the penile urethra in males, but without being covered by spongiosal tissue.

5. DIAGNOSTIC EVALUATION

A comprehensive diagnostic evaluation of urethral stricture disease encompasses clinical history and examination, urinalysis (+/- culture), uroflowmetry and post-void residual (PVR) assessment, radiography, and endoscopy.

5.1 Patient history

The purpose of history taking is to assess symptoms including severity and duration, possible aetiology, prior treatments, complications, associated problems, and patient factors that may impact upon surgical outcome.

The clinical presentation of urethral stricture disease is varied. In a retrospective analysis of 611 patients with an endoscopically confirmed diagnosis of urethral stricture, LUTS were the most common presentation (54.3%) followed by acute urinary retention (22.3%), urinary tract infection (UTI) (6.1%) and difficult catheterisation (4.8%) [148]. In a retrospective study of 214 patients who underwent anterior urethroplasty, weak stream was reported as the most common individual LUTS (49%) followed by incomplete emptying (27%) and urinary frequency (20%) [149]. A further retrospective series of 614 patients undergoing anterior urethroplasty found post-void dribble to be present in 73% [150].

Genitourinary pain is a common feature, affecting 22.9-71% [34, 148]. Pain may be felt in the bladder and/or urethra, is associated with more severe LUTS, is more likely to be felt by younger men and resolves in most following reconstruction [32]. Other complaints include spraying (9%), visible haematuria (3.1-5%), urethral abscess/necrotising fasciitis (2.3%), urgency (14%) and incontinence (1-4%) [148, 149].

To establish aetiology, an enquiry about a history of pelvic, genital, or perineal trauma, prior instrumentation, prior surgeries, irradiation or focal therapies and urethritis should be made. It is important to document prior surgical approaches and date of the most recent intervention (e.g., dilatation) as this may impact upon the timing of radiological evaluation or surgical treatment.
Problems of sexual function are common in patients with urethral stricture disease [151, 152] and sexual function may be impacted upon by surgical intervention [153, 154]; therefore, the status of erectile and ejaculatory function should be established and documented using validated tools.

The performance status of the patient should be determined as it may influence the choice of treatment (curative or palliative). A past medical history should assess for factors that may impact upon tissue healing including diabetes, immunosuppression, and smoking. Oral tobacco use or the chewing of betel leaves may increase the risk of morbidity at the harvest site or render oral mucosa too poor for use. Prior harvest of oral mucosa should be noted as alternative sources for tissue transfer may need to be considered [155] or alternative surgical approaches (e.g., perineal urethrostomy [PU]).

5.2 Physical examination
The abdomen should be examined for the presence of a palpable bladder. The location of any suprapubic tube should be noted to assess its potential utility for antegrade cystoscopy or the placement of a sound (to facilitate repair) [156]. Examination of the genitalia should note the presence of foreskin, the position and size of the meatus as well as any evidence of scarring suggestive of LS. Pre-operative biopsy to confirm LS may be performed if this alters management and is essential if malignancy is suspected [157].

The presence of penile or perineal fistulae should be noted. The urethra should be palpated to assess for induration suggestive of significant fibrosis. Rarely a mass may signify a urethral carcinoma. A rectal examination to assess for prostatic pathology, which may be the cause of urinary symptoms, should be undertaken. In patients with posterior urethral stenosis rectal adherence to the prostate and the mobility of the surrounding tissues should be assessed [158]. The oral cavity should be examined for the suitability of oral mucosa. Measurement of BMI will identify obese individuals who are at greater risk of leg compartment syndrome when placed in the lithotomy position for a prolonged time period [159]. Assessing hip mobility is important when considering an exaggerated lithotomy position as some patients may have limited hip flexion due to unresolved orthopaedic problems [156].

5.2.1 Further diagnostic evaluation
5.2.1.1 Patient reported outcome measure (PROM)
The first validated urethral stricture surgery PROM (USS-PROM) was reported in 2011 [160]. It consists of six LUTS questions derived from the International Consultation on Incontinence Questionnaire Male LUTS (ICIQ-MLUTS) module, a LUTS-specific QoL question, the Peeling voiding chart and the EQ-5D to assess overall health-related QoL (HRQoL). The post-operative questionnaire contains an additional two questions to assess overall patient satisfaction. This PROM has been validated in several other languages (German, Spanish, Italian, Dutch, Turkish, Polish, Japanese) and is increasingly used in research studies as well as clinical practice. A further PROM is in development in North America but requires validation [161] (see section 11. Follow-up).

5.2.1.2 Urinalysis and urine culture
Urinalysis is an essential component of the work up of patients with LUTS. If infection is suggested, urine culture should be performed to confirm the diagnosis and identify the causative organism and sensitivity to antibiotics. Bacteriuria should be treated prior to surgical intervention to prevent peri-operative sepsis [162] (see section 10. Peri-operative care).
5.2.1.3 Urinary flowmetry and post-void residual estimation

A reduced maximum flow rate with a prolonged plateau is characteristic of the constrictive obstruction caused by urethral stricture. However, interpretation of flow patterns is subjective and is not considered a reliable screening tool for the detection of stricture [163]. To overcome this, a statistical model based on uroflowmetry parameters was developed and found to predict urethral stricture with a sensitivity of 80–81% and a specificity of 77–78% [163]. Uroflowmetry is usually combined with ultrasound (US) estimation of PVR to identify patients with urinary retention who may require emergent bladder drainage. Uroflowmetry parameters can also be used for monitoring patients and in the assessment of treatment response (see section 11. Follow-up).

Urodynamic studies are not indicated in the vast majority of patients with urethral stricture disease. In patients with suspected bladder dysfunction (e.g., severe storage LUTS, history of irradiation or neurological disease), an assessment of bladder function may help surgical decision making and patient counselling. Similarly, when there is concern that flow impairment or increased PVR are due to detrusor underactivity or an acontractile detrusor, a urodynamic study may help predict the likelihood that the patient would need to perform intermittent self-catheterisation (ISC) post-operatively. The only urodynamic parameter found to distinguish a diagnosis of urethral stricture from BPO is urethral closure pressure which is lower in the former due to the constrictive nature of the obstruction (22.07 vs. 28.4 cm H2O, p=0.0039, r=0.61, BPO vs. stricture) [164].

5.2.1.4 Urethrography

Retrograde urethrography (RUG) has widely been used as the investigation of choice for evaluating the stricture presence, location, length, and any associated anomalies (e.g., false passages, diverticula) [165].

The reported sensitivity and specificity of RUG in the diagnosis of strictures is 91% and 72%, respectively [166]. The positive predictive value (PPV) was 89% and the negative predictive value (NPV) was 76% [166]. Most reports suggest that RUG underestimates stricture length [167, 168]. Interpretation of RUG findings by urologists were found to be more accurate at predicting urethral stricture location and length as compared to evaluation by an independent physician [169].

Limitations of RUG include difficulty assessing very distal strictures and assessing the proximal extent of strictures which are too narrow to permit passage of adequate contrast. Combining a RUG with voiding cystourethrography (VCUG) can allow adequate visualisation of the urethra proximal to the stricture and a more accurate assessment of stricture length in (nearly) obliterative strictures, stenoses and gap in pelvic fracture urethral injury (PFUI) [170, 171]. In addition, urethrography provides only a two-dimensional assessment of stricture and the results may be affected by the amount of penile stretch [172], degree of pelvic rotation and patient body habitus [173]. Risks of the procedure include infection, discomfort [164], contrast reaction from intravasation of contrast [174] in addition to the risk of radiation exposure. Urethrographic clamp devices (Brody, Knutson) are available and were found to be less painful than using the Foley catheter technique [175].

5.2.1.5 Cystourethroscopy

Cystourethroscopy allows for accurate visual detection of a suspected stricture or can rule out a stricture as cause of obstructive voiding [166]. It can detect narrowing of the urethral lumen before changes in uroflowmetry and symptoms [145]. Cystourethroscopy can also assess the presence of LS or other pathology but cannot usually assess stricture length as the calibre of most cystoscopes is greater than most symptomatic strictures [176]. To overcome this, use of smaller calibre ureteroscopes (6.5 Fr and 4.5 Fr) has been reported [176]. This also allows an assessment of the bladder prior to surgery and may identify other pathology such as bladder stones. Cystourethroscopy is particularly helpful for diagnosing proximal BMS which may be missed on RUG [177].

Retrograde urethroscopy combined with antegrade cystoscopy via the suprapubic tract may be used to evaluate PFUI and plan the surgical approach. It allows an assessment of the length of the defect, the competence of the bladder neck, the involvement of the bladder neck in scarring in addition to identifying the presence of bony spicules or other abnormalities (e.g., fistulae, stones) [178]. Combined retrograde and antegrade cystoscopy was found to provide similar estimates of length of urethral defect in patients with PFUI as combined retrograde and antegrade cystourethrography, but was more likely to detect fistulae, false passages, and calculi [178].

5.2.1.6 Ultrasound

Ultrasound of the urethra or sonourethrography (SUG) provides a non-invasive three-dimensional assessment of anterior urethral stricture disease; including stricture location, length, and the degree of associated spongiformis [179].

Several studies have compared SUG to RUG and cystoscopic or intraoperative findings. Sonourethography was found to be more accurate at diagnosing stricture presence compared to RUG [175, 180]. Sonourethography was also found to more accurately estimate stricture length (94% correlation with intraoperative findings) than RUG (59% correlation with intraoperative findings) (p < 0.001) [168]. A further study showed similar findings and found that the closest correlation for stricture length at operation was for strictures in the penile urethra [167]. Intraoperative sonourethrogram findings have also been found to change the planned reconstructive approach (based on pre-operative retrograde urethrogram) in 19% of men undergoing anterior urethral reconstruction [173]. Sonourethography incorporating real-time elastography can provide a qualitative and quantitative assessment of spongiformis [181, 182]. The clinical relevance of assessing the degree of spongiformis pre-operatively remains to be established. Three-dimensional reconstruction of sonographic images is investigational at present [183].

The advantages of SUG are that it can be performed in the outpatient setting, provides information on the degree of spongiformis and its relatively low cost [179]. Limitations of the technique include lower sensitivity for detection of strictures in the bulbar urethra, operator dependency, and the need for urethral distension requiring intraurethral anaesthesia. Sonourethography requires specialised training in the use of US and is currently not in widespread usage.

#### 5.2.1.7 Magnetic resonance imaging

Magnetic resonance imaging (MRI) has been used to image PFUIs, posterior urethral stenoses and anterior urethral strictures.

Several studies have compared MRI urethrogram to RUG and intraoperative findings. Magnetic resonance imaging urethrogram was found to be as accurate as RUG at detecting stricture site in anterior urethral strictures [184]. In terms of stricture length both MRI urethrogram and RUG reliably correlated with intraoperative findings [184]. On the other hand, a further study of patients with anterior urethral strictures found MRI urethrogram stricture length to correlate more closely with surgical findings than RUG [185].

In a mixed group of anterior urethral strictures and posterior urethral stenoses, MRI urethrogram was as accurate (sensitivity = 100%, specificity = 91.7%) as combined RUG and sonourethrography (sensitivity = 100%, specificity = 91.7%) at diagnosing strictures [186]. There was no significant difference in the measurement of stricture length [186]. In a further study of patients with posterior urethral stenosis, MRI estimation of stenosis length correlated more closely with operative findings compared to RUG [187]. In patients with PFUI, MRI measurement of pubo-urethral stump angle (angle between long axis of pubis and line between the distal end of the proximal urethral stump and lower border of inferior pubic ramus) was predictive of an elaborated approach on multivariate analysis [188].

Magnetic resonance imaging was also found to be more accurate at diagnosing associated pathologies e.g., diverticula, tumours, fistulae, and stones [186]. In cases of fistulation between the urinary tract and pubic symphysis after irradiation for prostate cancer, the fistula tract can be clearly demonstrated on MRI [189]. Other imaging modalities, including computed tomography (CT), may fail to identify the tract and the problem may be misdiagnosed as isolated osteomyelitis of the pubic bone leading to medical management with antibiotics rather than surgical excision [189].

The main advantage of MRI is greater anatomical detail, which is countered by the expense of the procedure and the greater complexity in interpreting images. The technique is not commonly used for routine situations, but it may be helpful in diagnosing associated pathologies which may alter patient management.

**MRI** = magnetic resonance imaging; **n** = number of patients; **RUG** = retrograde urethrography; **SUG** = sonourethrography; **VCUG** = voiding cystourethrogram.

### Summary of evidence

**LE**

Magnetic resonance imaging is more accurate than retrograde urethrography and voiding cystourethrogram at determining length of posterior urethral stenoses and can detect alternative associated pathologies e.g., diverticula, fistulae.

2a

### Recommendation

**Strength rating**

Consider magnetic resonance imaging urethrography as an ancillary test in posterior urethral stenosis.

### 6. DISEASE MANAGEMENT IN MALES

#### 6.1 Conservative options

##### 6.1.1 Observation

A stricture will usually result in diminution in flow once the calibre of the urethral lumen is < 10 Fr [144]. In other strictures (> 10 Fr), the diagnosis is often made by coincidence in asymptomatic patients because of a urologic examination for other reasons (e.g., cystoscopy, need for urethral catheterisation) [144]. Purohit et al., performed observation and repeated cystoscopic evaluation of 42 subclinical, incidentally encountered strictures (> 16 Fr). After a median follow-up of 23 months, only five (12%) strictures progressed to a low-grade stricture (11-15 Fr). No patient developed symptoms and none of them needed surgical intervention [144]. These patients are candidates for observation although no evidence exist on the long-term evolution of these strictures.

In a series of anatomic stricture recurrence (< 16 Fr) after urethroplasty, only 65% of patients were symptomatic [145]. Some asymptomatic patients refused further intervention because they had experienced substantial improvement after their primary urethroplasty. These patients were considered as functional “success” [145]. A multicentric study of the Trauma and Urologic Reconstructive Network of Surgeons observed an important discrepancy between cystoscopic recurrence and need for further intervention [143]. Patients with a large calibre (> 16 Fr) recurrence had a one and two-year need for intervention rate of 4% and 12%, respectively. Of note, patients with small-calibre (< 16 Fr) recurrence had a one and two-year need for intervention rate of [144].
only 41% and 49%. Patients who needed intervention had poorer PROMs suggesting clinical symptoms and bother. There is no information on long-term complications in patients with recurrences who did not undergo intervention. In cases of an asymptomatic stricture recurrence, it might be an option not to intervene but to perform regular follow-up.

Care must be taken about the term “asymptomatic” stricture (recurrence) as patients might conceal their bother and symptoms by different means (not drinking, social avoidance) and might only search for medical help once concealment is no longer tenable [190].

### 6.1.2 Suprapubic catheter

Radiation-induced urethral strictures are a difficult to treat population as stricture-free rates for urethral reconstruction are lower compared to those in non-irradiated patients [191]. Fuchs et al., evaluated 75 patients who were initially treated by suprapubic diversion for radiation-induced isolated BMS [192]. Only 51% eventually decided to undergo urethroplasty after a mean follow-up period of 25 months. Although there was no significant difference in overall performance status between patients with a chronic suprapubic catheter vs. those undergoing urethroplasty, all patients with a poor performance score remained with a suprapubic catheter. Patients with concomitant stress urinary incontinence (SUI) opted more often to keep their suprapubic catheter as the SUI improved in 61% of cases. On the other hand, patients who kept their suprapubic catheter suffered from catheter-related complications in 27% of cases. Urinary diversion by ileal conduit was performed in 30% of patients who remained with a suprapubic catheter while this was only the case in 8% who underwent urethroplasty. A suprapubic catheter is also an option in frail patients not able to undergo surgery or in patients who do not want (further) urethral surgery and are willing to accept the complications of a suprapubic catheter [193].

### 6.2 Endoluminal treatment of anterior urethral strictures in males

The ability to treat the majority of strictures by less invasive and time-consuming means, offers obvious benefits particularly when specialist surgical services are not available, or patients simply prefer a more pragmatic immediately available solution.

#### 6.2.1 Direct vision internal urethrotomy

In contemporary practice, direct vision internal urethrotomy (DVIU) is commonly performed as a first-line treatment of urethral strictures [194]. It is usually performed under general or spinal anaesthesia in well-resourced countries but shown to be well tolerated under local anaesthesia with or without sedation [195].

#### 6.2.1.1 Indications of “cold knife” direct vision internal urethrotomy

In the only high-level evidence study, Steenkamp et al., randomised 210 patients with seemingly comparable non-obliterative strictures at all locations of the urethra to either filiform dilatation vs. DVIU with local anaesthesia on an outpatient basis [196]. They collected objective data with RUG performed at seven follow-up visits (3, 6, 9, 12, 24, 36 and 48 months). This unique study showed that urethral dilatation is equally effective as DVIU but both procedure modalities become less effective with increasing stricture length (see section 6.2.1.1.3.1).

A retrospective cohort series on the primary treatment of patients with iatrogenic urethral strictures reported a significantly poorer patency rate for DVIU compared to urethroplasty techniques (32.2 versus 82.4-83.5%) [197].

Patency rates vary considerably between 8% and 77% after DVIU (predominantly without prior urethroplasty) in retrospective cohort studies with minimum follow-up of one year [67, 198-204] (Table 6.1). Median time to
recurrence was less than twelve months in most series [67, 198-202]. This large variation in patency rate can be in part explained by the heterogeneous nature of the strictures and various definitions of patency used by the authors in these series. Indication to perform DVIU is dependent on various stricture characteristics that are prognostic for a successful outcome.

DVIU = Direct vision internal urethrotomy; IQR = interquartile range; N = number of patients; NR = not reported; SD = standard deviation; TTR = time to recurrence.

6.2.1.1.2 Direct vision internal urethrotomy for recurrent strictures and as salvage treatment after failed urethroplasty

In the OPEN trial, a recurrent stricture was defined as at least one previous failed intervention (endoscopic urethrotomy, urethral dilatation, urethroplasty) [205]. The previous intervention was predominantly DVIU. Despite poor recruitment, 108 and 112 patients were randomised to urethroplasty and DVIU respectively in a 24-month study protocol. Both groups had a similar improvement in voiding score symptoms after intervention.
However, patients undergoing urethroplasty had 2.6 higher odds of experiencing an improvement of > 10 ml/s in their maximum urinary flow compared to those undergoing urethrotomy (p=0.001) [205]. Need for re-intervention was observed in 13.8% vs. 25.9% of cases respectively allocated to urethroplasty and DVIU resulting in a 48% lower risk for re-intervention with urethroplasty (HR: 0.52; 95% CI: 0.31-0.89; p=0.017) [205]. Of note, self-dilatation was not considered a re-intervention [205]. Despite more re-interventions in the DVIU group, both treatments resulted in a similar improvement in quality of life but with a higher cost for urethroplasty with the limitation that the follow-up is only two years. [206]. Direct vision internal urethrotomy is also used as salvage treatment for recurrent strictures after urethroplasty. Brown et al., used DVIU for stricture recurrence (mean length: 4 cm; range: 1.5-7 cm) after excision and primary anastomosis (EPA), buccal mucosa grafts (BMG) urethroplasty and penile skin graft urethroplasty [207]. Patency was obtained in thirteen out of 37 cases (35%) after a single DVIU. After free graft urethroplasty (FGU), a short, veil-like stricture (or “diaphragm”) might develop at the distal or proximal end of the graft. Rosenbaum et al., used DVIU to a selected cohort of 43 patients with a short (< 1 cm), veil-like stricture after BMG urethroplasty [208]. After a mean follow-up of twelve months, patency rate was 51%.

6.2.1.1.3 Predictors of failure of “cold knife” direct vision internal urethrotomy

Several groups tried to identify prognostic factors to predict which patients are most likely to fail initial treatment (Table 6.2).

In the absence of well-designed, adequately powered multi-centre trials it is difficult to answer the question as to which clinical factors are predictive of failure of DVIU in men with urethral strictures. However, based on the predictors evaluated above, one can summarise that the best candidates are previously untreated patients with a single, short (max. 2 cm) bulbar stricture. Barbagli et al., reported a five-year patency rate of 71% for patients with untreated short (1-2 cm) bulbar urethral strictures [199].

