8. CONFLICT OF INTEREST 118

9. CITATION INFORMATION 119
1. INTRODUCTION

1.1 Aims and scope
The European Association of Urology (EAU) Urolithiasis Guidelines Panel has prepared these guidelines to help urologists assess evidence-based management of stones/calculi in the urinary tract and incorporate recommendations into clinical practice. This document covers most aspects of the disease, which is still a cause of significant morbidity despite technological and scientific advances. The Panel is aware of the geographical variations in healthcare provision. In addition, information on the management of bladder stones is now also included in these guidelines.

It must be emphasised that clinical guidelines present the best evidence available to the experts but following guideline recommendations will not necessarily result in the best outcome. Guidelines can never replace clinical expertise when making treatment decisions for individual patients, but rather help to focus decisions - also taking personal values and preferences/individual circumstances of patients into account. Guidelines are not mandates and do not purport to be a legal standard of care.

1.2 Panel composition
The EAU Urolithiasis Guidelines Panel consists of an international group of clinicians with particular expertise in this area. All experts involved in the production of this document have submitted potential conflict of interest statements, which can be viewed on the EAU website Uroweb: http://uroweb.org/guideline/urolithiasis/.

1.3 Available publications
A quick reference document (Pocket guidelines) is available. This is an abridged versions, which may require consultation together with the full text versions. Several scientific publications are also available [1-3]. All documents can be accessed through the EAU website: http://uroweb.org/guideline/urolithiasis/.

1.4 Publication history and summary of changes
1.4.1 Publication history
The EAU Urolithiasis Guidelines were first published in 2000. This 2023 document presents a limited update of the 2022 version.

1.4.2 Summary of changes
The literature for the entire document has been checked and, wherever relevant, updated (see Methods section 2.1). References and supporting text have also been refreshed.

The literature for the entire document has been reviewed and, wherever relevant, updated (see Methods section 2.1) and references and supporting text have also been refreshed. A new recommendation has been given in section 3.4.7.1 related to endourology techniques for renal stone removal (see below). In addition, minor updates have been made to figures 4.2, 4.5, 4.6, 4.7 and 4.9.

2. METHODS

2.1 Data identification
For the 2023 Urolithiasis Guidelines, new and relevant evidence has been identified, collated, and appraised through a structured assessment of the literature.

A broad and comprehensive scoping exercise covering all areas of the guideline was performed. The search was limited to studies representing high levels of evidence only (i.e., systematic reviews with meta-analysis (MA), randomised controlled trials (RCTs), and prospective non-randomised comparative studies) published in the English language. The search was restricted to articles published between 1st May 2021 and 9th May 2022. A total of 635 unique records were identified and screened for relevance. A total of 66 new references have been added to the Urolithiasis 2023 Guidelines publication.
Databases covered by the searches included Medline, EMBASE, Ovid and the Cochrane Libraries. The search strategy is published online: https://uroweb.org/guidelines/urolithiasis/publications-appendices. The chapters on the treatment of bladder stones in adults and children are based on a systematic review [4].

For each recommendation within the guidelines there is an accompanying online strength rating form which includes an assessment of the benefit to harms ratio and patients’ preferences for each recommendation. The strength rating forms draw on the guiding principles of the GRADE methodology but do not purport to be GRADE [5, 6]. Each strength-rating form addresses a number of key elements, namely:

1. the overall quality of the evidence which exists for the recommendation, references used in this text are graded according to a classification system modified from the Oxford Centre for Evidence-Based Medicine Levels of Evidence [7];
2. the magnitude of the effect (individual or combined effects);
3. the certainty of the results (precision, consistency, heterogeneity and other statistical or study related factors);
4. the balance between desirable and undesirable outcomes;
5. the impact of patient values and preferences on the intervention;
6. the certainty of those patient values and preferences.

These key elements are the basis which panels use to define the strength rating of each recommendation. The strength of each recommendation is represented by the words ‘strong’ or ‘weak’ [8]. The strength of each recommendation is determined by the balance between desirable and undesirable consequences of alternative management strategies, the quality of the evidence (including certainty of estimates), and nature and variability of patient values and preferences.

Additional information can be found in the general Methodology section of this print, and online at the EAU website: http://www.uroweb.org/guideline/.

A list of associations endorsing the EAU Guidelines can also be viewed online at the above address.

2.2 Review
The 2015 Urolithiasis Guidelines were subjected to peer-review prior to publication. Chapter 6, detailing the treatment and follow-up of bladder stones was peer reviewed in 2019.

2.3 Future goals
For the 2024 text update the Urolithiasis Guidelines Panel aim to:

- Further evaluate the highest evidence for best clinical practice in endourology.
- Question the accuracy of stone size as the surrogate index on deciding the appropriate treatment of urinary stones.
- Complete two systematic reviews on:
  a) The relation of kidney stones and their treatment on chronic kidney failure and end stage kidney disease.
  b) Patient and personnel radiation protection during endourology.

3. GUIDELINES

3.1 Prevalence, aetiology, risk of recurrence

3.1.1 Introduction
Stone incidence depends on geographical, climatic, ethnic, dietary, and genetic factors. The recurrence risk is basically determined by the disease or disorder causing the stone formation. Accordingly, the prevalence rates for urinary stones vary from 1% to 20% [9]. In countries with a high standard of life such as Sweden, Canada or the USA, renal stone prevalence is notably high (> 10%). For some areas, an increase of more than 37% over the last 20 years has been reported [10-12]. There is emerging evidence linking nephrolithiasis to the risk of chronic Kidney disease (CKD) [13].

Stones can be stratified into those caused by: infections, non-infectious causes, genetic defects [14]; or adverse drug effects (drug stones) (Table 3.1). See also section 3.2.

3.1.2 Stone composition
Stone composition is the basis for further diagnostic and management decisions. Stones are often formed from a mixture of substances. Table 3.2 lists the most clinically relevant substances and their mineral components.

3.1.3 Risk groups for stone formation
The risk status of stone formers should be determined in a holistic way taking into consideration not only the probability of stone recurrence or regrowth, but also the risk of CKD and mineral and bone disorder (MBD) [16, 17], and is imperative for pharmacological treatment. About 50% of recurrent stone formers have just one lifetime recurrence [11, 18]. A recent review of first-time stone formers calculated a recurrence rate of 26% in five years’ time [19]. Highly recurrent disease is observed in slightly more than 10% of patients. Stone type and disease severity determine low- or high-risk stone formers (Table 3.3) [20, 21].
### Table 3.3: High-risk stone formers [20-36]

</table>

A comprehensive evaluation of stone risk in patients should also include the risk of developing CKD, end-stage kidney disease (ESKD), and MBD (Tables 3.4, 3.5 and 3.6) [16]. Urolithiasis can compromise renal function because of the renal stone (obstruction, infection), renal tissue damage due to the primary condition causing stone formation (some genetic diseases, nephrocalcinosis, enteric hyperoxaluria, etc.), or urological treatments for the condition [16]. Certain risk factors have been shown to be associated with such a risk in stone formers, as shown below.

## 3.2 Classification of stones

Urinary stones can be classified according to size, location, X-ray characteristics, aetiology of formation, composition, and risk of recurrence [11, 37, 38].
3.2.1 **Stone size**
Stone size is usually given in one or two dimensions, and stratified into those measuring up to 5, 5-10, 10-20, and > 20 mm in largest diameter.

3.2.2 **Stone location**
Stones can be classified according to anatomical position: upper, middle, or lower calyx; renal pelvis; upper, middle, or distal ureter; and urinary bladder.

3.2.3 **X-ray characteristics**
Stones can be classified according to plain X-ray appearance [kidney-ureter-bladder (KUB) radiography] (Table 3.6), which varies according to mineral composition [38]. Non-contrast-enhanced computed tomography (NCCT) can be used to classify stones according to density, inner structure, and composition, which can affect treatment decisions (Section 3.3) [37, 38].

3.3 **Diagnostic evaluation**

3.3.1 **Diagnostic imaging**

The most appropriate imaging modality will be determined by the clinical situation, which will differ depending on if a ureteral or a renal stone is suspected.

Standard evaluation includes a detailed medical history and physical examination. Patients with ureteral stones usually present with loin pain, vomiting, and sometimes fever, but may also be asymptomatic [39]. Immediate evaluation is indicated in patients with solitary kidney, fever or when there is doubt regarding a diagnosis of renal colic. Ultrasound (US) should be used as the primary diagnostic imaging tool, although pain relief, or any other emergency measures, should not be delayed by imaging assessments. Ultrasound is safe (no risk of radiation), reproducible and inexpensive. It can identify stones located in the calyces, pelvis, and pyeloureteric and vesico-ureteral junctions (US with filled bladder), as well as in patients with upper urinary tract (UUT) dilatation. Ultrasound has a sensitivity of 45% and specificity of 94% for ureteral stones and a sensitivity of 45% and specificity of 88% for renal stones [40, 41].