6.2.1.2 Indications of “hot-knife” direct vision internal urethrotomy

6.2.1.2.1 Laser urethrotomy

Lasers available for urological applications, including Neodymium:YAG, Argon, Holmium:YAG, Potassium titanyl phosphate (KTP) and Tm:Yag, have been used for the treatment of urethral strictures. A SR identified four RCTs comparing laser urethrotomy and the “cold knife” urethrotomy. All studies were limited by short-term outcome evaluation and none of these four studies specified the results based on the location of the stricture. Two of these studies reported specific recurrence rates and meta-analysis showed a relative risk (RR) for recurrence of 0.55 (95% CI: 0.18-1.66; p=0.29), 0.39 (95% CI: 0.19-0.81; p=0.01) and 0.44 (95% CI: 0.26-0.75; p=0.003) in favour of laser urethrotomy after three, six and twelve months respectively [210]. Jin et al., performed a SR including 44 case series on laser urethrotomy or “cold knife” DVIU [211]. This included nineteen articles on laser urethrotomy and 25 articles on “cold knife” DVIU. The overall weighted average stricture-free rate was 74.9% (371/495) and 68.5% (1874/2735) for laser vs. “cold knife” DVIU, respectively (p=0.004). Although statistically significant, the results must be interpreted with caution because of heterogeneity and because no details are provided on follow-up duration. Specifically looking at first DVIU, laser and “cold knife” DVIU obtained a stricture-free rate of 58.6% and 42.7%, respectively and the difference was no longer statistically significant (p=0.09). At the bulbar urethra, laser and “cold knife” DVIU yielded a stricture-free rate of 52.9% and 60%, respectively (p=0.66) [211].

After publication of this SR, the EAU Guideline Panel scope search identified three additional RCTs [212-214]. In the RCT of Yenice et al., patients with a primary, bulbar stricture were randomised either to “cold knife” DVIU (n=29) or holmium:YAG laser urethrotomy (n=34). After twelve months follow-up, no significant difference in patency rate was identified (79% for “cold knife” DVIU vs. 68% for laser urethrotomy, p=0.3) [213]. In their RCT, Chen et al., reported a better patency rate after one year with laser (n=24) compared to “cold knife” (n=22) DVIU (respectively 88% vs. 18%; p < 0.05). However, after two years the benefit for laser disappeared and after five years both techniques showed a low patency rate: 9% for “cold knife” DVIU vs. 12% for laser DVIU (p > 0.05) [212]. Gamal et al., randomized patients between “cold knife” DVIU (n=40) and Holmium:Yag laser DVIU (n=40). At one year, they found an equally effective improvement of maximum urinary flow in both groups.

6.2.1.2.2 Plasmakinetic (bipolar) urethrotomy

Cecen et al., conducted an RCT comparing plasmakinetic with “cold knife” DVIU (n=136) [215]. They reported patency rates for plasmakinetic and “cold knife” urethrotomy at nine months in respectively 86% and 70% of cases (p=0.025). At eighteen months, patency rates for plasmakinetic and “cold knife” urethrotomy were 63% and 67%, respectively (p=0.643) [215]. A prospective cohort study on primary strictures < 2 cm reported a patency rate at twelve months in 23/30 (77%) cases for plasmakinetic DVIU vs. 19/30 (63%) cases with “cold knife” DVIU (p=0.04) [216]. A retrospective case series (n=27) reported a 74% patency rate for short (1-2.5 cm) strictures after a mean follow-up of fourteen months [217]. They reported negligible blood loss during the procedure and no post-operative incontinence.

Based on the conflicting results described above and considering the heterogeneity of series and absence of long-term follow-up, overall, the available studies do not support the efficacy of one technique of DVIU over another. Given the similar complication rates between techniques (see section 6.2.1.3), no recommendation can be made in favour of one technique over another.

6.2.1.3 Complications of direct vision internal urethrotomy

6.2.1.3.1 Complications of “cold knife” direct vision internal urethrotomy

An overall complication rate of 6.5% was reported in a SR of Jin et al., based on twelve articles including 1,940 patients [211] (Table 6.3).

Notably, erectile dysfunction (ED) was reported in 5.3% of cases in this review [211]. In addition, Graversen et al., reported ED in eleven out of 104 (10.6%) patients [218]. This risk appears higher in strictures located in the penile urethra and, in addition to the poor patency rates, the use of DVIU in the penile urethra must be discouraged [218, 219].
6.2.1.3.2 Complications of “hot knife” direct vision internal urethrotomy
The SR of Jin et al., reported a total complication rate of 11.8% (39/330) [211] (Table 6.3).

6.2.1.3.3 Complications of “cold knife” vs. “hot knife” direct vision internal urethrotomy
In a SR of RCTs comparing “cold knife” DVIU vs. laser DVIU, only 1/4 series reported complications [210]. In the laser group, an 8.9% complication rate was found due to contrast extravasation to the perineum and stricture recurrence. For the “cold knife” DVIU, a 15.5% complication rate was reported related to bleeding [210]. Two later RCTs reported similar rates of urinary extravasation [212, 213] and urinary incontinence (UI) [212] with both techniques.

The SR of retrospective case series of Jin et al., found no significant differences in the incidence rates of UI, urinary extravasation and UTI between laser and “cold knife” DVIU [211]. However, urinary retention and haematuria were more frequent with laser compared to “cold knife” DVIU [211]. Conversely, in the series of Yenice et al., haematuria was only reported after “cold knife” DVIU but not after laser DVIU (p=0.6) [213] (Table 6.3).

DVIU = direct vision internal urethrotomy; NA = not applicable; NR = not reported.

6.2.1.3.4 Complications of direct vision internal urethrotomy vs. dilatation
A Cochrane review found no significant differences for overall intra-operative complications (single dilatation vs. DVIU respectively 14% vs. 11%; RR: 0.75; 95 CI: 0.36-1.55) nor for individual complications (difficulty urinating, haematuria, false passage, pain, knotting/breaking/bending filiform leader) [196, 220]. The low rate of false passage for both DVIU and dilatation (respectively 0.96 and 0.94%) might be explained by the systematic use of a filiform leader in both groups which was inserted endoscopically in the dilatation group followed by coaxial dilatators [196, 220].

A small retrospective study comparing balloon dilatation (n=31) with DVIU (n=25) showed less urethral bleeding (6.5 vs. 32%; p=0.017) and UTI (3.2 vs. 24%; p=0.037) with balloon dilatation [221].

Apart from acute peri-operative complications described above, the stricture length and number of strictures were reported to increase after DVIU. Other authors mention that repeat urethral manipulations (DVIU and/or dilatation) can increase stricture complexity and delays time to urethroplasty [222].

6.2.1.3.5 Complications of “cold knife” direct vision internal urethrotomy vs. urethroplasty
The OPEN-trial reported adverse events of any type in 61% and 26.1% after urethroplasty (all types) and DVIU respectively [205]. In the urethroplasty group, mouth pain (related to oral mucosa graft [OMG] harvesting) and
wound infection was noted as complication in respectively 14.6% and 4.9% of cases. Erectile dysfunction was 4.9% and 2.6% after urethroplasty and DVIU, respectively. Serious adverse events were reported in 8.5% and 8.7% after urethroplasty and DVIU respectively [205].

### 6.2.2 Single dilatation

#### 6.2.2.1 Modalities of dilatation and results

Dilatation can be done in the office, under local anaesthesia and without complex resources [223, 224]. With dilatation, the urethral mucosa at the stricture site is stretched and the scarring is disrupted. This is opposed to DVIU where the stricture is incised. However, both treatment modalities use the same principle to achieve urethral patency: a breach of the urethral mucosa at the site of the stricture in which re-epithelialisation should occur faster than wound contraction [220].

When dilators are used to dilate bulbar urethral strictures, considerable experience is required to avoid accidental perforation of the urethra at the level of the stricture. In order to reduce the risks (esp. false passage, spongiosal perforation, urethral bleeding) of “classic” blind dilatation with rigid sounds [224], other strategies have been developed and evaluated in which the dilatation is visually controlled after a guidewire has been inserted (Table 6.4).

Although no direct comparative studies of blind vs. visually controlled dilatation are available, several studies have reported a low complication rate with visually controlled modifications of dilatation. The recurrence rate largely varies between 23.5-64.5% (Table 6.4).

### 6.2.2.2 Effectiveness of dilatation compared with direct vision internal urethrotomy

A SR identified only one prospective RCT comparing dilatation with DVIU and failed to detect any differences [196, 220]. In a small (n=56) retrospective cohort study, the three-year estimated stricture recurrence-free survival was 35.5% and 28% for respectively balloon dilatation and DVIU (p=0.21) [221].

At present, there is lack of evidence to support the claim that dilatation is superior to DVIU (or vice versa) and therefore, the indications for single dilatation are the same as for DVIU.

Repetitive dilatation/DVIU with curative intent (see also section 6.2.1.3.6 Previous interventions) should be avoided as no long-term freedom of recurrence can be expected [223] and because of the significant risk of increasing stricture length and complexity and prolonging the time to urethroplasty (which has better patency rates) [222].

#### Summary of evidence

| Visually controlled dilatation after endoscopic or fluoroscopic guidewire placement has a low complication rate. | LE |
| Repetitive dilations/direct vision internal urethrotomy have no long-term freedom of recurrence and increase stricture complexity. | 1b |

#### Recommendations

| Use visually controlled dilatation in preference to blind dilatation. | Weak |
| Do not perform repetitive (> 2) direct vision internal urethrotomy/dilatations if urethroplasty is a viable option. | Strong |

### 6.2.3 Post-dilatation/direct vision internal urethrotomy strategies

Several strategies have been developed and evaluated to prevent wound contraction, improve the stricture-free rate and time to stricture recurrence after dilatation or DVIU.

It is noteworthy that these strategies tend to stabilise the stricture rather than to keep the patient stricture-free and the reported outcomes should be understood in this respect.

#### 6.2.3.1 Intermittent self-dilatation

**6.2.3.1.1 Results**

A SR identified six randomised and quasi-randomised trials comparing intermittent self-dilatation (ISD) with no ISD with a follow-up between eight and 24 months [227]. Stricture recurrence was reduced in men performing ISD (85/197, 43%) vs. those who did not (128/207, 62%) (RR: 0.70; 95% CI: 0.48-1.00; p=0.05). There was significant heterogeneity, and the quality of included studies were very low, which led the authors to conclude there is uncertainty about the estimate [227]. This review found no significant difference in adverse events between ISD and no ISD (RR: 0.60; 95% CI: 0.11-3.26; p=0.56) [227]. One trial containing 48 patients found no significant difference in six vs. twelve months duration of ISD (RR: 0.67; 95% CI: 0.12-3.64) and another trial (n=59) found no significant difference from using a low-friction hydrophylic vs. a polyvinyl chloride catheter (RR: 0.32; 95% CI: 0.07-1.40) [227]. Other studies have been published after this SR of 2014. Chhabra et al., reported that patients complying with ISD after dilatation had a lower need for re-intervention than those who did not, 12.3% vs. 20.5% respectively (p=0.02) [228]. After a mean follow-up of 25 months, Greenwell et al., found a need for subsequent intervention in 13/31 (42%) men performing ISD vs. 47/95 (49%) who did not (p=0.46). The number of reoperations in patients with need for subsequent intervention was lower in the group performing ISD vs. those who did not (2.6 vs. 3.4). No major complications were reported in both groups [229].
6.2.3.1.2 Complications
The potential benefit of ISD in stabilising the stricture must be balanced against the drawbacks. Commonly reported complications are urethral bleeding (7.1%) [230] and UTI/epididymitis (4.7-18.1%) [231, 232]. A multicentric prospective study (n=85) reported that respectively 35% and 26% of patients had moderate to severe difficulties in catheterisation and respectively 32% and 17% of patients suffered moderate to severe pain while performing ISD. This had a serious impact on QoL which was rated moderate and poor in 32% and 55% of patients, respectively [33]. Younger age was identified as predictor for poor QoL, and QoL was more impaired in proximal stricture location (posterior and bulbar) [33]. In a study of 286 patients (mainly > 60 years old) performing ISD, 20% experienced problems with ISD and 33% had at least one infection annually. After a mean follow-up of 58 months 67% still continued with ISD [233]. Khan et al., reported eight “drop-outs” of 30 (26.7%) men randomised to ISD [232]. Of these eight “drop-outs”, two were unable to perform ISD and one stopped because of pain.

As mentioned above, repetitive dilatation (including ISD) increases stricture complexity and delays time to urethroplasty [222, 234].

6.2.3.1.3 Intermittent self-dilatation combined with intra-urethral corticosteroids
To delay wound contraction at the stricture site, intra-urethral corticosteroids (as a catheter lubricant) have been used to improve the results of ISD. In 2014, a SR identified three prospective RCTs comparing ISD and local steroid (triamcinolone) ointment vs. ISD without local steroid ointment [235]. These three studies included a total 67 and 68 patients randomised to local steroid, or not, with a follow-up ranging between twelve and 36 months. There were fifteen (22.4%) recurrences in the steroid group and 25 (36.7%) in the control group (OR: 0.51; 95% CI: 0.24-1.10; p=0.09) [235]. Time to recurrence was longer in the steroid group vs. the control group (weighted mean difference = 0.29; 95% CI: 0.08-1.00; p=0.05). There was no difference in adverse events between groups [235].

Since 2014, two additional RCTs have been published. Ergun et al., evaluated patients after DVIU for primary short (< 2 cm), bulbar (82%) or posterior (18%) strictures that were further randomised between ISD (n=30) and ISD + triamcinolone ointment (n=30) for six weeks. Stricture recurrence rate after 24 months was not significantly different between ISD and ISD + triamcinolone (respectively 33.3 and 30%) [236]. On the other hand, Regmi et al., found a lower stricture recurrence rate (22% vs. 46%, p=0.04) in patients performing ISD + triamcinolone (n=27) vs. ISD alone (n=28) [237]. In this study, median time to recurrence was 7.4 ± 4.5 months vs. 11.9 ± 3 months in respectively ISD alone and ISD + triamcinolone (p=0.16). Both studies reported no complications related to ointment of triamcinolone [236, 237].

In a small (n=28) cohort with LS-related strictures, an intra-urethral steroid regimen was successful (no need for subsequent escalation of therapy) in 25 (89%) patients after a mean follow-up of 25 months [157]. This regimen consisted of applying clobetasol cream 0.05% as lubricant on a calibration device (10-16 Fr catheter or dilator) twice a day during a minimum of two months. As most of these patients further continued with instillation of steroids on a calibration device, this high “success” rate must be viewed with caution and should be considered as a stabilisation of the stricture rather than a cure. Eventually, twelve (42.8%) patients could reduce the interval of instillation/dilatation and three (10.7%) of them could finally stop the treatment [157].

**Summary of evidence**

| Stricture recurrence was reduced in men performing intermittent self-dilatation (ISD) versus those who did not. | 1a |
| Intra-urethral corticosteroids in addition to ISD delays the time to recurrence. | 1a |

**Recommendations**

| Perform intermittent self-dilatation (ISD) to stabilise the stricture after dilatation/direct vision internal urethrotomy if urethroplasty is not a viable option. | Weak |
| Use intra-urethral corticosteroids in addition to ISD to stabilise the urethral stricture. | Weak |

6.2.3.2 Intralesional injections
The rationale of adjuvant intralesional injections is to reduce fibroblast proliferation and excessive urethral scaring [238].
6.2.3.2.1 Steroids
A 2014 SR identified five studies comparing intra-urethral submucosal steroid injection vs. no intra-urethral submucosal steroid injection after DVIU, of which two were RCTs [235]. Meta-analysis of these two RCTs with 57 and 58 patients in, respectively, the steroid and control group showed no statistical difference in recurrence rate (OR: 0.53; 95% CI: 0.25-1.13; p=0.10). Time to recurrence was significantly longer in the steroid group (weighted mean difference = 4.43; 95% CI: 2.77-6.09, p < 0.00001). There were no significant differences regarding adverse events (infection, bleeding, extravasation) between both groups (weighted mean difference = 1.59; 95% CI: 0.71-3.58, p=0.26).

6.2.3.2.2 Mitomycin C
In 2021 a SR and meta-analysis of different adjuncts to minimally invasive treatment of urethral stricture in men, mitomycin C (MMC) was associated with the lowest rate of urethral stricture recurrence (intralesional injection: OR 0.23, 95% CI 0.11-0.48; P<0.001; intraluminal injection: OR 0.11, 95% CI 0.02-0.61; P=0.01) [239]. Another SR and meta-analysis in 2021 from Xu et al., on the efficacy of MMC combined with direct vision internal urethrotomy, revealed that the effect of MMC was significant in short (< 2cm), anterior urethral strictures, in the longer (>12 months) follow-up group [240].

In the absence of well-conducted and adequately powered RCTs along with the lack of standardisation (dose, technique, volume, etc.) in the current literature, careful clinical review and prospective data collection as part of a clinical trial is advised.

6.2.3.2.3 Platelet rich plasma
Rezaei et al., conducted an RCT comparing DVIU + platelet rich plasma (PRP) (n=44) vs. DVIU + saline (n=43) in primary, bulbar strictures < 1.5 cm in length [241]. The two-year stricture-free rate was 78% vs. 56% after DVIU with or without PRP, respectively (p=0.034). Complications were frequent but not significantly different between both groups (DVIU + PRP: 70%; DVIU + saline: 79%). All complications (urethral bleeding, haematuria, urethral pain, pelvic pain, urinary leakage and genitoperineal swelling) were classified as grade 1 according to the Clavien-Dindo system. Further validation of this treatment is needed before general clinical implementation.

6.2.3.3 Urethral stents
Urethral stents are designed with the aim to oppose wound contraction after dilatation or DVIU [242, 243]. Stent insertion is a short procedure (< 60 minutes) that can be done under local or spinal anaesthesia as “oneday” surgery [242, 244, 245]. Urethral stents are classified as permanent or temporary (removable, after six to twelve months).

6.2.3.3.1 Results
Permanent stainless-steel mesh stents are no longer commercially available. An RCT comparing dilatation/DVIU only vs. dilatation/DVIU followed by temporary stent insertion for bulbar strictures reported a significantly longer stricture-free survival time in favour of dilatation/DVIU followed by stent (median 292 vs. 84 days; p < 0.001) [246]. Only 20.6% of patients treated with a stent developed a recurrent stricture within one year vs. 82.8% in the control group. These results are corroborated by a prospective series of Wong et al., who found a median stricture-free survival of two months after DVIU alone vs. 23 months after DVIU followed by temporary (three months) stent for bulbar strictures [243]. Failure and need for re-intervention are frequent (30-53%) and are usually because of stricture recurrence, stent encrustation, stent migration and urethral hyperplasia. Other complications include recurrent UTI, recurrent haematuria and genito-perineal pain (Table 6.5). Although stents are mainly used to treat bulbar strictures, they have been used for posterior stenoses as well. Stents used in the posterior urethra have a high risk (82-100%) of causing UI and this is most pronounced in patients with previous irradiation and/or strictures extending into the membranous or bulbar urethra [247]. In the bulbar urethra, the risk of UI is higher if stent placement is adjacent to the external sphincter [248]. The use of stents in the penile urethra is anecdotal. Jung et al., reported stent failure in 4/7 (57%) patients with a penile stricture after a mean follow-up of eight months. Of
those patients who failed, no patient with distal or pan-penile strictures was rendered stricture-free [249]. In their series, stricture recurrence after stenting of the penile urethra was significantly higher when compared to the bulbar urethra [249]. Although no direct comparison is available, temporary stents tend to have fewer and less severe complications compared to permanent stents (Table 6.7).

6.2.3.4 Drug-coated balloon dilatation

Drug (paclitaxel)-coated balloon dilatation (DCBD) after standard dilatation or DVIU aims to reduce scar formation based on its antimitotic action. The ROBUST-3 trial prospectively randomized patients with predominantly bulbar strictures (< 3cm length) and at least two prior failed endoscopic treatments to DCBD (n=79) or standard dilatation/DVIU (n=48) [250]. Anatomic patency (assessed by cystoscopy) at six months was 75% for DCBD versus 27% after standard dilatation/DVIU (p<0.001). Estimated one year-retreatment free survival was 83% versus 22% for respectively DCBD and standard dilatation/DVIU (p<0.001). There were no serious adverse events related to DCBD although patients undergoing DCBD had a higher rate of hematuria and dysuria compared to controls (11.4% versus 2.1%). Paclitaxel was detected in semen up to six months after treatment which urges for contraception if the partner has child-bearing potential. If used, careful clinical review and prospective data collection ideally part of a post marketing registry or clinical trial is advised.