The sensitivity and specificity of KUB is 44-77% [42]. Kidney-ureter-bladder radiography should not be performed if NCCT is being considered [43]; however, it is helpful in differentiating between radiolucent and radiopaque stones and should be used for comparison during follow-up.

3.3.1.1 **Evaluation of patients with acute flank pain/suspected ureteral stones**

Non-contrast-enhanced computed tomography (CT) has become the standard for diagnosing acute flank pain and has replaced intravenous urography (IVU). Non-contrast-enhanced CT can determine stone diameter and density. When stones are absent, the cause of abdominal pain should be identified. In evaluating patients with suspected acute urolithiasis, NCCT is significantly more accurate than IVU or US [44].

Non-contrast-enhanced CT can detect uric acid and xanthine stones, which are radiolucent on plain films, but not indinavir stones [45]. Non-contrast-enhanced CT can determine stone density, inner structure of the stone, skin-to-stone distance, and surrounding anatomy; all of which affect selection of treatment modality [38, 46-48]. The advantage of non-contrast imaging must be balanced against loss of information on renal function and urinary collecting system anatomy, as well as higher radiation dose [49-52].

Radiation risk can be reduced by low-dose CT, which may, however, be difficult to introduce in standard clinical practice [53-57]. In patients with a body mass index (BMI) < 30, low-dose CT has been shown to have a sensitivity of 86% for detecting ureteral stones < 3 mm and 100% for calculi > 3 mm [58]. A meta-analysis (MA) of prospective studies [55] has shown that low-dose CT diagnosed urolithiasis with a pooled sensitivity of 93.1% (95% confidence interval [CI]: 91.5-94.4), and a specificity of 96.6% (95% CI: 95.1-97.7%). Dual-energy CT can differentiate uric acid containing stones from calcium-containing stones [59, 60].

3.3.2 Diagnostics - metabolism-related

Besides imaging, each emergency patient with urolithiasis needs a succinct biochemical work-up of urine and blood test. At this point, no distinction is made between high- and low-risk patients for stone formation.

3.3.2.1 Basic laboratory analysis - non-emergency urolithiasis patients

Biochemical work-up is similar for all stone patients. However, if no intervention is planned, examination of sodium, potassium, C-reactive protein (CRP), and blood coagulation time can be omitted. Only patients at high risk for stone recurrence should undergo a more specific analytical programme [21]. Stone-specific metabolic evaluation is described in Chapter 4.

The easiest method for diagnosing stones is by analysis of a passed stone using a validated method as listed in section 3.3.2.3. Once the mineral composition is known, a potential metabolic disorder can be identified.

3.3.2.2 Analysis of stone composition

Stone analysis should be performed in all first-time stone formers.

In clinical practice, repeat stone analysis is needed in the case of:

- recurrence under pharmacological prevention;
- early recurrence after interventional therapy with complete stone clearance;
- late recurrence after a prolonged stone-free period [61, 62].

Patients should be instructed to filter their urine to retrieve a concrement for analysis. Stone passage and restoration of normal renal function should be confirmed.

The preferred analytical procedures are infrared spectroscopy (IRS) or X-ray diffraction (XRD) [63-65]. Equivalent results can be obtained by polarisation microscopy. Chemical analysis (wet chemistry) is generally deemed to be obsolete [63, 66].

### 3.3.3 Diagnosis in special groups and conditions

#### 3.3.3.1 Diagnostic imaging during pregnancy

In pregnant women radiation exposure may cause non-stochastic (teratogenesis) or stochastic (carcinogenesis/mutagenesis) effects. Teratogenic effects are cumulative with increasing dose and require a threshold dose (< 50 mGy are considered as safe) and depend on the gestation age (minimum risk prior to 8th week and after the 23rd week). Carcinogenesis (doses even < 10 mGy present a risk) and mutagenesis (500-1000 mGy doses are required, far in excess of the doses in common radiographic studies) get worse with increasing dose but they do not require a dose threshold and are not dependent on gestational age [70].

There is no imaging modality that should be routinely repeated in pregnant women. Scientific societies and organisations agree on the safety of diagnostic evaluation when US [71], X-ray imaging [72, 73], and MRI [74, 75] are used as and when indicated [76-82]. A radiographic procedure should not be withheld from a pregnant woman if the procedure is clearly indicated and doing so will affect her medical care.

It is generally recommended that an investigation resulting in an absorbed dose to the foetus of greater than 0.5 mGy requires justification.

Ultrasound (when necessary, using changes in renal resistive index and transvaginal/transabdominal US with a full bladder) has become the primary radiological diagnostic tool when evaluating pregnant patients suspected of renal colic. However, normal physiological changes in pregnancy can mimic ureteral obstruction [78-80].

Magnetic resonance imaging can be used, as a second-line option [76], to define the level of urinary tract obstruction, and to visualise stones as a filling defect [74]. As 3 Tesla (T) MRI has not been evaluated in pregnancy, the use of 1.5T is currently recommended [77, 82]. The use of gadolinium is not routinely recommended in pregnancy to avoid toxic effects to the embryo [78].

For the detection of urolithiasis during pregnancy, low-dose CT is associated with a higher positive predictive value (95.8%), compared to MRI (80%) and US (77%). As per White et al., low-dose CT offers improved diagnostic accuracy that can avoid negative interventions such as ureteroscopy [83]. Although low-dose CT protocols reduce the radiation exposure, judicious use is currently recommended in pregnant women as a last-line option [78].

#### Summary of evidence LE

| Only low-level data exist for imaging in pregnant women supporting US and MRI. | 3 |

#### Recommendations

| Use ultrasound as the preferred method of imaging in pregnant women. | Strong |
| Use magnetic resonance imaging as a second-line imaging modality in pregnant women. | Strong |
| Use low-dose computed tomography as a last-line option in pregnant women. | Strong |

#### 3.3.3.2 Diagnostic imaging in children

Children with urinary stones have a high risk of recurrence; therefore, standard diagnostic procedures for high-risk patients apply, including a valid stone analysis (Section 3.1.3 and Chapter 4). The most common nonmetabolic disorders facilitating stone formation are vesico-ureteral reflux (VUR), UPJ obstruction, neurogenic bladder, and other voiding difficulties [84].

When selecting diagnostic procedures to identify urolithiasis in children, it should be remembered that these patients might be uncooperative, require anaesthesia, and may be sensitive to ionising radiation. Again, the principle of ALARA (As Low As Reasonably Achievable) should be observed [85-87].

#### Ultrasound

Ultrasound is the primary imaging technique [88] in children. Its advantages are absence of radiation and no need for anaesthesia. Imaging should include both the fluid-filled bladder with adjoining portion of the ureters, as well
as the upper ureter [89-93]. Colour Doppler US shows differences in the ureteral jet [90] and resistive index of the arciform arteries of both kidneys, which are indicative of the grade of obstruction [91]. Nevertheless, US fails to identify stones in > 40% of children [92-95] and provides limited information on renal function.

**Plain films (KUB radiography)**
Kidney-ureter-bladder radiography can help to identify stones and their radiopacity and facilitate follow-up.

**Intravenous urography**
The radiation dose for IVU is comparable to that for voiding cysto-urethrography (0.33 mSV) [96]. However, the need for contrast medium injection is a major drawback.

**Non-contrast-enhanced computed tomography**
Recent low-dose CT protocols have been shown to significantly reduce radiation exposure [52, 97, 98]. In children, only 5% of stones escape detection by NCCT [90, 98, 99]. Sedation or anaesthesia is rarely needed with modern high-speed CT equipment.

**Magnetic resonance urography**
Magnetic resonance urography (MRU) cannot be used to detect urinary stones. However, it might provide detailed anatomical information about the urinary collecting system, the location of an obstruction or stenosis in the ureter, and renal parenchymal morphology [100].

### 3.3.3.2.1 Summary of evidence and recommendations for diagnostic imaging in children

<table>
<thead>
<tr>

### Recommendations | Strength rating
| Complete a metabolic evaluation based on stone analysis in all children. | Strong |
| Collect stone material for analysis to classify the stone type. | Strong |
| Perform ultrasound as first-line imaging modality in children when a stone is suspected; it should include the kidney, fluid-filled bladder, and the ureter. | Strong |
| Perform a kidney-ureter-bladder radiography (or low-dose non-contrast-enhanced computed tomography) if ultrasound will not provide the required information. | Strong |

### 3.4 Disease Management

The treatment of urolithiasis is based on many parameters and is individualised for each patient. Parameters such as the size, number, location, and constitution of the stones are cornerstones for deciding the treatment. In addition, the morphology, shape, volume, mobility, and hardness of the stone should be considered. Finally, the anatomy and compliance of the entire pelvic-calyceal system should be assessed for each patient. The design of therapeutic algorithms including all of the above parameters is difficult mainly due to the great diversity of lithiasis disease per patient. Furthermore, there is a significant lack of comparative clinical studies to support development of algorithms using parameters other than stone size and composition.