Summary of evidence LE

Drug (paclitaxel)-coated balloon dilatation is associated with higher anatomic patency rates (at six months) and lower risk of retreatment (at one year) as compared to standard dilatation/DVIU in patients with short (< 3 cm), bulbar strictures that underwent at least two prior failed endoscopic treatments.

Recommendation Strength rating

Offer drug (paclitaxel)-coated balloon dilatation for a short (< 3 cm) bulbar stricture recurring after at least two prior endoscopic treatments, but only in patients for whom urethroplasty is not an option.

Weak

6.2.3.4.1 Treatment of stent failure

In the case of stent failure, subsequent urethroplasty (usually with stent removal) is possible, but this urethroplasty is very likely to be more complex than it would have been had it been performed initially [251-253]. Due to the fact that the stainless-steel wires are fully embedded into the urethral wall, over time the urethral spongiosum is severely damaged. Horiguchi et al., found that a history of urethral stenting was an independent significant predictor of increased stricture complexity (OR: 13.7; 95% CI: 1.7-318.3; p=0.01) and need for more complex urethroplasty (OR: 6.9; 95% CI: 1.1-64.5; p=0.04) [234]. The majority (62%) of patients in this study had a permanent stent and tend to be difficult to remove because they are epithelialised, usually within six months [234]. The type of urethroplasty required depends on the length of the stricture and quality of local tissues [252]. In the majority of cases, it is possible to preserve the urethral plate and to perform a one-stage substitution urethroplasty [251, 252, 254]. The patency rates after different types of urethroplasty vary greatly between 16.7-100% [251-254] and this variation probably reflects variation in complexity of the stricture, rather than that the superiority of one technique of urethroplasty over another (for further information see supplementary Table S6.2). Due to these limitations, the use of stents should be avoided if subsequent urethroplasty is considered [242, 253]. Urethral stents are not a first-line treatment for urethral strictures but can be considered in co-morbid patients who have a recurrent stricture after DVIU/dilatation and are unable to have more complex urethroplasty or who refuse urethroplasty [242, 246, 247].

Summary of evidence LE

Permanent urethral stents have a high complications and failure rate and make subsequent urethroplasty more challenging if they fail.

Stents have a higher failure rate in the penile urethra.

Temporary stents after DVIU (direct vision internal urethrotomy) /dilatation at the bulbar urethra prolong time to next recurrence compared to DVIU/dilatation alone.

Recommendations Strength rating

Do not use permanent urethral stents.

Do not use urethral stents for penile strictures.

Use a temporary stent for recurrent bulbar strictures after direct vision internal urethrotomy to prolong time to next recurrence only if urethroplasty is not a viable option.

Weak
### Table 6.5: Failure rate and complications associated with urethral stents

| Study                        | Type of stent                  | Duration | N    | FU (months) | Stricture length (cm) | Stricture location | Previous interventions | Failure rate | Definition failure | Complications                       | Study                        | Type of stent                  | Duration | N    | FU (months) | Stricture length (cm) | Stricture location | Previous interventions | Failure rate | Definition failure | Complications                       |

6.3 Open repairs (urethroplasty): site and aetiology (clinical scenario) treatment options

6.3.1 The role of urethroplasty in the management of penile urethral strictures

Due to the specific aetiology and the associated problems, strictures related to failed hypospadias repair and LS will be discussed separately. However, many series reporting on the outcome of penile strictures have a mixed aetiology also including failed hypospadias repair and/or LS [255, 256]. Due to their specific location, distal penile strictures will be discussed separately.

6.3.1.1 Staged augmentation urethroplasty

Classically called “two-stage” urethroplasty, this approach may become a multi-stage urethroplasty as revision (usually due to graft contracture) after the first stage has been reported in 0-20% of cases [256-259]. Therefore, the term “staged” should be used instead [260]. Revision rates before second stage were 0-20%, stressing that a two-stage urethroplasty might become a multi-stage urethroplasty. In general, reconstructive urologists tend to follow this approach in men with more complex urethral stricture disease (multiple interventions in the past, unfavourable clinical findings such as significant spongiosfibrosis or scarring that requires excision, poor quality of the urethral plate). An interval of at least four to six months has been proposed before proceeding to the tubularisation of the urethra, provided that the graft has healed uneventfully [261-263].

A SR by Mangera et al., has shown an average patency rate of 90.5% with the use of all types of grafts for staged penile urethroplasties with an average follow-up of 22.2 months [264]. Patency rates of staged oral mucosa graft (OMG) urethroplasty in specific locations vary between 73.3 and 100% [255, 256, 258, 259, 265, 266]. Post-operative urethrocutaneous fistula (UCF) rates were 17.2% and 2.6% in the studies of Ekerhult et al., and Joshi et al., respectively, and either not reported or unclear in the remaining studies [255, 256].

6.3.1.2 Single-stage augmentation urethroplasty

Single-stage urethroplasty offers the option for reconstruction of the stricture without the need for multiple operations, the associated peri-procedural risks, and the cosmetic and functional implications that by definition follow the first part of staged urethroplasties [267-269]. There is some evidence to suggest a considerable number of patients (50% or more in some studies) who were offered first stage urethroplasty never returned for the second stage because they were either satisfied with their functional status after the first stage (this particularly applied to older men or patients with multiple failed procedures in the past) or they were disappointed with the need for another operation [267, 268].

In the SR of Mangera et al., overall patency rate for all types of single-staged graft urethroplasties is 75.7% with an average follow-up of 32.8 months [264].

The patency rate for different one-stage techniques in particular are:

- dorsal OMG (n=320): 63-100% [265, 266, 259, 270-276];
- ventral OMG (n=54): 55-92.6% [265, 277, 278];
- double (dorsal + ventral) onlay with penile/scrotal skin graft /OMG (n=14/8/4): 88.5% [272];
- dorsal penile skin graft (n=44): 62-78% [272, 273];
- penile skin flap (n=367): 67-100% [265, 266, 272-274, 279].

No high-level evidence exists to state that one technique is superior to another, but it seems that the dorsal graft location is more commonly used compared to the ventral one. Mangera et al., reported that the patency rate was better with OMG compared to other grafts (mainly penile skin) [264]. Jiang et al., showed that combined (dorsal + ventral) BMG onlay had significantly better stricture-free rates for penoscrotal strictures (patency rate 88.9% vs. 60.9% with single-onlay approach); however, follow-up was significantly shorter in the double-onlay group [280]. Few studies have reported dedicated results on sexual function parameters that do not appear to be significantly impaired post-operatively [258, 281].

A critical factor with respect to single-staged procedures is the careful selection of patients, as men with long and complex strictures might not be good candidates for single-stage reconstruction and attempts to offer single-staged operations in these patients might lead to higher recurrence rates. Sometimes, this selection can only be done based on intra-operative findings. Therefore, any scheduled single-staged procedure might be converted into a staged one [267, 282]. Palminteri et al., highlighted the fact that single-stage augmentation urethroplasties in men with LS-related strictures enlarge rather than remove the diseased segment of the urethra; therefore, there is always a risk of recurrence in the future [283]. The role of previous interventions (especially multiple urethrotomies or history of previous urethroplasties) remains unclear as several studies on single-staged operations do not provide information on previous procedures, or excluded patients with operations in the past [274, 281]. Although favourable outcomes in patients with previous history...
of urethrotomies/urethroplasties were reported by Barbagli and Kulkarni, in the study by Pfalzgraf et al., all recurrences post-previous urethroplasty took place in the single-stage group while Ekerhult et al., identified prior history of urethral operations as a risk factor for recurrence in the group of single-stage procedures [255, 258, 259, 272]. In addition to previous urethral surgery, high BMI has also been identified as a poor prognostic factor after single-stage penile urethroplasty [255].

6.3.1.3 Anastomotic urethroplasty in men with penile urethral strictures
Historically, the use of anastomotic urethroplasty in the management of urethral stricture disease has been discouraged due to the risk of chordee post-operatively [263, 284]. Nevertheless, it has been performed in selected patients with very short strictures (usually < 1 cm) with 80-93% patency rate, with satisfactory QoL and sexual function and without any case of chordee [285] and with results comparable to augmentation urethroplasty [286].

6.3.1.4 Specific considerations for failed hypospadias repair-related strictures
The term “failed hypospadias repair” (FHR) includes a wide range of abnormalities after previous attempts for reconstruction, such as glans deformity, recurrent urethral stricture, glans/urethral dehiscence, UCF and penile chordee [287-289]. The management of FHR is challenging as the urethral plate, penile skin and dartos fascia are often deficient/non-existent. Management of these patients is often made more difficult due to incomplete health records and a lack of critical information (original meatal site, number, and type of previous repairs) [261, 290]. In addition, multiple operations might need to be offered to reach satisfactory outcomes [287]. As a result, FHR should always be considered as a complex condition and it is advised that FHR management takes place in high-volume centres [288, 289, 291, 292].

“Hypospadias cripples” is a term widely used to describe the group of men with multiple previous failed attempts to correct the condition resulting in unfavourable results such as severe scarring, penile deformity and shortening, hair or stones in the urethra, UCF, chordee and functional disorders (e.g., urinary, or sexual dysfunction). This term should be avoided and a more neutral one should replace it as it further stigmatises men with hypospadias who have been shown to have reduced self-esteem and confidence due to unsatisfactory cosmesis, and problematic urinary and sexual function. Moreover, it has been reported that FHR patients experience high rates of disappointment after failure of attempted repair and a sense of helplessness as they are frequently advised that their failed hypospadias is too complex to correct and they should not pursue further repair [288-290, 293, 294].

Two main approaches are applicable: single-stage or staged procedures. In general, it is advised that staged
procedures should be followed when the urethral plate is inadequate for a single-stage operation. Surgeons should consent patients for both types of urethroplasty as the surgical approach might need to be modified intra-operatively depending on favourable/unfavourable intra-operative findings. Besides poor-quality of the urethral plate, these unfavourable findings include high degree of scarring and presence of concomitant LS, UCF and/or chordee. It is not uncommon for men with FHR to have scarred skin or concurrent LS and thus, skin grafts or flaps should be avoided as the risk of recurrence due to LS is very high (90% in long-term follow-up as reported by Depasquale et al.) [39, 295, 296].

Staged repairs (using mainly BMG) reported patency rates ranging from 71-95% [293, 295, 257, 297, 298], while single-stage repairs had patency rates from 80-100% [295, 297, 299-302]. It needs to be highlighted that, as FHR is an umbrella term that covers various clinical conditions apart from urethral stricture disease only (such as UCF, chordee, penile deformity), “success” rates as reported by the authors in their studies do not represent urethral patency rates only. Unfortunately, the number of previous operations is either not reported or refers to the whole FHR study group collectively rather than to the subgroups of staged/single-staged procedures.

A comparative analysis is reported by Barbagli et al., in 345 FHR patients at five-year follow-up. Overall failure-free survival rate was 48% for all urethroplasties, and in sub-analysis, staged techniques had significantly lower treatment failure-free survival rates compared to single-stage techniques [303]. However, it is unclear whether these groups were comparable in terms of baseline characteristics such as age, length of stricture, number of procedures, comorbidities etc. [303]. If the patients in the staged group had a more unfavourable background, this on its own could explain the final outcome rather than the surgical approach itself.

Kozinn et al., reported a 16% and 14% revision rate after the first and second stage, respectively, and observed that these revision rates were higher in the FHR group compared to non-FHR patients with penile strictures [257]. There is conflicting evidence whether FHR as aetiology is a poor prognostic factor in the outcome of urethroplasty for penile strictures [255, 304-306]. Concomitant UCF can be successfully managed at the same time of urethroplasty [303].

Saavendra et al., reported 89.3% stricture-free rate in 56 FHR patients with penile urethral strictures at a median of 21 months follow-up using mainly staged urethroplasty and perineal urethrostomy. Verla et al., presented departmental experience with the use of various urethroplasty techniques in a total of 76 FHR patients with penile strictures. Follow-up was long, at a median of 89 months and stricture-free rates ranged from 29% (anastomotic repair) to 90% first stage only of multistage urethroplasty).

For further information see supplementary Table S6.3.

### Summary of evidence

| Men with failed hypospadias repair (FHR) have history of multiple interventions, and poor-quality tissues, and might require complex procedures for a satisfactory functional and cosmetic outcome. | LE 4 |
| Men with FHR may have low self-esteem due to urinary and sexual dysfunction and unsatisfactory cosmesis. | 2b |
| Men with FHR can have scarred penile skin or concurrent lichen sclerosus and outcomes with skin grafts or flaps can be unsatisfactory. | 3 |

### Recommendations

| Men with failed hypospadias repair (FHR) should be considered complex patients and referred to specialist centres for further management. | Weak |
| Propose psychological and/or psychosexual counselling to men with unsatisfactory cosmesis and sexual or urinary dysfunction related to FHR. | Weak |
| Do not use penile skin grafts or flaps in failed FHR patients with lichen sclerosus or scarred skin. | Strong |

### 6.3.1.5 Specific considerations for lichen sclerosus-related penile urethral strictures

Given the fact that LS affects the skin, the use of genital skin as a flap or graft is not advised as the risk of disease recurrence has been reported to be high (50-100%) and while most of recurrences tend to occur within the first two to three post-operative years, late recurrences have been reported [307].
Main strategies are single-stage or staged oral mucosa graft urethroplasty.

The EAU Urethral Strictures Guidelines Panel conducted a SR [6] to explore the role of single-stage oral mucosa graft urethroplasty in the management of LS-related urethral strictures and to compare its outcomes with alternative management options (surgical dilatations +/- ISD; surgical dilatations + local steroids +/- ISD; staged oral mucosa urethroplasty; penile skin urethroplasty; meatoectomy/meatoplasty; urethrotomy [Otis, DVIU]; perineal urethrostomy; urinary diversion [e.g., suprapubic catheterisation]).

In total, fifteen studies met the inclusion criteria, recruiting a total of 649 patients (366 from five non randomised comparative studies and 283 from ten, single-arm retrospective observational studies). Singlestage OMG urethroplasty resulted in success rates ranging from 65-100% after twelve to 67 months mean or median follow-up. For staged OMG urethroplasty, the most commonly reported comparator, the success rates were somewhat lower and varied between 60-79%. Methodological issues (mainly selection bias) could explain the difference in success rates rather than the intervention itself. Complications were uncommon (0-12%) and mainly comprised Grade 1-3 events.

Due to the overall very poor quality of evidence, the SR did not provide a clear answer as to whether single stage OMG urethroplasty is superior to other management options, although careful patient selection is highlighted. In the absence of adverse local tissue conditions, a single-stage approach could lead to high success rates with an improvement in voiding symptoms and QoL.

### 6.3.1.6 Distal urethral strictures (meatal stenosis, fossa navicularis strictures)

Open repair of distal urethral strictures can be in the form of Malone meatoplasty, skin flap meatoplasty or graft (skin [SG]/OMG) urethroplasty.

For short distal meatal strictures, the Malone meatoplasty (dorsal + ventral meatotomy) provides a technique with patency rates up to 100%, and 83% patient-reported satisfaction with the cosmetic results [308]. Similarly, Hofer et al., presented their technique variation (ventral excision of scar and eversion of the urethral mucosa) and showed 81% stricture-free rates at 41-month mean follow-up.

Skin flap meatoplasty showed excellent patency rates ranging from 90-96% based on three studies comprising 67 patients [309-311]. In addition, based on their results, patient satisfaction with post-operative outcomes and cosmesis was high, there were no cases of ED and functional complaints were minimal (mainly spraying of the urine flow).

Patency rates with the use of grafts (OMG or SG) ranged from 69-91% in 106 patients overall [312, 313, 300]. Where reported, patients were satisfied with cosmesis, and mild spraying of the urine flow self-resolved. Although tubularised grafts in a single-stage procedures are not routinely recommended (see also section 9. Tissue transfer), one series reported an 89.9% patency rate for this approach (“two-in one approach”) in selected patients with mainly distal penile strictures [314].

Finally, Daneshvar et al., presented a novel transurethral ventral inlay OMG technique and showed excellent stricture-free rates (96%) at short follow-up though (median 16 months).

For further information see supplementary Table S6.4.

6.3.2 Urethroplasty for bulbar strictures
6.3.2.1 “Short” bulbar strictures

The length of a “short” bulbar stricture is poorly defined. In general, “short bulbar strictures” are those amenable to stricture excision and subsequent tension-free anastomotic repair. The limit is usually around 2 cm [315].

In fit patients, the choice of urethroplasty is between EPA (transecting or non-transecting) and FGU.

6.3.2.1.1 Excision and primary anastomosis
6.3.2.1.1.1 Excision and primary anastomosis with transection of corpus spongiosum (transecting EPA)

Transecting EPA (tEPA) is based on the full thickness resection of the segment of the bulbar urethra where the stricture and surrounding spongiosfibrosis is located. Reconstruction is performed by a tension-free spatulated anastomosis.

6.3.2.1.1.1.1 Patency rates

The International Consultation on Urological Diseases (ICUD) performed an extensive review of the literature and reported a composite patency rate of 93.8% for tEPA [316]. Based on this, they endorsed tEPA as treatment of choice for short bulbar strictures if other techniques have an expected patency rate below 90%. However, penile complications were not taken into account for this advice and as discussed below, these are a concern with tEPA.

Prospective data report a patency rate of 88% at twelve months follow-up [315].

Usually, no need for further intervention is used to evidence that the urethra is patent. In the few studies using an anatomic definition for failure (an inability to pass a 16 Fr endoscope) tEPA urethroplasty achieves a similar patency rate, ranging between 85.5-97% [145, 317-319] (Table 6.12). The median time for recurrence after tEPA is between 3.5 and thirteen months [145, 320, 321].

Several authors suggested that tEPA is the technique of choice for short post-traumatic bulbar strictures with complete obliteration of the urethral lumen and full thickness spongiosfibrosis [319, 322]. These strictures are a specific entity and usually the result of a straddle injury with complete or nearly complete rupture of the bulbar urethra. These obliterations are predominantly short and can be treated with tEPA yielding a patency rate of 98.5% as reported in the series of Horiguchi et al., [323]. They also reported an improvement in erectile function after urethroplasty measured one year post-operatively. Straddle injury (and perineal trauma) are a common aetiology in papers published about tEPA; however, separate data on the outcomes for this specific aetiology is usually lacking.

6.3.2.1.1.1.2 Complications

Nilsen et al., conducted an RCT comparing tEPA with FGU for short (< 2 cm) bulbar strictures [315]. Compared to FGU, penile complications were more frequent with tEPA. After three months, worse ejaculation (26%), reduced glans filling (26%), penile shortening (16%) and penile chordee (10%) were significantly more reported with tEPA. After 12 months, reduced glans filling (19%) and penile shortening (26%) remained significantly more reported with tEPA. A scrotoperineal hematoma was significantly more frequent with tEPA compared to FGU (resp. 24 versus 4%). Despite these complications IIEF-5 was not significantly different between both groups at three and twelve months.

These latter complications (as well as ED) might be attributed to complete transection of the corpus spongiosum at the level of the stricture, thereby disrupting the antegrade blood flow of the urethra and corpus spongiosum. To spare this, the non-transecting EPA (ntEPA) has been described [324] and later modified [325].
6.3.2.1.2.1 Patency rates

Except for straddle injuries that are usually associated with complete obliteration of the lumen and full thickness scarring of the corpus spongiosum [319, 326], ntEPA is a good alternative for short bulbar strictures of all other aetiologies. With median follow-ups ranging between 17.6 and 37.1 months, the patency rates reported are 93.2-99%; with the lack of further intervention as success criteria [322, 327, 328]. Even with the anatomic criteria (16 Fr cystoscopy passage) the success rate achieved was 97.9% at twelve months [319] (see supplementary Table S6.7).

Two comparative analyses evaluated tEPA vs. ntEPA. Waterloos et al., reported patency rates of 88.4% and 93.2%, respectively, for tEPA and ntEPA (p=0.33) but with significantly longer follow-up for tEPA (118 vs. 32 months, p < 0.001). Of patients scheduled for ntEPA, 11.1% were converted to tEPA, highlighting that ntEPA is not always possible. Chapman et al., using anatomic success criteria (16 Fr cystoscope passage), reported patency in 93.8% of tEPA vs. 97.9% of ntEPA. Follow-up was also significantly shorter at 74.1 (SD: 45.4) months for tEPA vs. 37.1 (SD: 20.5) months for ntEPA (p < 0.001) [319].

6.3.2.1.2.2 Complications

When erectile function after urethroplasty was assessed (at six months), ntEPA had significantly lower ED rates (a decrease of > 5 points on the sexual health inventory for men [SHIM] scale) compared to tEPA (4.3 vs. 14.3%, respectively) [319]. Urethral transection performed during tEPA was the only factor associated with sexual dysfunction in a multivariate analysis [319]. Other series reported ED lasting for more than six months in 2-6% of cases after ntEPA [322, 328, 329]. Grade > 2 Clavian-Dindo complications were 3.6-8.1% vs. 4.3-6.8%, respectively, for tEPA and ntEPA, without reaching statistical significance [319, 327].

To date, no trials comparing ntEPA with FGU have been published to report on comparative patency outcomes and complications.

6.3.2.1.2 Free graft urethroplasty

Despite the very high patency rates of EPA, FGU has been performed for short bulbar strictures as well. This is mainly driven by reports of ED after EPA. A meta-analysis of ten papers [340] comparing tEPA with BMG FGU for short strictures, found that tEPA is better than BMG FGU in terms of patency rates (91.5% vs. 70%), whilst BMG FGU has less erectile complications (9% vs. 25%). However, the methodology of this meta-analysis must be disputed as it was performed on cohort studies without risk of bias assessment and without further specification of timing of assessment of ED. On the other hand an RCT comparing tEPA with BMG FGU, found no significantly different patency rates for EPA compared to BMG FGU (88% versus 87% respectively) and no significant differences in erectile function for tEPA compared to BMG FGU [315]. As mentioned earlier, penile complications were more frequent with EPA.

Dogra et al., [283] looked prospectively at sexual function in 87 patients after different urethroplasties (EPA, penile/bulbar substitution) and found a 20% reduction in sexual function in all groups, which resolved after six months.

Details on where to place the graft during FGU are discussed below.

6.3.2.2 “Longer” bulbar strictures

6.3.2.2.1 Free graft urethroplasty

For strictures not amenable to EPA, FGU is the technique of choice and buccal mucosa is, at the moment, the most widely used graft. Other grafts (and flaps) are possible and discussed in the tissue transfer chapter. Patency rates of FGU of the bulbar urethra are 88-91% with twelve to 40 months follow-up [264, 330]. There is a suggestion that patency rates deteriorate with time [331].

During bulbar urethroplasty, the bulbospongious muscle is usually separated at the midline which may cause damage to the muscle and perineal nerves. This might subsequently provoke post-void dribbling and ejaculation disorders. In order to reduce this, the muscle and nerve-sparing perineal approach has been introduced [332]. Although it is mostly used in graft urethroplasty, this approach is also possible for EPA [333]. Elkady et al., [329] randomised 50 patients between a muscle and nerve-sparing perineal approach vs. a classic perineal approach and found no difference in operative time (100 vs. 105 min), but significantly less dribbling (4% vs. 36%, p=0.01), and significantly less ejaculatory changes (8% vs. 40%, p=0.02) in the nerve and muscle-sparing group. Fredrick et al., [333] did the same in 50 patients in a multicentric study with bulbar urethroplasty but could not find a statistical difference regarding post-void dribbling and ejaculatory changes. Due to the limited and conflicting evidence, no recommendation can be made about the routine use of nerve and muscle-sparing modification during bulbar urethroplasty.

See supplementary Table S6.8 for further information.

6.3.2.2.2 Augmented anastomotic repair

Augmented anastomotic repair has been described for these strictures. It has been mainly performed in cases where the stricture was just too long (+/- 2-4 cm) for tension-free EPA [334]. It can also be performed for longer strictures with a shorter (nearly) obliterative segment [335]. In this case, only the most obliterative segment is excised, the urethral plate is anastomosed, and the urethra is further reconstructed with an onlay graft [335]. Patency rates after AAR vary between 91.1 - 91.9% with twelve to 28 months follow-up [334]. The use of this technique has been challenged by Redmond et al., who found a 4.8 higher risk of recurrence when AAR was used compared to (dorsal) free graft urethroplasty [336] (see supplementary Table S6.9).

A non-transecting alternative has also been described to overcome the previously mentioned inconveniences related to spongiosal transection (augmented non-transecting anastomotic bulbar urethroplasty [ANTABU]). With this technique, Bugeja et al., [337] reported a 100% patency rate in sixteen patients after a median follow-up of thirteen months. One patient (6.7%) suffered permanent ED.

### Summary of evidence

| For strictures not amenable to EPA, FGU provides an 88-91% patency rate at short to medium follow-up | 1b |
| Augmented anastomotic repair provides good (88-92%) patency rates for bulbar strictures with a nearly obliterative segment, despite deterioration with time. | 3 |

### Recommendations

| Use free graft urethroplasty for bulbar strictures not amenable to excision and primary anastomosis (EPA). | Strong |
| Use augmented anastomotic repair for bulbar strictures not amenable to EPA but with a short, nearly obliterative segment within the whole strictured segment. | Weak |

6.3.2.2.3 Location of the graft during urethroplasty for bulbar strictures

The best location for graft positioning into the bulbar urethra remains to be determined. There are many techniques described with ventral, lateral, dorsolateral, or dorsal graft as an onlay or an inlay. Onlay means from the outside onto the urethra, inlay means from the inside after opening the urethra.

Regarding the site of graft placement, the Panel has conducted a SR assessing the literature from 1996 onwards, including studies with at least 20 patients and a minimum of twelve months follow-up [7]. This yielded one RCT, four non-randomised comparative series and 36 case series comprising 3,683 patients. The RCT of Vasudeva et al., compared ventral (n=40) with dorsal (n=40) onlay BMG urethroplasty and reported a patency rate of 90 - 92.5%, respectively at twelve months follow-up (p=0.51) [330]. The non-randomised comparative studies could not identify any significant differences in patency rates for dorsal onlay vs. ventral onlay, dorsal...
inlay vs. ventral onlay or dorsal onlay vs. ventral onlay vs. dorsolateral onlay. Case series reported a patency rate of 62.1-98.3% for dorsal onlay, 74.3-94.4% for ventral onlay and 78.4-92% for dorsal inlay. There are no arguments to assume a higher risk of ED with one of the four techniques. Post-void-dribbling was reported in 0-28.1% with dorsal onlay and in 20-21% with ventral onlay. Other complications were also similar in incidence between techniques. Urethrocutaneous fistula and urethral diverticulum were only reported with the ventral onlay technique although this consisted of only two and one cases, respectively.

Double ventral-dorsal onlay, proposed for high-grade/nearly obliterative strictures, yielded a patency rate of 90-91% after 22-33 months follow-up [146, 338].

**Summary of evidence LE**

| Location of the graft has no impact on patency rates. | 1b |

**Recommendation**

| Use dorsal, dorsal-lateral, or ventral approach according to surgical practice, expertise, and intra-operative findings. | Strong |

6.3.2.3  **Staged urethroplasty for bulbar urethral strictures**

6.3.2.3.1 Indications

Staged urethroplasty may be considered when:

- there are locally adverse conditions such as fistula, false passage, abscess, cancer [282, 339, 340];
- there has been a previously unsuccessful complex urethroplasty including failed hypospadias repair [257, 339];
- there is a lack of certainty on behalf of the surgeon regarding the most appropriate form of urethroplasty for the patient [339];
- the stricture is radiotherapy induced [257];
- the stricture is consequent to LS [257] (this is controversial and for some groups LS is a contraindication for a staged urethroplasty [305]; Kozinn et al., recommend leaving at least ten months between 1st stage and 2nd stage re-tubularisation in patients with LS to allow graft complication to develop) [257];
- there is severe spongiofibrosis [341].

6.3.2.3.2 Outcomes

Patency rates of 33.3-94.6% at mean follow-up of 11.2-50 months have been described for staged urethroplasty in series which include men with bulbar urethral stricture disease [257, 305, 318, 341-343]. Grafts (mesh graft, preputial skin, oral mucosa) can be used in staged augmentation as well as marsupialisation [318, 341]. In patients affected by LS, a 52.2% patency rate for staged urethroplasty was reported whereas this was 86% for single-stage buccal mucosa urethroplasty (p < 0.01) [305]. It is highly likely that different stricture and patient characteristics contributed to the differences reported and this should be kept in mind when interpreting the data. Of note, 19-45.5% of patients planned for staged urethroplasty declined to proceed to 2nd stage re-tubularisation [257, 342].

Early complications after staged procedures include wound dehiscence, UTI, epididymitis, scrotal abscess, and penile numbness. Specific to 2nd stage Johanson urethroplasty UCF occurs in 3-15%. The actual incidence of UCF is probably higher as many small fistulae close spontaneously with conservative management and are not formally reported [305, 318, 341].

Late complications of 1st stage urethroplasty include a need for revision in up to 19% - as a consequence of recurrence of LS in graft(s) (8.8%), graft contracture (6.6%) and stomal stenosis (3.3%) [257]. Late complications of 2nd stage urethroplasty include post-micturition dribble in 14-18%, SUI in up to 16%, penile curvature in up to 9%, ED in up to 4%, urethral diverticulum formation in 1% and cold glans [305, 341, 343]. Stress urinary incontinence, penile curvature and ED appear to be particularly associated with mesh graft stage urethroplasty [341, 343].

After their procedure, 86% and 96.6% of men with, respectively, mesh graft and buccal mucosa graft staged urethroplasty were satisfied. The patient groups included in the review were too small to detect significant differences [341]. All are retrospective series – with heterogenous indications, stricture locations (not exclusively bulbar), stricture lengths and patient groups. It is consequently difficult to draw meaningful conclusions from the little data that are available.
See supplementary Table S6.10 for more information.

6.3.2.3.3 Risk factors

There is a lot effort in identifying risk factors affecting the success rate of urethroplasties. The evidence is not clear about age, obesity, aetiology or prior radiation or prior surgery. The only clear risk factors in multivariate analysis are the length and the site of the stricture, success rates are better in shorter or bulbar strictures and worse in longer or penile strictures [317, 344-346]. Patient should be informed about the higher risk in longer and penile strictures.

6.3.2.3.4 Risk factors for adverse outcomes

In four series specifically dedicated to risk factors for failure after urethroplasty using multivariate analysis, there is conflicting evidence about several factors (aetiology, comorbidity, stricture length, prior therapy) that might be predictive for failure after urethroplasty (Table 6.6). Advanced age does not appear to be a risk factor for urethroplasty failure in the majority of studies, with the exception of Viers et al., 2017 [347] retrospective case series which found that the risk for recurrence was significantly higher beyond the age of 60 (< 50 yrs 94%, > 70 yrs 74%) in 184 patients having a wide variety of urethroplasties. Previous radiation therapy was also found to be a risk factor for stricture recurrence in both Viers’ [347] retrospective case series and Ahlayi’s 2015 series [348] – with only a 71% patency rate at a median follow-up of 29 months in those with previous radiotherapy. Based on these data, a clear and evidence-based recommendation cannot be formulated.

6.3.2.4 Management of recurrence after bulbar urethroplasty

Kahokehr et al. [334] followed nearly 400 patients after urethroplasty and found a recurrence rate of 6% (n=25). Ninety-two percent of the failed cases were treated successfully with DVIU and only 8% needed another open reconstruction. However, they did not mention characteristics of the recurrent cases nor the duration of follow-up. Rosenbaum et al. [352] and Javali et al. [353] retrospectively analysed the outcomes of BMG FGU for ReDo urethroplasty in 51 and 21 patients, respectively, using the other cheek as donor side. Patency rates were 82-86%, which is in the range of primary cases.

Vetterlein et al. [354] compared primary (no previous open urethroplasty) vs. ReDo (previous open urethroplasty with BMG) vs. secondary (previous open urethroplasty without use of BMG) cases in a retrospective series of 534 patients with BMG FGU. The patency rates in primary and ReDo cases were comparable (87%) whilst the outcome in secondary cases was worse (71%).

A small series (n=37) reported on the use of EPA for revision surgery after failed urethroplasty in strictures of 2.1 (range 1-3.5) cm length on average. Patency rates using EPA after failed primary EPA (51%) and after any other technique of urethroplasty (49%) were 95 and 94% respectively with a mean follow-up of 30 months [321].

Summary of evidence LE

Buccal mucosa free graft urethroplasty after failed urethroplasty achieves the same patency rates as primary cases.

3

Recommendation Strength rating

Use oral mucosa free graft urethroplasty for ReDo urethroplasty in case the of a long stricture. Strong

6.3.3 Urethroplasty for penobulbar or panurethral strictures

The possibilities for reconstruction are various and often include combinations of different techniques or grafts other than OMG. The patency rates are usually lower than in shorter reconstructions (Table 6.7). Hussein et al. [355] performed a RCT comparing skin grafts vs. skin flaps in strictures of mean length 15 cm and found no difference in patency rates (72% vs. 79%) or complications.

Warner et al. [305] performed a multi-institutional review in 2015 including 466 patients with stricture length > 8 cm and found an overall patency rate of 77.5%. As discussed previously, Kozinn et al. [257] reported on the outcome of staged urethroplasty in a cohort of which 54.9% had panurethral strictures (Table 6.7).

Kulkarni et al. [356] proposed a one-stage completely perineal approach with invagination of the penis and one-sided urethral dissection. After 59 months the overall patency rate was 83.7% in 117 men with a mean stricture length of 14 cm.

Another option in patients refusing or unfit for complex reconstructive surgery is PU (see section 6.3.4 Perineal urethrostomy).

6.3.4 Perineal urethrostomy

6.3.4.1 Indications

Perineal urethrostomy offers a permanent or temporary solution for restoration of voiding in men with complex urethral stricture disease in whom:

- there are no further options to restore urethral patency either due to multiple previous failed urethroplasties [305, 339] or multiple co-morbidities precluding a more expansive surgical undertaking after failed endoscopic management [363];
- there is a lack of certainty on behalf of the surgeon regarding the most appropriate form of urethroplasty for the patient;
- following urethrectomy and/or penectomy for cancer [364].

6.3.4.2 Types of perineal urethrostomy

Johanson described an inverted anterior scrotal funnel PU in 1953. This was later modified by Gil-Vernet and Bandy to utilise a posteriorly based scrotal flap. Both these techniques utilise an inverted U or lambda incision. The Gil-Vernet-Bandy PU has been further modified with the addition of dorsal and/or ventral free OMG augment to allow use of PU in men with strictures consequent to radiotherapy [365] or LS [259] and/or in men with PU stenosis or stricture extending into the proximal bulbar or membranous urethra (“augmented Blandy”) [363].

More recently, the ‘7 flap’ PU utilising a unilateral posteriorly based scrotal flap has been developed for use in the very obese, or in men of all BMI with stricture extension into the proximal bulbar or membranous urethra [366]. Initially this was performed with transection of the distal bulbar urethra but latterly the technique has been modified to a non-transection technique with loop mobilisation of the bulbar urethra (“loop PU”) [367]. The “7-flap” utilises a midline incision – which has been shown to have a significantly reduced side-effect profile in terms of superficial wound infection (1.9% c.f. 18.6%) and superficial wound dehiscence (11.9% c.f. 23.3%) than the inverted U or lambda incision [368, 369] and may be associated with improved urethroplasty (and by inference PU) outcomes, at least in the short term (0% failure c.f. 6.2% failure at six months) [368]. Operative time is similar for all types of PU with mean operative time varying between 97.2 minutes to 112 minutes [364, 370].
The utilisation of PU is increasing [371] – constituting 4.5% of 403 procedures for complex urethral stricture disease in a tertiary centre in 2008 and 38.7% in 2017 [372]. Perineal urethrostomy patients are generally older than those having urethroplasty with a median of 62.6 years of age for men having PU in Fuchs et al., 2018 series compared with a median of 53.2 years for men having anterior urethroplasty [372]. Between 18.7% and 73.4% of men having staged urethroplasty for complex anterior urethral stricture decline to proceed to 2nd stage re-tubularisation after a successful 1st stage and remain voiding from the PU of their 1st stage urethroplasty [257, 339, 342].

6.3.4.3 Outcomes
6.3.4.3.1 Patency rates
Patency rates of 70-95% at mean/median follow-up of 20–63 months have been described [305, 339, 347, 363-366, 370, 372]. All reports are retrospective series – all of which are heterogenous in terms of indications and patients. There is consequently little data available to determine which is the best technique for PU. McKibben et al., reported a patency rate of 92.9% in 42 patients for “7-flap” PU at median follow-up of 53.6 months, whilst they had a 100% patency rate with loop PU in twenty patients at a median follow-up of thirteen months [367].

Lumen et al., in 2015 reported a 74.3% patency rate for Johanson PU compared with an 87.5% patency rate for Gil-Vernet-Blandy PU (p=0.248), but with a significantly longer follow-up after Johanson PU (median 36 vs. nine months) [364]. Barbagli et al., published the largest series of PU patients to date – including 173 men (all of whom had been planned to have a staged urethroplasty for their complex anterior urethral stricture disease and 127 (73.4%) of whom declined to proceed with 2nd stage re-tubularisation). The median follow-up in this series was 62 months and the patency rate was 70% - confirming that patency rates for PU (and indeed for all urethroplasty [273, 346]) reduce with time [339].

See supplementary Table S6.11 for further information.

6.3.4.3.2 Complications
Perineal urethrostomy complications occur in 2.5-11.4% and include superficial wound dehiscence, scrotal abscess, UTI and urosepsis, bleeding, and transient scrotal pain and numbness [305, 364, 373]. The majority of complications are Clavien-Dindo grades 1 (2.9-18.8%) and 2 (0-2.9%). Grade 3 complications are rare and only occur in 5.7-6.2%. In the medium-term 22.2-30.8% of men with PU report post-micturition dribble [364].

6.3.4.3.3 Patient reported outcomes
Barbagli et al., reported that 168/173 (97.1%) of men were satisfied or very satisfied with the outcome of their Gil-Vernet-Blandy PU and would have the procedure again at median 62 months follow-up. Of these, 166/173 (95.9%) felt they had excellent or good results from their Gil-Vernet-Blandy PU, 145/173 (85%) felt it caused them no problems and 141/173 (82%) felt it caused their partner no problems [339]. The Trauma and Urologic Reconstructive Network of Surgeons (TURNS) collaborative found no significant change in sexual function and a significant improvement in urinary symptoms following PU in a small group of patients [374], whilst Lumen et al., found satisfactory or acceptable International Prostate Symptom Score (IPSS) outcomes in 26/32 (81.25%) of men with Johanson or Gil-Vernet-Blandy PU at a median follow-up of 32 months and nine months, respectively.

McKibben et al., found a mean patient global impression of improvement (PGI-I) of 1.3 in nineteen patients with either loop PU or “7-flap” PU [367] at median 31 months follow-up.

6.3.4.3.4 Risk factors for patency failure of the perineal urethrostomy
Lichen sclerosus, trauma and infection urethral strictures have poorer outcomes from PU, with PU patency failure in 36.7-67% at a median 62 month follow-up [339, 373]. Worse outcomes were also observed in patients with previous failed urethroplasty and multiple previous endoscopic and open treatments [339, 364, 365]. Barbagli et al., found that stricture length was inversely related to PU patency, as was patient age [339]. Conversely Viers et al., found outcomes worsened with age, reporting patency rates of 100% in men < 50 years old compared with 83% in men aged 60-69 years old [347]. Lopez et al., found increased risk of PU failure in men with ischaemic heart disease which makes sense and would be a putative explanation for the age-related worsening of outcomes noted by Viers et al., [373].

Failure of PU is most commonly treated with surgical revision of PU using V-Y plasty, augmentation or complete ReDo but can also be managed with periodic dilatation or urinary diversion [339, 363, 364].

6.3.5 Posterior urethra

6.3.5.1 Non-traumatic posterior urethral stenosis

6.3.5.1.1 Treatment of non-traumatic posterior urethral stenosis

Several treatment modalities including conservative management (see section 6.1 Conservative options), endoluminal, open or minimally invasive surgical procedures are currently available, depending on patient's goals and health status.

6.3.5.1.2 Endoluminal management of non-traumatic posterior urethral stenosis

6.3.5.1.2.1 Dilatation of non-traumatic posterior urethral stenosis

This can be done under loco-regional anaesthesia [375-379]. Dilatation is used for VUAS [375-380] or radiation induced BMS [381] and in the majority of reported cases, patients were not previously treated for their stricture (see supplementary Table S6.12). Patency rates vary widely between 0-89% [117, 375-381]. The risk of de novo UI was low (0-11%) and no other complications were reported. It is of note that most series report on visually controlled dilatation [375-379] in VUAS without complete obliteration.