#### 3.4.1 Renal colic

**Pain relief**
Non-steroidal anti-inflammatory drugs (NSAIDs) (including metamizoliedipyrone), and paracetamol are effective in patients with acute stone colic [101], and have better analgesic efficacy than opioids [102]. Ibuprofen compared to ketorolac is a more rapid acting drug in controlling pain caused by renal colic with a similar side effect profile [103].

Pain relief from intramuscular (i.m.) diclofenac compared favourably with those from intravenous (i.v.) ibuprofen and i.v. ketorolac; however, no recommendation can be given due to the way in which the results have been reported [104]. The addition of antispasmodics to NSAIDs does not result in better pain control. Patients receiving NSAIDs are less likely to require further analgesia in the short term. It should be taken into consideration that the use of diclofenac and ibuprofen increased major coronary events [101, 102]. Diclofenac
is contraindicated in patients with congestive heart failure (New York Heart Association class II-IV), ischaemic heart disease and peripheral arterial- and cerebrovascular disease. Patients with significant risk factors for cardiovascular events should be treated with diclofenac only after careful consideration. As risks increase with dose and duration, the lowest effective dose should be used for the shortest duration [105, 106].

In a RCT including 150 patients, Intradermal sterile water injection (ISWI) and diclofenac (i.m.) were shown equally effective for pain relief in acute renal colic. Intradermal sterile water injection may be an alternative to NSAIDs in pregnant patients or others where NSAIDs are contra-indicated [107].

Opioids, particularly pethidine, are associated with a high rate of vomiting compared to NSAIDs and carry a greater likelihood of further analgesia being needed [101, 108] (see below). If an opioid is used, it is recommended that it is not pethidine. Combination of opioids and NSAIDs increase analgetic effect compared to opioids alone [109]. Data on other types of non-opioid and non-NSAID medication is increasing. Ketamine in combination with morphine, compared to morphine alone, leads to morphine consumption reduction, less pain, nausea and vomiting [110-112]. Patients receiving ketamine and NSAIDs attained greater reduction in pain scores with less side effects, and better functional state, as well as less further analgesia requirement than those administered pethidine [113]. However, when comparing ketamine vs. NSAID (ketorolac) alone, equal efficacy but higher rates of dizziness, agitation and hypertension with ketamine were observed [114]. Conflicting results have been reported regarding the utility of intravenous lidocaine. Acupuncture seems to be effective in renal colic alone or in combination, but there is limited data [115, 116].

Prevention of recurrent renal colic
Facilitation of passage of ureteral stones is discussed in Section 3.4.9. For patients with ureteral stones that are expected to pass spontaneously, NSAID tablets or suppositories (e.g., diclofenac sodium, 100-150 mg/day, 3-10 days) may help reduce inflammation and the risk of recurrent pain [117, 118]. Although diclofenac can affect renal function in patients with already reduced function, it has no functional effect in patients with normal renal function [119].

The systematic review and MA by Hollingsworth et al., [120] addressed pain reduction as a secondary outcome and concluded that medical expulsive therapy (MET) seems efficacious in reducing pain episodes of patients with ureteral stones.

If analgesia cannot be achieved medically, drainage, using stenting, percutaneous nephrostomy, or stone removal, is indicated [121].

* Maximum single oral dose recommended 1000 mg, total daily dose up to 5000 mg, not recommended in the last three months of pregnancy [122].
** Affects glomerular filtration rate (GFR) in patients with reduced renal function.
*** Recommended to counteract recurrent pain after ureteral colic.

3.4.2 Management of sepsis and/or anuria in obstructed kidney
The obstructed kidney with all signs of urinary tract infection (UTI) and/or anuria is a urological emergency. Urgent decompression is often necessary to prevent further complications in infected hydronephrosis secondary to stone-induced, unilateral or bilateral, renal obstruction.
Decompression
Currently, there are two options for urgent decompression of obstructed collecting systems [123]:
- placement of an indwelling ureteral stent;
- percutaneous placement of a nephrostomy tube.

There is little evidence to support the superiority of percutaneous nephrostomy over retrograde stenting for primary treatment of infected hydronephrosis. There is no good quality evidence to suggest that ureteral stenting has more complications than percutaneous nephrostomy [124, 125].