6.3.5.1.2.2 Endoscopic incision/resection of non-traumatic posterior urethral stenosis (Table 6.8)

Incisions can be performed at multiple locations according to surgeon's preference [382]. However, aggressive incisions at the six and twelve o’clock positions should be avoided because of the risk of, respectively, rectal injury and urovesical fistulation [189, 383-385]. The risk of urovesical fistulation is especially a concern after previous radiotherapy [386]. Result of bladder neck incision for VUAS are poorer after radiotherapy [387]. Direct vision internal urethrotomy is mainly performed in patients with primary or recalcitrant VUAS although one series performed it in a mix of patients with VUAS and BNS [388] and two series reported it for radiation-induced BMS [117, 381]. Direct vision internal urethrotomy/ dilatation for non-irradiated BMS are usually included in series reporting on anterior strictures (see section 6.2 Male endoluminal treatment of anterior urethral strictures). Patency after a 1st “cold/hot knife” DVIU ranges between 25-80% [375, 376, 380, 382, 388-393]. Laser incision yields a 69-100% patency rate [376, 380, 394, 395]. In a retrospective and unbalanced series, La Bossiere et al., found better patency rates for laser incision as compared to dilatation, “cold knife” DVIU and transurethral resection (TUR) [376]. Redshaw et al., reported inferior patency rates for “cold knife” incision vs. “hot knife” incision followed by MMC for BNS (50 vs. 63%; p=0.03) [236] (see supplementary Table S6.13).

Urinary incontinence largely varies between 0 and 53% but some series have not assessed urinary continence before DVIU [389, 391]. In series where pre- DVIU continence data were available, de novo urinary continence after DVIU ranges between 0% and 10% [375, 380, 390, 392, 394]. Noteworthy, of 21 patients that were incontinent pre-DVIU in the series of Giannarini et al., eleven (52%) patients became continent, and eight (38%) patients experienced improvement after DVIU [390]. As most recurrences will occur early [390, 391], it
is advised to wait for three to four months after DVIU [382, 391, 396] to proceed with incontinence surgery, if necessary, although others wait for twelve months [397]. The presence of recurrence must be ruled out by cystoscopy prior to incontinence surgery [382, 391, 396, 397].

Another option is to resect the stenosis. Popken et al., reported a 47% patency rate with TUR for untreated VUAS and no patient suffered de novo SUI [392]. Kranz et al., compared the results of TUR in 87 and 60 patients with, respectively, VUAS after RP and BNS after TURP. After a median follow-up of 27 (range: 1-98) months, patency rate was 40.2% for VUAS and 58.3% for BNS (p=0.031). The rate of de novo incontinence was significantly higher in patients treated for VUAS compared to BNS (13.8 vs. 1.7%; p=0.011) [398]. There is conflicting evidence whether resection is associated with higher incontinence rate compared to incision. [379, 399] Brodak et al., compared TUR by bipolar resection (n=22) with holmium laser incision and vaporisation (n=17). After a mean follow-up of 42 months, two (9.1%) and four (23.5%) patients suffered a recurrence with bipolar and laser resection respectively (p=0.37). After six months, patients treated with bipolar resection had a significantly better Qmax compared to laser treatment (13 vs. 6.1 ml/s; p < 0.001) [395]. Bipolar plasma vaporisation produced an 82% patency rate at a mean 24-month follow-up in 28 patients with VUAS who previously failed endoscopic treatment [400].

Cut-to-the-light technique for a complete obliteratorative stricture is not advised because of the very-low likelihood of durable patency and for the risk of false passage towards the rectum [396, 401, 402].

Repeat DVIU was often able to stabilise the stricture [117, 375, 376, 381, 388-390, 398], but ultimately 6-10% required urinary diversion [391] or chronic suprapubic cystostomy [381, 388].

Transurethral resection can be performed for prostatic obstruction due to sloughing after high-energy treatments (HIFU, cryoablation) [100]. Transurethral resection for obstructive necrotic debris after radiotherapy is possible but is of limited role. Risk of recurrence is 50% and risk of de novo UI is 15-25% [100].

### Post-Dilatation/Direct Vision Internal Urethrotomy Strategies for Non-traumatic Posterior Urethral Stenosis

#### 6.3.5.1.2.3.1 Intermittent Self-Dilatation for Non-traumatic Posterior Urethral Stenosis

As for anterior strictures, ISD can be offered to patients for recurrent posterior stenosis after dilation/DVIU to stabilise the stenosis. This is especially relevant for patients unfit/unwilling to undergo surgery or in patients with radiation-induced BMS [117, 376, 381, 403]. Although ISD may be acceptable to many urologists and patients, it usually is associated with a reduced QoL and poor patient compliance [33].

#### 6.3.5.1.2.3.2 Intravesical Injections for Non-traumatic Posterior Urethral Stenosis

In order to stabilise the luminal fibrosis and consequently to reduce the risk of recurrence, injection of antifibrotic agents at the time of endoluminal treatment has been proposed. The majority of patients in these studies were patients with recalcitrant/recurrent non-obliterative VUAS/BNS. Two series used corticosteroids [379, 396], whilst the others used MMC [397, 401-405]. Patency rates with corticosteroid injections range between 50-100% [379, 396]. Patency rates with MMC vary between 50-94% [397, 404-406]. No trials comparing endoluminal treatment with or without adjuvant intravesical injections were identified.

See supplementary Table S6.13 for further information.

### Complications

Complications are low across most studies, but all studies were retrospective in nature. Redshaw et al., also reported grade 3 complications in four out of 55 (7%) patients, including osteitis pubis (n=2), bladder neck necrosis (n=1) and rectourethral fistula (n=1) in one multi-institutional study [404]. Three of these patients ultimately required urinary diversion with additional faecal diversion in one patient [404]. Given the severity of these complications, although rare, MMC should not be used outside the framework of a clinical trial [407].

### Urethral Stent for Non-traumatic Posterior Urethral Stenosis

Stents have been used anecdotally in the posterior urethra [247, 248, 376]. Patency rates are relatively low (47-60%) [247, 248, 376] at the cost of a high-risk for UI (19-82%) [247, 248].

BNS = bladder neck stenosis; DVIU = direct vision internal urethrotomy; FU = follow-up; ISD = intermittent self-dilatation; NR = not reported; TUR = transurethral resection; VUAS = vesico-urethral anastomosis stricture.

*patency rate after 1st endoluminal treatment evaluated in the study.
* requiring incontinence surgery (artificial urinary sphincter or male sling).
** slightly problematic urinary incontinence by questionnaire post DVIU (no data on pre DVIU continence).
***all incontinent pre-operatively.

---

### Summary of evidence

- For non-obliterative VUAS and radiation-induced BMS, visually controlled dilatation and DVIU yield a patency rate of respectively 0-89% and 25-100% with a low complication rate. It can be performed under loco-regional anaesthesia.
- During DVIU, deep incision might provoke injury to the rectum at the six o’clock position and might provoke uro-symphyseal fistulation at the twelve o’clock position. LE 3
For BNS, TUR and “hot-knife” incision yield a patency rate of respectively 58.3 and 72% with a low complication rate.

Repeat endoluminal treatments in non-obliterative VUAS, radiation-induced BMS or BNS can stabilise the posterior stenosis and are easy to perform compared to reconstructive surgery.

Any form of endoluminal treatment might be associated with de novo UI (up to 25%) or worsening of existing UI (up to 15%).

Vesicourethral anastomosis stricture, BMS and BNS with complete obliteration are not included in present series and endoluminal treatment is unlikely to be successful.

Urethral stents at the posterior urethra have a rather low patency rate (47-60%) and incontinence rate (19-82%).

6.3.5.1.3 Lower urinary tract reconstruction for non-traumatic posterior urethral stenosis

If endoluminal treatment (repeatedly) fails or in case of a completely obliterated posterior stenosis [401, 402, 408, 409], lower urinary tract (LUT) reconstruction may be considered in fit patients motivated to undergo surgery (Figure 6.1). The choice of LUT reconstruction will depend upon the length, location, calibre and aetiology of the stenosis, continence status, bladder function, previous radiotherapy, patient’s preference, and surgeon’s expertise.

Figure 6.1: Options for lower urinary tract reconstruction of non-traumatic posterior urethral obstruction (stenosis/stricture)
6.3.5.1.3.1 Redo vesico-urethral anastomosis for vesico-urethral anastomotic stenosis after radical prostatectomy

After excision of the stenosis, ReDo vesico-urethral anastomosis (ReDo VUA) can be performed. This may be performed via a retropubic, perineal, combined abdominoperineal or robot-assisted approach. Nikolavsky et al., proposes a retropubic approach for VUAS involving the bladder neck, a perineal approach for short VUAS with intact bladder neck and an abdominoperineal approach for long segment (> 3 cm) VUAS with bladder neck involvement [408]. The ReDo VUA must be performed in a tension-free fashion which can be achieved either by mobilisation of the bladder (retropubic approach), mobilisation of the bulbar urethra with corporal splitting and inferior pubectomy if necessary (perineal approach) or both (abdominoperineal approach) [408, 410]. Dinerman et al., reported a robot-assisted abdominoperineal approach in a case with 4.5 cm long complete obliteration [411]. Kirshenbaum et al., reported a pure robot-assisted abdominal approach. Regardless of the approach, the procedure is technically demanding due to the location deep under the pubic symphysis, and the proximity of the external sphincter [410]. As a consequence, surgical morbidity must be considered. As most patients with VUAS were healthy enough to undergo RP, most patients will likewise remain fit and eligible for VUAS surgical reconstruction [408, 410].

* incontinent before ReDo VUA.
** de novo incontinence in four out of eleven patients.
*** social continent (1 pad/day).

ReDo VUA in non-irradiated patients yields patency rates of 60-91% (Table 6.9) [408-410, 412-414]. Prior radiotherapy is a risk factor for failure [410, 412]. In addition, radiation-induced bladder toxicity might provoke reduced bladder capacity, low bladder compliance, bladder spasms and pain, and urethral necrosis making reconstruction futile (see below) [386, 410, 415]. ReDo VUA should only be done in patients with adequate bladder function and in the absence of (peri)-urethral pathology (urethral necrosis, calcification, fistulation). Flaps (gracilis flap, peritoneal flap) to support and protect the anastomosis may be beneficial in irradiated patients [408].

With the transperineal approach, UI is inevitable, as this approach disrupts the external sphincter [409, 410, 412, 414]. With the retropubic approach, Pfalzgraf et al., reported de novo incontinence in only four out of eleven (36%) patients [413]. In the series of Nikolavsky et al., where a retropubic approach was predominantly used, incontinence rate was 58% [408]. Kirshenbaum et al., reported no incontinence in five patients.
treated by robot-assisted retropubic approach [409]. Giudice et al., reported incontinence in one out of four patients treated with the retropubic approach [414]. Therefore, some authors [100, 408, 409] have proposed a preference for the retropubic approach in patients with good pre-operative urinary continence, although both approaches have never been directly compared for UI. In addition, the lack of perineal dissection by a retropubic approach will preserve the perineal anatomy and vascularisation which makes subsequent artificial urinary sphincter (AUS) less demanding [409]. Artificial urinary sphincter implantation should be deferred because of the risk of VUAS recurrence and difficulty of treating any recurrent VUAS with the cuff of the AUS in place [391, 410]. The exact timing of AUS placement is not consensual in the literature but most advise waiting at least three to six months to ensure stability of the VUA patency [386, 407, 410, 412].

Due to the complexity of this pathology the EAU Urethral Strictures Panel advises that VUAS reconstruction should be performed only in experienced high-volume centres, particularly after prior radiotherapy or other energy ablative treatments.

6.3.5.1.3.2 Posterior stenosis after surgery for benign prostatic obstruction

6.3.5.1.3.2.1 Bladder neck reconstruction for bladder neck stenosis after surgery for benign prostatic obstruction

The bladder neck is augmented by advancement of local bladder flaps (Y-V or T-plasty) with or without resection of scar tissue. They are used for BNS refractory to endoscopic treatments [409, 416-418]. Patency rates vary between 83-100% with fourteen to 45 months follow-up [409, 416-418]. There is a trend to perform bladder neck reconstruction by minimally invasive approach (laparoscopic, robot-assisted) [409, 417, 418]. De novo incontinence rate ranges from 0-14% [409, 416-418]. Satisfaction among patient is high with 88.5% of patients stating that they are pleased with the surgery, with an improvement of QoL in 75% of patients [416, 418]. Recently, a robot-assisted augmentation technique with subtrigonal buccal mucosa inlay has been successfully reported in a case report, but this technique requires further investigation [419].

See supplementary Table S6.14 for further information.

6.3.5.1.3.2.2 Bulbomembranous strictures after surgery for benign prostatic obstruction

Bulbomembranous urethral strictures (BMS) after TURP or simple prostatectomy are managed as bulbar strictures and can be treated by EPA or augmentation urethroplasty with a graft, taking into account the length and tightness of the stricture [82]. Kulkarni et al. reported a similar patency rate for dorsal and ventral onlay urethroplasty (resp. 81.8% versus 84.6% after mean follow-up of 14 months) [420]. As reconstruction is in the proximity of the external sphincter and the bladder neck was already damaged during BPO surgery, the risk of incontinence (up to 25%) is present [82].

6.3.5.1.3.3 Radiation/high-energy induced posterior strictures

6.3.5.1.3.3.1 Bulbomembranous strictures secondary to radiation/high energy sources

The major challenge in treating radiation-induced strictures is the consequent tissue damage with impaired healing capacity, involving not only the stricture itself but also the adjacent proximal and distal areas of the scar [421]. Additionally, proximity of the stricture to the external sphincter can further complicate surgery [421]. Due to these challenges, patients with radiation-induced BMS have long been considered poor candidates for urethral reconstruction and have been treated with urinary diversion if endoscopic treatments failed or were not possible [421].

Most radiation-induced BMS are short and in these cases, EPA is possible avoiding the use of a graft or a local flap in an area of poor vascular health. However, EPA will not be possible for BMS with a long bulbar segment and in these cases, augmentation urethroplasty will be necessary despite the aforementioned concerns. A systematic review reported a pooled patency rate of 80% with no significant differences between type of urethroplasty (EPA versus augmentation urethroplasty). Stress UI was reported in 19% of cases [421]. Rourke et al., reported no significant differences between EPA and augmentation urethroplasty regarding de novo UI (26 vs. 25%; p=1), new onset ED (35 vs. 0%; p=0.06) or other adverse events (30% vs. 33%; p=1) [422].

6.3.5.1.3.3.2 Prostatic strictures secondary to radiation/high energy sources

Radiotherapy and high-energy modalities (cryoablation, HIFU) might provoke prostatic necrosis, sloughing and obstruction [100]. Cases refractory to TUR and with good bladder capacity might be salvaged by prostatectomy taking into account the morbidity associated with salvage RP (rectal injury, VUAS, incontinence) [100, 423]. Mundy et al., treated nine patients with patency in six, (67%) and one (11%) needing an AUS for severe incontinence [410].

Cases with impaired bladder function, urethral necrosis and/or peri-urethral pathology should be considered for supravesical diversion, especially if a suprapubic catheter is not tolerated due to bladder pain or spasms [386, 407, 410, 415].

Recently, a “pull-through” procedure has been reported as an alternative to cutaneous diversion for reconstruction of the devastated posterior urethra associated with a defunctionalised bladder after radiation where tissue vascularity and quality is poor [424]. This novel technique of total LUT reconstruction combines salvage cystectomy, ileal neobladder formation and urethral pull-through. An AUS was implanted in a second stage. All eight patients maintained a patent posterior urethra after a median follow-up of 58 (range 16-84) months. Five patients experienced low-grade complications after the first stage, but no high-grade complications were reported. Four out of eight (50%) patients experienced cuff erosion with need for removal and subsequent reimplantation. After a median of two revision surgeries (range 0 to 4), all patients achieved social continence enhancing QoL [424]. This technique requires further validation before its use can be recommended.

Summary of evidence

| Patency rates of urethroplasty for radiation-induced BMS is 80% with no significant differences between EPA and augmentation urethroplasty. | LE 3 |
| Radiation-induced BMS longer than 2-2.5 cm are rarely amenable for EPA. | LE 3 |
| De novo incontinence and new onset ED after urethral surgery for radiation-induced BMS are reported in respectively 19-26% and 0-35% of cases. | LE 3 |
| Salvage prostatectomy can achieve patency in 67% of patients for prostatic strictures after irradiation or high-energy treatments but morbidity is substantial. | LE 4 |

6.3.5.1.4 Extirpative surgery and urinary diversion for non-traumatic posterior urethral stenosis

In complex and/or recurrent cases [408], LUT reconstruction is not possible or not indicated due to severe necrosis, calcification and significant morbidity, especially severe pain [407]. Intractable haematuria or fistulation might be other reasons to abandon the urethral outlet. Typically, the patient has a history of pelvic irradiation or high energy prostate cancer treatment and several previous attempts to achieve cure. Moreover, and equally important, any of the options used to deal with a devastated posterior urethra are dependent upon good bladder capacity, compliance and function allowing for bladder preservation as well as healthy distal ureters [386, 407]. The last resort therapeutic option is urinary diversion (continent or incontinent) with or without cystectomy [410, 415]. Different techniques have been described and the choice between them largely depends on the bladder capacity, presence of local symptoms, performance status and expectations of the patient. Cystectomy during urinary diversion is able to palliate symptoms of intractable bladder pain, spasms and haematuria which are especially prevalent after pelvic radiotherapy [425-428]. The satisfaction rate was reported to be 100% and the overwhelming majority of patients would have undergone this extirpative surgery an average of thirteen months sooner in a study of fifteen patients by Sack et al. [429]. In a report by Faris et al., 27% of the patients also required bowel diversion due to intractable gastrointestinal morbidity, highlighting the complexity of this pathology [415].

6.3.5.2 Post-traumatic posterior stenosis

The acute and early management of PFUIs is discussed in the EAU Guidelines on Urological Trauma. A nonobliterative stenosis is the result of a partial injury at the membranous urethra or occurs after unsuccessful early realignment of a partial or complete injury. An obliterative stenosis is the consequence of a complete injury with a distraction defect between the ruptured urethral ends. The gap between these ends fills up with dense fibrotic tissue [11].

The deferred management of PFUI is at earliest three months after the trauma. After that period, the pelvic haematoma has nearly always resolved, the prostate has descended into a more normal position, the scar tissue has stabilised [430] and the patient is clinically stable and able to lie down in the lithotomy position [430].

6.3.5.2.1 Endoluminal treatment for post-traumatic posterior stenosis

6.3.5.2.1.1 Endoluminal treatment as primary treatment for post-traumatic posterior stenosis

Endoluminal treatment (dilation, DVIU) of an obliterative stenosis using the cut-to-the-light principle will not be successful [46] and has a risk of creating a false passage towards the bladder base or rectum [431]. For a non-oblitervative, short (< 1.5 cm) stenosis, one attempt of endoluminal treatment (endoscopic incision or dilation) can be performed. Kulkarni et al., reported a 92.3% and 96.5% stricture-free rate with "cold knife" and holmium laser urethrotomy, respectively (median follow-up respectively 61 and 57 months) [432]. These results are challenged by Barbagli et al., who reported a 51% stricture-free rate with holmium laser urethrotomy but with no data on length of follow-up available [433]. Cai et al., compared patient outcomes between bipolar plasma vapourisation and "cold knife" DVIU in 53 patients with posterior traumatic (80%) and iatrogenic (20%) urethral strictures with significantly different stricture-free rates of 81.5% vs. 53.8% at a mean follow-up of 13.9 months, respectively [434]. No severe complications were reported in either group. A statistically significant shorter operative time was found in the bipolar group [434]. Barratt et al., calculated a composite
The stricture-free rate of 20% after all types of endoscopic treatments (but with a mix of obliterator and non-obliterator stenoses) [46]. De novo UI was reported in 4% of cases [46]. Repetitive endoluminal treatments are unlikely to be curative and must be discouraged as this delays the time to definitive cure and can lead to more complications [435, 436].

6.3.5.2.1.2 Endoluminal treatment after failed urethroplasty for post-traumatic posterior stenosis

In case of a non-obliterator and short (< 1 cm) recurrence after failed urethroplasty, endoluminal treatment can be performed [437]. Although a 1st and 2nd DVIU can be successful with a stricture-free rate of 22.9-77.3% and 0-60%, respectively, three or more incisions are never successful (see supplementary Table S6.16) [437-440]. Therefore, repetitive endoluminal treatments (dilatations and/or endoscopic incisions) can only be considered as a palliative option [441].

6.3.5.2.2 Urethroplasty for post-traumatic posterior stenosis

In view of the complexity and difficulty of urethroplasty and the fact that the best results are obtained with its first attempt, this surgery must be performed in high-volume centers [442]. It has been calculated that to achieve and maintain sufficient experience in the reconstruction of PFUI, one center per twelve million inhabitants is sufficient (for well-resourced countries) [443].

6.3.5.2.2.1 First urethroplasty for post-traumatic posterior stenosis

6.3.5.2.2.1.1 Indication and technique of urethroplasty for post-traumatic posterior stenosis

Progressive perineal EPA is the standard treatment for an obliterator stenosis and for a non-obliterator stenosis as first attempt, or after failure of primary endoluminal treatment [46, 444].

Although both a midline and inverted U-incision are possible to gain access to the posterior urethra, a midline incision is associated with a significant reduction in trauma to the superficial perineal and posterior scrotal nerves and vessels, in the rate of surgical site infections (3.1% vs. 16.4%) and reduced length of hospitalisation [369].

A combined transpubic abdomino-perineal approach is only necessary in complicated cases such as those with associated para-urethral bladder base fistula, trauma-related recto-urethral fistula, and bladder neck injury [431]. Total pubectomy during transpubic abdomino-perineal reconstruction has a higher complication rate (bleeding, pelvic instability, dead space) compared to partial (superior or inferior) pubectomy with no gain in surgical exposure [445]. Although also considered complex situations, iatrogenic recto-urethral fistula (after misdirected endoscopic treatment), traumatic recto-urethral fistula < 5 cm from the anus, UCF and urinoma cavity can usually be corrected by a progressive perineal approach only [431, 446].

6.3.5.2.2.1.2 Patency rate after urethroplasty for post-traumatic posterior stenosis

The overall patency rate after deferred EPA is 85.7% [46]. Complete excision of scar tissue is a strong predictor for freedom of stricture whereas number (3-5 vs. 6-7) and size (3.0 vs. 4.0) of sutures are not [447]. A retrospective study showed an improved patency rate after eversion of the urethral mucosa of both urethral ends before anastomosis (“valgus urethral mucosa anastomosis”) [448], but this finding has yet to be confirmed in a prospective fashion.
To preserve the antegrade arterial inflow of the bulbar urethra and reduce the surgical trauma of “classic” deferred EPA, bulbar artery sparing EPA has been described [449]. Initial patency rates vary between 88.5-100% with 20-45 months of follow-up (see supplementary Table S6.17) [449-451]. Xie et al., only used this technique for distraction defects less than 2.5 cm [451]. No evidence exists to date whether bulbar artery sparing EPA is superior to the “classic” EPA in terms of patency rate and potency and continence rates.

In case of a very deep location of the proximal urethral end that makes anastomotic suturing impossible, Badenoch described a pull-through technique which has a 33.3-96.5% patency rate after 43-126 months of follow-up (see supplementary Table S6.18 for further information) [432, 452, 453]. With the aim to reduce stricture recurrence, Wong et al., advise a 1.5 cm segment overlap of the bulbar stump within the prostatic urethra during the pull-through technique [452]. To facilitate the suturing at the proximal part of the urethra located deep under the pubic bone, the robotic approach is under exploration but there is no evidence so far of improved outcome with this approach [454].

6.3.5.2.2.1.3 Sexual function, urinary continence, and rectal injury after urethroplasty for post-traumatic posterior stenosis

Regarding erectile function, a prospective study by Hosseini et al., found no significant difference before, and three or six months after EPA for posterior traumatic stenosis [455]. Another prospective study by Tang et al., also demonstrated no significant overall change in ED after urethroplasty. However, in the subgroup of patients with pre-operative non-vascular ED, a significant post-operative increase in ED was observed [456]. A meta-analysis of retrospective studies showed a significant decline of the rate of ED from 43.27% before to 24.01% after posterior urethroplasty (p < 0.001) [457]. Assessment of erectile function and its definitive treatment (e.g., penile prosthesis) should be performed two years after the trauma because of the potential return of normal erectile function within that time [458, 459].

After deferred EPA, antegrade ejaculation is present in 98.3-100% of cases [460, 461]. Decreased ejaculatory volume and/or diminished ejaculatory force were reported in 17.2-18.7% of cases but it cannot be assessed whether this is due to the trauma or due to the surgery [460, 461].

Continence after PFUI and urethroplasty is generally attributed to a competent bladder neck [46]. On the other hand, as most ruptures occur at the bulbomembranous junction just below the external sphincteric mechanism, at least a part of the external sphincter mechanism can be spared during urethroplasty [462]. Therefore, incontinence is rare with deferred EPA (6.8-8.5%) and is usually due to incompetence of the bladder neck although an incompetent bladder neck will not necessarily result in incontinence after urethroplasty [46, 462, 463].

Rectal injury is a relatively rare (0-10.2%) but severe complication after deferred EPA (see supplementary Table S6.19) [430, 438, 445, 463-467]. The risk of rectal injury tends to be higher in complicated cases or cases with previous urethral manipulations [430, 468, 469].

6.3.5.2.2.2 ReDo-urethroplasty for post-traumatic posterior stenosis

In case of a recurrent stenosis, a repeat (“ReDo”) urethroplasty is possible. In the majority of cases, especially if not all consecutive length-gaining manoeuvres have been used during the 1st EPA, another EPA can be performed [463, 467, 468, 470-472]. The Badenoch pull-through technique is again an option if no adequate mucosa-to-mucosa suturing is possible (See supplementary Table S6.18) [452, 453]. In case of excessive dead space after resection of the fibrosis, gracilis muscle [469] or omental flaps (laparoscopically harvested if urethroplasty was performed using perineal approach only) [431, 465] have been advised to fill up this space and support the anastomosis. These flaps, or alternatively bulbspongious muscle or local subcutaneous dartos flaps, are also useful to separate the suture lines in case of a concomitant recto-urethral fistula [431, 442, 446, 469]. If the urethra cannot be anastomosed in a tension-free fashion, despite the aforementioned manoeuvres, or in cases of ischemic narrowing/necrosis of the bulbar urethra, options are a tubed preputial island flap, staged BMG urethroplasty with flap, staged buccal mucosa ducros flap, radial forearm free flap urethroplasty or entero-urethroplasty [442, 467, 471, 473]. In case of entero-urethroplasty, the sigmoid colon is preferred above ileum (which is in turn better than stomach) because of the proximity of the vascular pedicle to the perineum. Entero-urethroplasty should only be done in the presence of a competent bladder neck because subsequent implantation of an AUS is nearly impossible [473]. Patency rate of different types of ReDo-urethroplasty varies between 50-100% (Table 6.11) [442, 463, 467, 468, 471, 473]. An alternative is to abandon the normal urinary outlet and opt for Mitrofanoff-vesicostomy, PU (if local perineoscutal skin is suitable) or permanent suprapubic diversion [467, 473].

BMG = buccal mucosa graft; EPA = excision and primary anastomosis; N = number of patients; NA = not applicable.

Summary of evidence

The best results are obtained after the 1st urethroplasty. 4
The overall stricture-free rate after EPA is 85.7%. By using the progressive perineal approach, a combined transpubic abdomino-perineal approach is usually not needed. 3
After failed endoluminal treatment, EPA is the standard treatment for a non-obliterative stenosis. 3
Both a midline and inverted U perineal incision equally gain access to the posterior urethra, but a midline incision is associated with less anatomical damage to local vessels and nerves, reduced risk of surgical site infection and hospital stay. 2b
Total pubectomy during transpubic abdomino-perineal reconstruction has a higher complication rate (bleeding, pelvic instability, dead space) compared to partial (superior or inferior) pubectomy with no gain in surgical exposure. 4
By using the progressive perineal approach, a combined transpubic abdomino-perineal approach is usually not needed except for very long distraction defects and in case of complicated situations, which include associated para-urethral bladder base fistula, trauma-related recto-urethral fistula, and bladder neck injury. 3
If the urethra cannot be anastomosed in a tension-free fashion or in case of ischaemic narrowing/necrosis of the bulbar urethra, options are a tubed preputial island flap, staged buccal mucosa graft urethroplasty with flap, staged buccal mucosa darts flap, radial forearm free flap urethroplasty or entero-urethroplasty. 3
In case of excessive dead space after resection of the fibrosis, local flaps have been advised to fill up this space and support the anastomosis. These flaps are also useful to separate the suture lines in case of a concomitant recto-urethral fistula. 3

Recommendations

Perform open reconstruction for post-traumatic posterior stenosis only in high-volume centres. Weak
Perform progressive perineal excision and primary anastomosis (EPA) for obliterative stenosis. Strong
Perform progressive perineal EPA for non-obliterative stenosis after failed endoluminal treatment. Strong
Perform a midline perineal incision to gain access to the posterior urethra. Strong
Do not perform total pubectomy during abdomino-perineal reconstruction. **Strong**

Reserve abdomino-perineal reconstruction for complicated situations including very long distraction defect, para-urethral bladder base fistula, trauma-related recto-urethral fistula, and bladder neck injury. **Weak**

Perform another urethroplasty after 1st failed urethroplasty in motivated patients not willing to accept palliative endoluminal treatments or urinary diversion. **Weak**

Use a local tissue flap to fill up excessive dead space or after correction of a concomitant recto-urethral fistula. **Weak**

### 7. DISEASE MANAGEMENT IN FEMALES

#### 7.1 Signs and symptoms of female urethral strictures

The symptoms of female urethral strictures are non-specific and therefore generally non-diagnostic. Female urethral stricture presents with mixed filling and voiding symptoms with frequency in 63%, urgency in 55%, incomplete emptying in 36%, poor flow in 32%, urinary incontinence in 31% (stress, urge or mixed), strain void in 21.5%, UTI in 20.5%, nocturia in 20.5% and dysuria in 20%. It very rarely presents with urethral pain (2.7%), terminal dribble (2%), haematuria (1.6%) or renal failure (0.5%) (see supplementary Table S7.1).

There is often a significant delay in diagnosis of FUS from time of development of symptoms with mean delays of 4.3-12 years described (range 1-30 years) [137].

#### 7.2 Diagnosis of female urethral strictures

Twenty-four studies detail investigations leading to a diagnosis of FUS (see supplementary Table S7.2). In all cases a full history was taken, and a detailed pelvic examination was performed to assess for prolapse, masses, scars and vulval dermatological disorders such as LS, lichen planus or vulvo-vaginal atrophy. Flow rate and US PVR assessment was evaluated in nineteen (75%) and eighteen (71%) studies, respectively. Lateral VCUG was performed routinely in sixteen studies (63%) and as required in one study (4%). Cystourethroscopy was performed routinely in fourteen studies (54%) and as required in two studies (8%). Urodynamics (UDS) were performed routinely in four studies (17%) and as required in seven studies (30%) whilst video-urodynamics (VUDS) were performed routinely in three studies (13%) and urethral calibration also in four studies (13%). Pelvic MRI was performed as required in four series (17%) whilst transrectal US (TRUS) and renal US were each performed routinely in two series (8%) and intravenous urography (IVU) in ten (4%).

Flow rate and PVR assessment make inherent sense as initial non-invasive screening tools and allow for simple monitoring of effect of treatment. Voiding cystourethography and/or VUDS will permit diagnosis of BOO [23, 474], visualisation of ballooning above the proximal end of the FUS [135], and delineation of alternate or co-existent diagnoses such as detrusor overactivity (DO) and SUI [128], although VCUG, VUDS and UDS require the ability to insert a 6 Fr catheter and may not be possible without preliminary urethral dilatation in all cases of FUS [475]. Likewise, passage of a cystourethroscopy will require a preliminary dilation in the majority of cases even when a paediatric uretero-renoscope is utilised [126]. Cystourethroscopy will allow for formal identification of the distal end of the FUS and will also allow for exclusion of a functional cause of BOO [135]. Magnetic resonance imaging is performed mainly to exclude alternate pathology such as urethral diverticulum and urethral carcinoma and also allows assessment of the degree of urethral fibrosis associated with FUS [475]. Proponents of TRUS utilise it in lieu of MRI and also for visualisation of the dilated urethra above the proximal end of the FUS. Recent gel-infused USS has been assessed and found to more accurate means of diagnosing stricture and associated spongiosis than cystoscopy and videourodynamics in a small preliminary study (n=8) [476].

#### 7.3 Treatment of female urethral strictures

##### 7.3.1 Minimally invasive techniques for treatment of female urethral strictures

Several minimally invasive treatments have been reported; these include urethrotomy, dilatation, meatotomy and meatoplasty. Meatotomy and meatoplasty are essentially the same procedure in the female urethra and the term ‘meatoplasty’ will be used throughout this document.

##### 7.3.1.1 Urethrotomy for treatment of female urethral strictures

No papers were found detailing the use and outcomes of urethrotomy specifically for the management of FUS. Internal urethrotomy or dilation was used by Massey and Abrams [477] to treat a variety of pathologies,
including FUS, causing symptoms of obstructed voiding, and resulted in symptomatic improvement in 80% of patients. As this study included women with a variety of complaints and did not assess urodynamic parameters, the results in the patient subset with true urethral stricture are unclear. If utilised, urethrotomy in the female urethra involves incisions at three, nine and occasionally twelve o’clock [477].

7.3.1.2 Urethral dilatation for treatment of female urethral strictures
With this treatment, the urethra is dilated to between 24 Fr and 41 Fr. Some patients will continue with ISD. Romman et al., 2012 [478] and Popat & Zimmern [475] also described suture plication of bleeding areas of the meatus if required post-urethral dilatation.

Four studies described the results after 59 months follow-up of, in total, 183 patients having dilatation only. Patency rates ranges from 7.5-51% (see Table 7.1) [128, 129, 475, 478]. In another four studies that included, in total, 31 patients that continued to perform ISD, stabilisation of the stricture with “patency” was obtained in 37.3-100% of cases at twelve to 21 months of follow-up (see Table 7.1) [13, 133, 136, 479].

New onset SUI (1.4%) and other complications are very rare after dilation (see supplementary Table S7.3). Due to the low complication rate, the minimally invasive nature of the technique and the reasonable success rate, it is acceptable to start with urethral dilatation as a first-line treatment for an uncomplicated FUS. If the stricture recurs then repeat urethral dilatation is unlikely to be curative.

7.3.1.3 Meatoplasty for treatment of female urethral strictures
Meatal stenosis is extremely rare, with only 2/58 (3%) of females evaluated for voiding dysfunction found to have true meatal stenosis [480]. Only one meatoplasty paper contains more than five patients and has been included for analysis (see supplementary Table S7.4) The patency rate of meatoplasty in girls in this paper is excellent with 96% of the 50 girls in Heising’s series having a successful outcome with no reported side effects at twelve months. Forty-eight of 50 patients experienced resolution of their recurrent UTIs and improved voiding symptoms one year after meatoplasty [481]. There was no incontinence or other acute complications reported. For short meatal strictures, meatoplasty is the first-line treatment option.

7.3.2 Urethroplasty for treatment of female urethral strictures
Twenty-five papers report the outcomes of urethroplasty for FUS disease in 253 patients in total after the scope search of the Panel. The Panel have analysed the outcomes of these urethroplasty according to flap or graft type as: vaginal graft, vaginal flap, labial/vestibular graft, labial/vestibular flap and buccal or lingual graft. In female urethroplasty, a dorsal approach is via a stricturotomy at twelve o’clock, a ventral approach is via a stricturotomy at six o’clock and circumferential is a full circumference reconstruction.

7.3.2.1 Vaginal graft augmentation urethroplasty for treatment of female urethral strictures
There were five studies reporting vaginal graft urethroplasty containing 72 patients. All 72 vaginal graft urethroplasties were performed via a dorsal approach in women with a mean/median age of 47.5-60.6 years (range 28-79). At a mean/median follow-up time of 8.5-24.65 months (range 6-36) following vaginal graft urethroplasty 59 (82% range 73-94%) of patients had no recurrent stricture. No complications and no new onset urinary incontinence were reported. Mean/median flow rate (with range) improved from 6.2-8.23 ml/s (2.2-10.2) to 16.64-27.6 ml/s (12-32.7) whilst mean/median PVR (with range) reduced from mean/median 113.2-187.1 ml/s (44-420) to mean/median 20-90.31 ml/s (0-122).

See supplementary Table S7.5 for further information.

7.3.2.2 Vaginal flap augmentation urethroplasty for treatment of female urethral strictures
Vaginal flap urethroplasty was reported in 150 women and was always via a ventral approach, utilising an inverted U vaginal flap inlay in seven studies (n=96) [127, 128, 131, 482, 483], a lateral C vaginal flap in three studies (n=58) [125, 133, 137] and one vaginal island flap urethroplasty in one patient [131]. At a mean/median follow-up time of 12- 80.7 months (range 3-198), patency rates of 67-100% were reported (Table 7.1). Eight (5.3%) patients had a simultaneous pubo-vaginal sling (PVS), four (2.7%) had a simultaneous Martius fat pad flap interposition and one (0.7%) had a simultaneous excision of urethral diverticulum. Fourteen (9.3%) patients developed new onset UI, and fourteen (9.3%) developed other acute complications including UTI and intravaginal direction of the urinary stream.

See supplementary Table S7.6 for further information.
7.3.2.3 Labial/vestibular graft augmentation urethroplasty for treatment of female urethral strictures

There were four papers detailing the outcomes of 42 patients having labial or vestibular graft urethroplasty (see supplementary Table S7.7): fifteen had ventral labial minora graft [132, 139, 484] and thirteen had dorsal labia minora graft [136] and fourteen had dorsal labia majora graft. At a mean follow-up of 18 to 24 months, patency rates of 75-86% were reported with ventral grafting whilst this was 100% with dorsal grafting at twelve to nineteen month’s follow-up (Table 7.1). One (2.4%) ventral graft patient developed an UTI post-surgery. There were no other complications (including UI). Post void residual volume reduced from 141.9 +/- 44.2 mls to 24.5 +/- 2.9 ms post dorsal onlay labial minora graft urethroplasty.

7.3.2.4 Labial/vestibular flap urethroplasty for treatment of female urethral strictures

There were two papers detailing the outcomes of twenty-one patients having labial/vestibular flap urethroplasty: seventeen had a dorsal vestibular flap [16], whilst twelve had a dorsal labia minora flap [485]. At a mean/median follow-up of 24 months the two ventral flap patients (100%) remained stricture-free whilst fifteen (88%) dorsal flap patients remained stricture-free at a mean of twelve months follow-up (Table 7.1 and supplementary Table S7.8). There were no adverse short- or long-term effects reported in either group.

7.3.2.5 Buccal and lingual mucosal graft augmentation urethroplasty for treatment of female urethral strictures

There were eleven papers detailing the outcomes of 234 patients, all treated with BMG except in the series of Sharma et al., who used lingual mucosa graft (LMG) in fifteen patients at the dorsal urethra [126]; 44 patients with dorsal onlay oral (buccal or lingual) mucosa graft (DOOMG) [126-128, 131, 134, 474, 486-488]; 27 with ventral onlay BMG (VOBMG) [127, 135, 489, 490]. The outcome of circumferential BMG urethroplasty in two patients were only detailed in one paper [127]. At a mean/median follow-up of six to 33 months, 62.5-100% of DOOMG urethroplasty patients were stricture-free whilst 92-100% of VOBMG patients were stricture-free at a mean of six to 24.5 months follow-up. Both circumferential BMG patients were stricture-free at a mean of 21 months follow-up (Table 7.1). Twenty-four (10.7%) DOOMG patients suffered a low-grade short-term adverse effect and no patients in any subgroup developed new onset UI. No patients developed acute complications or new onset stress urinary incontinence following VOBMG urethroplasty or circumferential BMG urethroplasty (although this was only performed in two patients). Mean/median flow rate improved from 5.0-12.5 ml/s (range 3-11.2) to 12.1-28 ml/s (range 14-37) and mean/median PVR reduced from 101-270 mls (range 90-200) to 6.5-122.6 mls following DOBMG. Likewise mean/median flow rate improved from 5.1-7.6 ml/s (range 3-11.2) to 18-29.2 ml/s (range 5-33.4) whilst mean/median post void residual reduced from 100-149 ml (range 0-300) to 15-59.2 ml (range 0-360 mls) following VOBMG. The flow rate and post void residual changes following circumferential BMG urethroplasty have not been detailed as this technique was performed in two patients only and the outcomes detailed in the describing paper are not specific to this technique.

One prospective randomized trial compared VOBMG with DOBMG and found equivalent stricture free rates and improvements in maximum flow rate, post void residual and sexual function. However, there were only twelve patients in each group and follow-up was limited to six months [491].

For further information see supplementary Tables S7.9, S7.10 and S7.11.

7.3.2.6 Anastomotic urethroplasty

Anastomotic urethroplasty has only been described in two cases in the literature – both in women with very short mid-urethral stricture and both of whom were stricture-free at four and 24-months follow-up respectively. None of them suffered from UI post-operatively [127, 496] (see supplementary Table S7.12).

FU = follow-up; ISD = intermittent self-dilatation; N = number of patients; UI= urinary incontinence.

Summary of evidence LE
Female urethral stricture symptoms are long standing and non-specific, the most commonly reported are frequency, urgency, poor flow, incomplete emptying, and urinary incontinence. It is important to exclude FUS in female patients with LUTS.

Urethral dilatation alone to 24-41 Fr provides low stricture-free rates of mean 40.1% at mean follow-up 36 (12-59) months.

Isolated repeat dilatation yields patency rates of 26.6%. However, urethral dilatation followed by ISD or regular planned dilatation, as palliation, provides patency rates of 97% at mean FU 6-21 months.

Urethroplasty provides patency rates of 62.5-100%. VOBMG and DOBMG reported patency rates are 92-100% and 62.5-100%, respectively.

Meatotomy/meatoplasty for short meatal strictures has a success rate of 97% at twelve months follow-up.

Recommendations
Perform flow rate, post-void residual and voiding cystourethrogram or video-urodynamics in all women with refractory lower urinary tract symptoms. Strong
Perform urethral dilatation to 24-41 Fr as initial treatment of female urethral stricture (FUS). Weak
Perform repeat urethral dilatation and start planned weekly intermittent self-dilatation (ISD) with a 16-18 Fr catheter for the 1st recurrence of FUS, or plan repeat dilatation. Weak
Perform urethroplasty in women with a 2nd recurrence of FUS and who cannot perform ISD or wish definitive treatment. The technique for urethroplasty should be determined by the surgeon’s experience, availability and quality of graft/flap material and quality of the ventral versus dorsal urethra. Strong
Treat meatal strictures by meatotomy/meatoplasty. Weak

8. DISEASE MANAGEMENT IN TRANSGENDER PATIENTS

8.1 Treatment of strictures in trans men

In trans men, stricture treatment depends on the time after neophallic reconstruction, stricture location, stricture length and quality of local tissues [147, 494].

8.1.1 Management of strictures early after neophallic reconstruction

Urethral surgery on tissues in the acute phase urethra has been stabilised. This usually takes six months [495]. Endoscopic incision for short (< 3 cm) urethral strictures has been performed, mainly at the anastomotic...
site, with a maximum stricture-free rate of only 16.7% when performed within six months after neophallic reconstruction [496]. Insertion of a suprapubic catheter is the first-line treatment in cases of obstructive symptoms severely affecting the patient’s QoL, recurrent UTI or retention. The alternative is perineostomy, which is a specialist procedure and should be performed by a urologist familiar with transgender urethral anatomy. The perineostomy may be closed at the time of formal urethral reconstruction [497].

8.1.2 Treatment of meatal stenosis in trans men
Intermittent urethral dilatation is an option as palliative treatment for low-grade meatal stenosis [31]. Patients with high-grade meatal stenosis, those who refuse ISD, or those who want a durable solution should be offered simple meatotomy. Patency rates are 50% and 75% for transmasculine after respectively metoidioplasty and phalloplasty [147]. The drawback is that the meatus will be in a hypospadiac position. Alternatively, a staged urethroplasty can be offered [147].

8.1.3 Treatment of strictures at the neophallic urethra
The standard treatment for these strictures is staged urethroplasty with or without graft augmentation (BMG or full thickness SG). A patency rate of 50-88% [147, 495, 498] has been reported after phalloplasty and up to 100% after metoidioplasty [147, 495].

For complex (e.g., fully obliterated) or recurrent strictures at the neophallic urethra, a complete urethral substitution with a tubularised radial forearm free flap has been proposed with a 67% patency rate [147].

8.1.4 Treatment of strictures at the anastomosis neophallic urethra-fixed part of the urethra
Short, non-obliterative, strictures can be treated by endoscopic incision. A first endoscopic incision has a 37-45.5% patency rate, but this dropped to 0% in case of three or more attempts (median follow-up of 51 months) [495, 496]. Therefore, repetitive endoscopic incisions should be discouraged unless with palliative intent.

For very short (< 1.5 cm) low-grade strictures, Heineke-Mikulicz urethroplasty is an option reporting a 58-80% after phalloplasty and up to 100% after metoidioplasty [147, 495].

If the stricture is nearly or completely obliterative, options are EPA, graft augmentation urethroplasty or staged urethroplasty. Excision and primary anastomosis yields a patency rate of 46-57% after phalloplasty and 78% after metoidioplasty [147, 495]. Alternatively or if EPA is not possible (structure length >2 cm), a graft augmentation urethroplasty can be performed with a 56-100% patency rate [147, 495]. In case of insufficient ventral tissue during graft urethroplasty, it is advised to support this graft by a local fasciocutaneous flap [147]. An alternative (especially after failure of the previous techniques) can be a staged approach [147, 495].

8.1.5 Treatment of strictures at the fixed part of the urethra
This part of the urethra has a more reliable blood supply, and the dorsal part of the urethra is supported by the corporal bodies of the clitoris. Therefore, single-stage dorsal inlay graft urethroplasty is possible for strictures at this site, especially after metoidioplasty, with up to 100% patency rate [495]. Staged repair with or without a dorsal graft is an alternative for these rare strictures [495].

8.1.6 Definitive perineostomy in trans men
Definitive perineostomy should be offered to patients with refractory strictures or to those with strictures who do not wish to have complex reconstructive surgery [147, 495].

8.2 Peri-operative care after treatment of strictures in trans men
Anecdotally, after endoscopic incision and urethroplasty, the urethral catheter is maintained for two to three weeks [496, 499]. Peri-catheter urethrography is advised before catheter removal as it might be challenging to reinsert the urethral catheter in case of urinary extravasation [499].

8.3 Strictures in trans women
It is acceptable to start with dilation of a short and non-obliterative stricture in trans women although no long term data about the effectiveness are available [31]. If this is not possible or if it fails, a short (< 1 cm) meatal stricture can be treated by Y-V meatoplasty with an 85% stricture-free rate [500]. Somewhat longer (1-2 cm) meatal strictures can be treated by a neovaginal advancement flap (inverted U or “7-flap”) with no recurrence observed after 37 months median follow-up [501].

9. TISSUE TRANSFER

9.1 Comparison of grafts with flaps

One small RCT (LS excluded) comparing OMG with PSF found no significant difference in urethral patency rate [502]. Penile skin flaps had a higher urogenital morbidity (superficial penile skin necrosis, penile torsion, penile hypoesthesia, and post-void dribbling) and longer operation time compared to OMG. Furthermore, patient dissatisfaction was significantly higher with penile flaps [502]. Another small RCT (LS excluded) comparing penile skin grafts with PSF confirmed these findings with longer operation time and more superficial penile skin necrosis in the group of the flaps, whereas the urethral patency rate was similar between both groups [355]. Several retrospective series also found a comparable urethral patency rate between PSF and grafts [272, 274, 503, 504] (Table 9.1).

* if not reported: recalculated by EAU Urethral Strictures Panel with chi²-statistics.

Due to their robust vascular pedicle, flaps can be used as a tube as well as a patch in a single-stage approach [442]. Castagnetti et al., showed that grafts used as a tube have significantly higher complication rates as compared to onlay grafts (OR: 5.86; 95% CI: 1.5-23.4) [505]. A review by Patterson et al., also reported high (circa 50%) complication and recurrence rates for tubularised grafts [506]. Iqbal et al., have...
shown an encouraging 87% stricture-free rate in 23 patients who were offered single-stage circumferential skin flap urethroplasty [281]. Therefore, if there is a need to reconstruct a complete urethral segment with a tissue transfer tube in a one-stage operation, flaps are usually the preferred option. As flaps carry their own vascular supply to the reconstruction site, they do not rely on the local vascularisation of the recipient site. Therefore, they need to be considered in case of poor urethral vascularisation (e.g., after irradiation or dense scarring after previous urethroplasty) [504, 507]. In addition, flaps survive well in the presence of active urinary infection [508].

Grafts and flaps should not be considered competitors in urethral surgery. A combination of a flap with a graft is possible for complex, multifocal or penobulbar strictures [504, 509, 510].

### 9.2 Comparison of different types of flaps

Different local flaps have been described. Penile skin flaps are generally hairless, although the ventral penile skin can be hair-bearing around the raphe in some ethnic groups/phenotypes. They can be harvested as a transverse preputial skin flap [511], a transverse distal PSF [358, 508, 512, 513] or as a longitudinal island flap [514]. Urethral patency rates vary between 74.2-100% [274, 358, 508, 511-514]. Complications include skin necrosis (0-3.8%), fistula (0-7%), penile deformity (0-7%), post-void dribbling (0-79%) and sacculation (0-16.5%) (see supplementary Table S9.1). As there are no direct comparative series available about these flaps it is not possible to determine which performs better.

Hair-bearing perineal and scrotal flaps have been described as well. Fu et al., demonstrated that PSF had a significantly better urethral patency rate compared to scrotal and perineal skin flaps (respectively 87.7%, 69% and 66.7%) [274]. The hair-bearing perineal and scrotal skin flaps are associated with hairball formation and chronic infection which may cause failure of the repair. A study of Blandy with long-term follow-up, reports 3% revision for calculi and 3% revision for diverticula [515].

An alternative is to epilate the needed scrotal skin prior to tissue transfer [516, 517] or to patch an OMG to the underlying dartos tissue of the scrotum after incision of the scrotal skin and use this patch as a flap in a second attempt [442].

**Summary of evidence**

| LE   | Hair-bearing flaps have a lower urethral patency rate compared to non-hair-bearing flaps. | 3  |

**Recommendation**

| Strong | Do not use hair-bearing perineal or scrotal flaps unless no other option is feasible. |

### 9.3 Comparison of different types of grafts

Buccal mucosa is at present the most commonly used graft. A systematic review on anterior urethral strictures reports a urethral patency rates of buccal mucosa of 86.6% with an average follow-up of 31.5 months [518].

Penile skin is another popular graft, especially in uncircumcised men where the foreskin is an abundant source of graft material.

In case of LS, Trivedi et al., demonstrated a significantly higher urethral patency rate when using non-genital mucosal grafts for reconstruction (82.6%) compared to genital skin grafts (4%) [519]; therefore, the use of genital skin in LS cases is not indicated.
In one RCT (Pee’BuSt trial) comparing buccal mucosa with penile skin as a graft for dorsal onlay augmentation urethroplasty for anterior strictures, no significant difference in outcome could be observed [520]. A systematic review and meta-analysis suggests that BMG augmented urethroplasty, may be superior to penile skin graft urethroplasty. However, there were a lot of confounding factors, and clear conclusions cannot be made [521]. Lengthy skin grafts (up to 20 cm) can be taken from the foreskin in a spiroid fashion which is clearly more difficult with OMG.

The main disadvantage of BMG harvesting is the oral morbidity and because of this morbidity, lingual mucosa has been proposed as alternative. A SR and meta-analysis of comparative studies comparing LMG with BMG (four prospective, two retrospective studies) showed no significant differences in urethral patency rate and overall long-term complication rate [522-524]. These studies revealed that LMG was associated with more difficulties in eating/drinking, speaking, tongue protrusion and dysgeusia [522, 523]. In 13.8-20%, speaking problems remained after six months [522, 523]. A retrospective study of Xu et al., reported difficulties in tongue movements, numbness over the donor site and speaking difficulties in 6.2%, 4.9% and 2.5% of patients, respectively after twelve months [301]. On the other hand, BMG harvesting provoked more oral tightness which was present in up to 24% of patients after six months [522, 523]. Chauhan et al., showed that immediate and early donor site complications were more common in the BMG group, except for bleeding being more common in the LMG group. Numbness (61%), difficulty in chewing (54%), swelling (48%) and articulation (40%) were the most common problems during the first week. Late donor site complications were rare [525]. Pal et al., describes more short-term complications (difficulty in tongue movement and slurring of speech) in the LMG group, compared to the BMG group. Long-term complications (after three months) at the donor site (persistent pain, perioral numbness, tightness of mouth, salivary disturbance, scarring of the cheeks) were only seen in the BMG group [526]. For long strictures, buccal mucosa can be combined with lingual mucosa [301].

The use of lower lip mucosa was described, especially when smaller grafts are needed, and has similar qualities to lingual mucosa. However, a narrative review based on the experience from retrospective series showed that these grafts have a higher post-operative donor site morbidity and can lead to permanent sequelae (persistent discomfort, neurosensory deficits, salivary flow changes and important aesthetic changes) at the donor site, which have not been described with lingual mucosa [527].

Beyond the oral mucosa and penile skin graft, a multitude of other autologous grafts have been described. These include: postauricular skin [510, 528], abdominal skin [360], split-thickness mesh graft from the thigh [341], inguinal skin [300] and colonic mucosa [529] (Table 9.2). Manoj et al., only used the postauricular skin when both genital skin and oral mucosa were not usable [528]. Marchal et al., used postauricular skin in addition to oral mucosa to reconstruct lengthy strictures [510]. Meeks et al., reported the use of abdominal skin graft mainly in patients with lengthy strictures where OMG harvesting would be insufficient, in case of prior OMG urethroplasty or if OMG was refused by the patient [360]. Pfalzgraf et al., reported a comparable urethral patency rate for split-thickness mesh graft and BMG (respectively 84 and 83%), but more penile deviation (9% vs. 0%) and lower satisfaction (83.3% vs. 96.7%) with split-thickness mesh graft [341]. Xu et al., used colonic mucosa for lengthy (> 10 cm) strictures. Urethral patency rate was 85.7% but graft harvest requires an abdominal procedure, and 1/35 (2.9%) patient developed a colonic-abdominal fistula [529]. Due to the limited experience with grafts other than oral mucosa and penile skin, they should only be considered if oral mucosa and penile skin are not available, indicated, or desired.

### 9.4 Tissue engineered grafts

#### 9.4.1 Cell-free tissue engineered grafts

These grafts are derived from cadaveric or animal sources (e.g., porcine small intestine submucosa [SIS], acellular bladder matrix, acellular dermal matrix), are completely cell-free and serve as a scaffold for host cell ingrowth [530]. The main advantage suggested for their use is the off-shelf availability [530].

A small RCT (n=30) comparing acellular bladder matrix with BMG reported a urethral patency rate of respectively 66.6% and 100%. The poorer results of acellular bladder matrix were the most apparent in cases of an unhealthy urethral bed [531].

Several small retrospective case series using mainly porcine small intestinal submucosa, demonstrate varying patency rates from 20-110%. The patient groups were heterogenous in terms of aetiology, previous treatment, urethral location and definition of success rate. An overview can be found in Table 9.3. Most papers report a poorer outcome in case of extensive spongiofibrosis, poor vascular graft bed, previous treatments and longer strictures [531-535] (Table 9.3).

#### 9.4.2 Autologous tissue engineered oral mucosa grafts

These grafts contain a matrix seeded with autologous oral mucosa cells. Production requires a small oral mucosa biopsy (at 0.5 cm²) and the graft is further manufactured in the lab. The main advantage suggested is the reduction of oral donor site morbidity whereas the main disadvantages are costs and the strict time frame between manufacturing and implantation of the graft [530].

The clinical use of autologous tissue-engineered OMG was evaluated in a prospective, multicentre study including 99 patients [536]. Estimated twelve- and 24-months urethral patency rate was 67.3 and 58.2%, respectively. Oral adverse events were minimal. No comparative studies with acellular grafts or native OMGs are available nor are there any data about the cost-effectiveness [530].
Summary of evidence

Safety, patency rate and cost-effectiveness of autologous tissue-engineered grafts is currently under research.

**PERI-OPERATIVE CARE OF URETHRAL SURGERY**

**10.1 Urethral rest**

After any form of urethral manipulation (urethral catheter, ISD, dilatation, DVIU), a period of urethral rest is necessary in order to allow tissue recovery and stricture “maturation” before considering urethroplasty. This improves the ability to identify the true extent of the fibrotic segments during subsequent surgery. If the patient develops incapacitating obstructive symptoms or urinary retention, a suprapubic catheter should be inserted. Terlecki et al., propose diagnostic evaluation after two months and urethroplasty after three months of urethral rest. These timings are based on the general principles of wound healing [541]. In their study, it has been shown that these periods allow for reliable stricture evaluation during urethrography which is, in turn, important to ensure selection of the most appropriate urethroplasty technique [541]. Utilising this strategy, similar outcomes were obtained compared to patients with stable previously unmanipulated strictures [541]. However, the optimal duration of urethral rest for all patients is not known and the degree of associated infection and inflammation should be taken into account as well, with longer periods of rest in those with greater degrees of infection and inflammation.

**Summary of evidence**

After any form of urethral manipulation, a minimum period of three months urethral rest is necessary to allow for tissue healing before performing urethroplasty.

10.2 Antibiotics

Post-operative wound infection and UTI are common post-operative complications and infection at the site of reconstruction may contribute to failure of urethroplasty. The vast majority of reconstructive urologists perform urine culture one to two weeks prior to surgery [542]. Urine culture is superior to urine-analysis which can be omitted in the pre-operative evaluation [542]. If infection or colonisation is present, a therapeutic course with antibiotics is recommended pre-operatively. Preoperative UTI, even when properly treated, could increase the risk of post-operative UTI [543]. In case of an indwelling catheter general principles would suggest at least an attempt to suppress the colonisation with pre-operative antibiotics [542]. These practices are in accordance with the strong recommendations of the EAU Guidelines on Urological Infections:
- “Screen for and treat asymptomatic bacteriuria prior to urological procedures breaching the mucosa.”
- “Treat catheter-associated asymptomatic bacteriuria prior to traumatic urinary tract interventions.”

An intra-operative prophylactic regimen with antibiotics (according to local antibiotic resistance profiles) is effective in reducing the rate of post-operative surgical site and UTIs [542]. Although most urologists continue with post-operative antibiotics upon and even beyond catheter removal, there is no evidence that such a prolonged administration would reduce the infective complication rate [542]. A retrospective study from Baas et al., revealed that extended postoperative antibiotic prophylaxis (three weeks until catheter removal versus 3 days around catheter removal) does not appear to affect UTI rates following urethroplasty [544]. The EAU Guidelines on Urological Infections do not routinely recommend the use of antibiotic prophylaxis to prevent clinical UTI after urethral catheter removal. There is no evidence that this recommendation would not apply to catheter removal after urethral surgery.

10.3 Catheter management

After uncomplicated DVIU, there is no advantage in maintaining the catheter for a prolonged period and it should be removed within 72 hours [545].

After one-stage urethroplasty and closure of the urethral plate after staged urethroplasty, urinary extravasation at the site of reconstruction must be avoided [546]. For this purpose, urinary diversion by either transurethral catheter or suprapubic catheter with urethral stent can be used. With respect to the type of catheter material, a prospective randomised (but underpowered) trial comparing silicone vs. hydrogel coated latex transurethral catheters showed no significant difference in the time to stricture recurrence nor in the overall recurrence rate [546]. The size of the urethral catheter utilised usually varies between 14 Fr and 20 Fr [547, 548]. Systematic use of anticholinergic drugs has not shown a significant reduction in the rate of involuntary pericatheter voiding whilst catheterised [549].

After urethroplasty an indwelling catheter is commonly left in situ for two to three weeks [548, 550]. After three weeks of urethral catheterisation, an extravasation rate of 2.2-11.5% at urethrography has been reported after different types of urethroplasty [550-553]. However, success with early catheter removal under three weeks has also been reported. A study after EPA for non-complicated anterior strictures demonstrated no significant difference in extravasation (6.8% vs. 4.5%) and recurrence rates (4.9% vs. 5.2%) between catheter removal at one or two weeks respectively [554]. Poelaert et al., reported an extravasation rate of 3.5% vs. 8.3%, when the catheter was removed < 10 days or > 10 days respectively after all types of urethroplasty (n=219) (p=0.158) [547]. Importantly, patients who had a duration of catheterisation of > 10 days had longer and more complex strictures [547]. Beiske et al., revealed a higher incidence of UTI in patients with a three week catheterization after open urethroplasty, compared to two weeks [555].

Prior to catheter removal after urethroplasty, it is important to assess for urinary extravasation to avoid ensuing complications including peri-urethral inflammation, abscess formation and fistulation [550, 552]. Importantly, some authors have identified urinary extravasation as a predictive factor for stricture recurrence [547, 556]. Other series, however, could not confirm the prognostic significance of urinary extravasation but they included any form of extravasation (including minor leaks) [552, 553]. Grossgold et al., found that high-grade leaks (defined as length > 1.03 cm and width > 0.32 cm) were significantly associated with higher restricture rates.
This study also found length of extravasation > 1.03 cm alone to be an independent predictor of restricture [556]. In cases of persistent and significant urinary extravasation, the catheter should be maintained or reintroduced and the examination repeated after one week [550]. However, low-grade (“wisp-like”) extravasation does not appear to affect long-term restricture rate and the catheter can be removed in these cases without subsequent urethrogram [552, 556]. In case of any doubt about the significance of extravasation, it is safe to keep the catheter in for an additional week and ReDo the assessment.

The assessment of urinary extravasation is achieved by either pericatheter retrograde urethrography (pcRUG), classic RUG or VCUG [550]. A prospective study (n=80) comparing pcRUG and VCUG in a within-patient fashion demonstrated a comparable sensitivity for contrast extravasation. Moreover, pcRUG averts the risk of having to reinsert the catheter, avoids the problem of patients being unable to void during VCUG and requires significantly less radiation (120 mGy/cm² versus 241 mGy/cm²; p < 0.001) [557].

In cases of attempted VCUG where the patient is not able to void during fluoroscopy after catheter removal, RUG should be performed [556].

Although limited evidence for urethroplasty care in trans men exists, one study advised a three-week period of transurethral catheterisation with pcRUG upon catheter removal [499].

After perineostomy or the 1st stage of staged urethroplasty, the catheter can be removed without need for urethrography after three to five days [339, 552].

### Summary of evidence

| Prior to catheter removal after urethroplasty, it is important to assess for urinary extravasation with urethrography to avoid ensuing complications including peri-urethral inflammation, abscess formation and fistulation. | 2b |
| After uncomplicated DVIU, there is no advantage in maintaining the catheter for a prolonged period. | 3 |
| Early catheter removal may be appropriate for a subset of patients with short, uncomplicated, strictures. | 3 |

### 11. FOLLOW-UP

#### 11.1 Rationale for follow-up after urethral surgery

The rationale for following-up patients after urethral stricture surgery is to detect and manage any complication or recurrence. As with any surgical procedure, following urethroplasty some patients will present with complications at short to medium follow-up: up to 34-38% of all anterior urethroplasties. Most of these complications (92-99.1%) would be classified as Clavien grade 1 or 2 [558, 559]. Even though urethroplasty techniques provide the highest chances for successful treatment of urethral strictures, some patients will experience recurrence [346]. For further details on particular outcomes in each urethral segment, please review the individual chapters of this Guideline.

#### 11.2 Definition of success after urethroplasty surgery
The “traditional academic” definition of post-operative success after urethroplasty has been considered as “The lack of any post-operative intervention for restricture” [560]. This definition, despite being widely used [305, 558] is problematic as it ignores asymptomatic or even symptomatic recurrences in patients not willing to undergo further surgeries [560]. There is some variation as to what is considered intervention with some groups accepting endoscopic treatments as success, while considering failure only as the requirement for a ReDo urethroplasty [306].

A more objective definition of success is the “anatomic success”, defined as “Normal urethral lumen during RUG or cystoscopy, regardless of patient symptoms”. Using this definition, stricture recurrence or anatomical failure is considered by some groups as urethral narrowing found to be endoscopically impassable – without force – with a 16 Fr flexible endoscope [145, 561]. This definition is certainly stricter, with up to 35% of cystoscopic recurrences after bulbar urethroplasty remaining asymptomatic, and thus would have been considered as successful if a “lack of further intervention” definition was used [145]. Other groups consider cystoscopic recurrence as any stricture that is visible on post-operative cystoscopy, even the so-called “large calibre re-strictures” (> 17 Fr) [143]. Not all anatomic recurrent strictures would need further treatment [560]. It was suggested to intervene when the anatomic recurrence is associated with recurrence of symptoms, stricture-related high post-void residuals or a stricture calibre of < 14 Fr – even if these are asymptomatic [560].

Over the last ten years, the evaluation of urethral surgery outcomes has shifted towards a “patient-reported definition of success”. The aim of any urethral intervention is to allow patients to return to a normal state of voiding while maintaining QoL or to minimise symptoms, reduce disability, and improve HRQoL by restoring normal urinary function [562]. Even if the surgeon reconstructed a wide and patent urethra, if patients experience pain, sexual dysfunction or perceive their urinary function as not improved, they will not rate their outcome as successful [560]. On a multivariate analysis including both patient-reported and clinical parameters, urine flowmetry parameters failed to demonstrate significant contribution to satisfaction [563]. Kessler et al., reported that only 78.3% of patients with clinical success described themselves as (very) satisfied. More dissatisfaction significantly appeared with penile curvature, penile shortening, worsening of erectile function and impairment of sexual life [564]. Conversely, 80% of patients defined as clinical failures considered themselves as (very) satisfied with their outcomes [564]. Regardless of anatomic success after urethroplasty, post-operative pain, sexual dysfunction and persistent LUTS were independent predictors of patient dissatisfaction [563]. Improvement in voiding function (i.e., statistical improvement on IPSS) alone does not predict patient satisfaction after urethroplasty [565]. On a multivariate analysis including both patient-reported and clinical parameters, after adjusting for disease recurrence and age, persistence in voiding symptoms (weak stream), genitourinary pain, and post-operative sexual function alterations were the greatest independent drivers of post-operative dissatisfaction [563]. In addition, penile shortening (OR: 2.26; 95% CI: 1.39-3.69) and chordee (OR: 2.26; 95% CI: 1.44-4.19) were independent predictors of patient dissatisfaction after urethroplasty [565] (Table 11.1).

SHIM = Sexual Heath Inventory for Men; MSHQ = Male Sexual Health Questionnaire; CLSS = Core Lower Urinary Tract Symptom Score; IPSS = International Prostate Symptoms Score.
Due to this evident discrepancy between surgeon’s assessment and patient assessment, PROMs have been developed for the follow-up after urethroplasty [160, 562].

A complete approach for urethral surgery outcomes would combine both anatomic, endoscopic, and Patient-reported success [560, 566]. The Panel suggest using a functional definition of success in clinical practice, namely “lack of symptoms and/or need for further interventions”.

Collecting standardised documentation of the patient’s subjective assessment of their symptoms and objective anatomic outcomes would be limited for academic purposes, in order to allow comparison of surgical outcomes among reconstructive urologic surgeons and centres. Those objective and subjective outcomes measures should therefore be assessed and reported (simultaneously but separately) when evaluating urethroplasty results [560].

11.3 Follow-up tools after urethral surgery

11.3.1 Diagnostic tools for follow-up after urethral surgery

11.3.1.1 Calibration during follow-up after urethral surgery

The difference between calibration and urethral dilatation is usually subjective as soft strictures may be dilated during calibration [567]; therefore, urethral calibration should be used with caution for follow-up after urethroplasty. Dedicated calibration bougies should be used and not dilatators.

11.3.1.2 Urethrocystoscopy during follow-up after urethral surgery

Urethrocystoscopy has been considered the most useful tool to confirm the presence or absence of a recurrent stricture [143, 568], as up to 35% of patients with re-strictures remain asymptomatic [145]. Also, the cystoscope could be a measure to calibrate the strictured lumen, bearing in mind the most commonly used endoscopes: 15.7 Fr (5 mm diameter) or 17.3 Fr (5.5 mm diameter) [568]. Urethrocystoscopy allows differentiation of recurrences as diaphragm/cross-bridging – responding to simple intervention, or significant urethral restrictures – requiring repeated interventions or ReDo surgeries [569]. Endoscopic assessment at three months after anterior urethroplasty can predict the risk for further re-intervention at one year. Compared to normal endoscopy, large calibre (> 17 Fr) restrictures have a HR of 3.1 (1.35-7.29) for repeat intervention while small calibre (< 17 Fr) restrictures have a 23.7 HR (12.44-45.15) adjusted for age, stricture length, location, and aetiology [143]. The main problem with using urethrocystoscopy for routine follow-up is the low compliance of patients as only 54% of patients underwent endoscopy at one year after urethroplasty, even when it was a part of a study protocol [145].

11.3.1.3 Retrograde urethrogram and voiding cystourethrogram during follow-up after urethral surgery

Retrograde urethrogram combined with VCUG are commonly used to confirm suspected recurrence [570, 571] or as part of a routine protocol to assess post-operative urethral patency [572, 573].

11.3.1.4 Urethral ultrasound – Sonourethrography during follow-up after urethral surgery

The use of SUG as a follow-up tool is not very common. It would be a reliable tool for diagnostic recurrent strictures [570].

11.3.2 Screening tools for follow-up after urethral surgery

These tools are used to assess whether there is suspicion of stricture recurrence and need for subsequent diagnostic evaluation (see section 5. Diagnostic evaluation).

11.3.2.1 Flow-rate analysis during follow-up after urethral surgery

Evaluating the $Q_{max}$ is the commonest follow-up tool. Different cut-off points from $Q_{max}$ 15 ml/s or 12 ml/s were suggested to consider the intervention as a failure or to trigger a confirmatory test for recurrence [574]. There is no clear threshold, and 19% of patients with $Q_{max} < 14$ ml/s would still have a patent urethra, allowing passage of 15 Fr cystoscope [146].

Flow rates may be affected by operator error, BPO/LUTS, bladder dysfunction, and variations in bladder capacity. Further limitations of uroflowmetry include the need for a minimum voided volume of 125-150 ml to reach a voided flow rate that reliably predicts an abnormality [567]. Even in controlled settings, the percentage of patients with adequate pre- and post-operative uroflowmetry analysis is only 31% [573]. Comparing both pre- and post-operative $Q_{max}$ levels was suggested, and a difference in $Q_{max}$ of 10 ml/s or less is found to be a reliable screen tool for recurrence (sensitivity 92%, specificity 78%). This measure also has strong reproducibility ($R=0.52$) [573]. Unfortunately, this improvement after urethroplasty is significantly different between age groups, with less than 10 ml/s average change in those over 65 years old, probably affected
by BPO and/or bladder dysfunction [575]. Another parameter to consider is the shape of the voiding curve, recording it as flat (obstructed) or bell-shaped [576]. An obstructive voiding curve demonstrated 93% sensitivity to predict recurrent strictures, while a combination of urinary symptoms and obstructive voiding curve achieved 99% sensitivity and 99% NPV [576].

11.3.2.2 Post-void residual ultrasound measure during follow-up after urethral surgery
Post-void residual US measure is significantly increased in patients with recurrent strictures compared with those without recurrences [570]. Unfortunately, PVR measurement is affected by abdominal ascites, bladder diverticula and/or poor bladder function [567], with some studies reporting inconsistent correlation with obstruction in the presence of BPO. Also, US measures of PVR are user dependent, showing high interobserver variability. Combined with other tests – uroflowmetry, IPSS, and SUG – PVR achieves adequate predictive values [570], but currently there is no literature to support its solo use, to assess urethral stricture recurrence [577].

11.3.2.3 Symptom questionnaires during follow-up after urethral surgery
The IPSS questionnaire, despite being designed for BPO, showed significant improvement after successful urethroplasty and inverse significant correlation with Q_max [565, 567]. The mean improvement of IPSS is around -11 points (range -19 to -5) [575].

N = number of patients; NR = not reported; IPSS = International Prostate Symptoms Score; IQR = interquartile range.

Combination of IPSS and Qmax analysis was suggested to diagnose recurrences. Using an IPSS cut-off point of 10 points associated with Q_max > 15 ml/s would prevent further invasive studies in 34% of patients, while only 4.3% of strictures < 14 Fr would have been missed. Using an IPSS cut-off point of 15 points associated with Q_max > 15 ml/s would prevent further invasive studies in 37% of cases, while 6% of strictures < 14 Fr would have been missed [579].

The Visual Prostate Symptom Score (VPSS) was also used to diagnose recurrent urethral strictures, offering a significantly shorter time to completion compared with IPSS, especially in cases of illiteracy or limited education. Visual Prostate Symptom Score showed a good correlation with IPSS, Q_max, and urethral diameter. A combination of VPSS > 8 with Q_max < 15 ml/s had a NPV of 89% and a PPV of 87% for recurrent urethral strictures [580].

Post-micturition dribble, assessed by the specific question of the USS-PROM questionnaire, was present in 73% of patients pre-operatively and 40% after anterior urethroplasty, while only 6.3% was de novo. Incidence was not predicted by stricture location nor urethroplasty type [150].

11.3.3 Quality of life assessment, including disease specific questionnaires during follow-up after urethral surgery
Urethral stricture affects QoL evaluated by EQ-5D-3L questionnaire. Pre-operative anxiety and depression was found in 29% of patients. De novo AD after urethroplasty is uncommon (10%) and has two predictors: decreased sexual function and poor reported image of overall health [581]. A more recommended approach is the assessment of the condition-related QoL [582]. The USS-PROM proved useful to assess outcomes in anterior urethroplasty patients [562]. Its use also received criticism, as some of the individual generic QoL questions do not improve after successful urethroplasty, as they are not condition-specific [583]. Currently, there is another version of PROM, being developed and validated by a North American collaborative group, including questions related to the sexual consequences of urethral stricture disease [161]. PROM questionnaires should be implemented in each visit to check for functional success, as they are able to show improvement over time.
The Core Lower Urinary Tract Symptom Score (CLSS) questionnaire was used to assess pre- and post-urethroplasty pain in the bladder, penis/urethra, and perineum/scrotum. Most of the parameters improved after urethroplasty, but up to 29% of patients reported worsening of perineal pain after surgery [584].

Sexual function should be evaluated by validated tools if not assessed in a PROM. The international index on erectile function (IIEF), SHIM, O’Leary Brief Male Sexual Function Inventory (BMFSI), SLQQ (Sexual Life Quality Questionnaire), Male Sexual Health Questionnaire (MSHQ) have all been used after urethroplasties for evaluation of erectile and ejaculatory functions. Other non-validated tools were suggested such as the Post-Urethroplasty Sexual Questionnaire (PUSQ) [585] or specific questionnaires for genital appearance (length, curvature) or sensitivity [586].

### 11.4 Ideal follow-up interval after urethral surgery

The optimal follow-up strategy must allow for an objective determination of anatomic and functional outcomes to assess surgical success whilst avoiding excessive invasive testing that leads to unnecessary cost, discomfort, anxiety, and risk [560].

After anterior urethroplasty, 21% of recurrences are clinically evident, and cystoscopically confirmed, after three months [587] and 96% after one year [569]. Early recurrences are more frequent in patients with LS and older age, in longer strictures and when skin grafts were used [587].

### 11.5 Length of follow-up after urethral surgery

The median time of recurrence after bulbar urethroplasty is approximately ten months [334]. In case series, between 55.4% [587] and 96% [569, 572] of all recurrences are detected during the first year of follow-up after urethral surgery. Twenty-three percent of bulbar stricture recurrences are detected during the second year of follow-up, and the percentage of recurrences decreases after the second year [346].

On the other hand, long-term follow-up studies highlighted the role of length of follow-up as a predictor for stricture recurrence after bulbar urethroplasty [346, 588]. Late recurrences – later than five years after urethroplasty – could be observed in up to 15% of cases [144, 331, 346]. This should be considered mainly after augmentation urethroplasties, especially in case skin grafts were used [571]. Certainly, patients should be instructed to seek urological evaluation if they experience late recurrent symptoms [588].

### 11.6 Risk-stratified proposals during follow-up after urethral surgery

Cost of follow-up after urethroplasty is higher in the first year after the procedure [589]. In a literature review it ranged between 205 to 1,784 US Dollars, with higher costs associated to posterior urethral repairs [589]. As the risk of recurrence and side effects are related to the type of stricture and urethroplasty, a different follow-up schedule was proposed and shown to be cost-effective in the USA, potentially saving up to 85% of costs after five years [561]:

- Urethroplasties with a low risk of recurrence (EPA urethroplasty without history of radiotherapy, hypospadias, or LS features) could be safely followed up based on monitoring of symptoms, using self-administered IPSS questionnaire, every three months for one year, and annually thereafter.
- Urethroplasties with standard risk of recurrence (urethroplasty using grafts, flaps, and/or post-irradiation, hypospadias and/or LS patients) could combine IPSS questionnaire + flowmetry every three months for one year, and annually thereafter. Additionally, RUG at three and twelve months should be performed.
In this protocol, urethrocystoscopy is only performed if required [561]. Another suggested follow-up protocol includes urethrocystoscopy or RUG/VCUG at three months post-operatively, in order to rule out early failures, especially in case of graft use. If there is evidence of good anatomical outcome in these tests, flowmetry and questionnaire results at three months should be considered as the new baseline. Thereafter, follow-up could be safely and routinely performed with non-invasive tests (flowmetry – evaluating $Q_{\text{max}}$ and the shape of curve – and questionnaires). Any deterioration should be further investigated with a urethrocystoscopy [577].

A recently suggested protocol also included assessment of LUTS, sexual function (erectic and ejaculatory), and LUT pain, that need to be compared with pre-operative findings which should include a PROM questionnaire [560]. Cystoscopy and flowmetry should be performed between three to six months postoperatively, and flowmetry findings should be considered as the new baseline for longitudinal follow-up. Future significant decline (25-30%) in $Q_{\text{max}}$ or $Q_{\text{max}} - $ (average flow rate) should trigger new cystoscopy to rule out anatomic recurrence, even in patients who are symptom-free [560]. A routine cystoscopy at twelve to fifteen months should be performed at the surgeon’s discretion, based on risk assessment of three aspects: higher-risk patients, evidence of partial urethral narrowing at three-month assessment, low-volume surgeons [560].

</tbody>
</table>

*Follow-up could be discontinued after two years, advising the patient to seek urological evaluation if symptoms worsen. Academic centres could increase the length of follow-up for research purposes.

**The Panel suggests performing an anatomic assessment at three months.

##### 11.7.2 Surgical management options with standard risk of recurrence

- Anastomotic urethroplasties in the bulbar segment with prior history of radiotherapy, hypospadias, or BXO/LS features;
- Penile urethroplasties;
- Non-traumatic posterior urethroplasties;
- Graft or/and flap – substitution – urethroplasties.

*Follow-up could be discontinued after five years, advising the patient to seek urological evaluation if symptoms worsen. A longer follow-up period should be considered after penile and substitution urethroplasties. Academic centres could increase the length of follow-up for research purposes.
Please see Figure 11.1 for further guidance.

**Figure 11.1: Follow-up after urethroplasty**

- **Urethroplasty**
  - 3 months
  - Uroflowmetry
    - PROM – including sexual function
  - Urethrocystography / RUG-VCUG

  **Consider Flowmetry values, PROM and scores as new baseline values**

  **Consider**
  1. Location of stricture
  2. Urethroplasty technique
  3. Prior radiotherapy
  4. Hypospadias
  5. BXO/LS

- **Low-risk of recurrence**
  - 12 months after urethroplasty
    - Uroflowmetry
      - PROM – including sexual function
    - Urethrocystography / RUG-VCUG
      - If flowmetry $Q_{max} < 15$ ml/s
      - If flowmetry $Q_{max}$ descends 10 ml/s from new baseline (3 months value)
      - If significant worsening on PROM values
      - If clinically indicated

- **Standard-risk of recurrence**
  - 24 months after urethroplasty
    - Uroflowmetry
      - PROM – including sexual function
  - 5 years after urethroplasty
    - Uroflowmetry
      - PROM – including sexual function
    - Urethrocystography / RUG-VCUG
      - If flowmetry $Q_{max} < 15$ ml/s
      - If flowmetry $Q_{max}$ descends 10 ml/s from new baseline (3 months value)
      - If significant worsening on PROM values
      - If clinically indicated

**Discharge patient**, advising to seek urological evaluation if symptoms worsen.

**BXO** = balanitis xerotica obliterans; **LS** = lichen sclerosus; **PROM** = patient reported outcome measure; $Q_{max}$ = maximum flow rate; **RUG** = retrograde urethrography; **VCUG** = voiding cystourethrography.