Only one RCT [126] compared different modalities of decompression of acute infected hydronephrosis. Two other small RCTs compared stenting vs. nephrostomy tube placement in patients with acute kidney injury and demonstrated both to be effective in decompressing the collecting system [127, 128]. The complications of percutaneous nephrostomy insertion have been reported consistently, but those of ureteral stent insertion are less well described [124]. Definitive stone removal should be delayed until the infection is cleared following a complete course of antimicrobial therapy. A small RCT showed the feasibility of immediate ureteroscopic stone removal combined with an appropriate antibiotic regimen; however, at the cost of longer hospital stay and higher analgesic requirements [129].

Further measures
Following urgent decompression of the obstructed and infected urinary collecting system, both urine- and blood samples should be sent for culture-antibiogram sensitivity testing and antibiotics should be initiated immediately thereafter or continued, if initiated prior to testing. The regimen should be re-evaluated in the light of the culture-antibiogram results. Although clinically well accepted, the impact of a second antibiogram test on treatment outcome has not yet been evaluated. Intensive care might become necessary [130].

3.4.3 Medical expulsive therapy
Several drug classes including α-blockers, calcium channel inhibitors and phosphodiesterase type 5 inhibitors (PDEI-5) are used for MET [131-134]. A class effect of α-blockers in MET has been demonstrated in MAs although this is an off-label indication [135-137]. However, there is contradictory evidence between these studies and several well-designed, multicentre, placebo-controlled, double-blinded randomised studies showing limited, or no, benefit using α-blockers, besides some advantage for distal ureteral stones > 5 mm [138-142]. Based on studies with a limited number of patients [134, 135, 143, 144], no recommendation for the use of PDEI-5 or corticosteroids in combination with α-blockers in MET can be made. The panel concludes that MET using α-blockers seems efficacious in the treatment of patients with distal ureteral stones > 5 mm who are amenable to conservative management. Medical expulsive therapy in special situations is addressed in the relevant chapters.

Alpha-blockers increase stone expulsion rates in distal ureteral stones > 5 mm.  
A class effect of α-blockers has been demonstrated.

**Recommendation**  
Consider α-blockers as medical expulsive therapy as one of the treatment options for (distal) ureteral stones > 5 mm.  

**Strength rating**  
Strong

### 3.4.4 Chemolysis

#### Percutaneous irrigation chemolysis

Percutaneous chemolysis is rarely used nowadays, for practical reasons. Percutaneous irrigation chemolysis may be an option for infection-stones and theoretically also for uric acid stones. For dissolution of struvite stones, Suby’s G solution (10% hemiacidrin; pH 3.5-4) can be used. The method has been described in case series and literature reviews [145-147].

#### Oral chemolysis

Stones composed of uric acid, but not sodium or ammonium urate stones, can be dissolved by oral chemolysis. Prior stone analysis may provide information on stone composition. Urinary pH measurement and X-ray characteristics can provide information on the type of stone.

Oral chemolitholysis is based on alkalinisation of urine by application of alkaline citrate or sodium bicarbonate. The pH should be adjusted to 7.0-7.2. Chemolysis is more effective at a higher pH, which might, however, promote calcium phosphate stone formation. Patients will need to adjust the dosage of alkalisising medication by self-monitoring the pH of their urine. No RCTs are available for this therapy, which has been in use for decades. Rodman, et al., [148] reviewed the principles and provided guidance to its clinical use, which was supported by Becker, et al., in 2007 [149] and Elsawy et al. in 2019 [150]. Monitoring of radiolucent stones during therapy is the domain of US; however, repeat-NCCT might be necessary [148, 149].

In the case of uric acid obstruction of the collecting system, oral chemolysis in combination with urinary drainage is indicated [151]. A combination of alkalinisation with tamsulosin can increase the frequency of spontaneous passage of distal ureteral uric acid stones as shown in one RCT for stones > 5 mm [151]. Additional shock wave lithotripsy (SWL) might help to improve the results but evidence is weak [152].

### 3.4.5 Extracorporeal shock wave lithotripsy (ESWL)

The success of SWL depends on the efficacy of the lithotripter and the following factors:
- size, location (ureteral, pelvic or calyceal), and composition (hardness) of the stones (Section 3.4.9.3);
- patient’s habitus (Section 3.4.10.3);
- performance of SWL (best practice, see below).

Each of these factors significantly influences the retreatment rate and final outcome of SWL.

**Best clinical practice**

**Stenting**

Routine use of internal stents before SWL does not improve stone free rates (SFRs), nor lowers the number of auxiliary treatments. It may, however, reduce formation of steinstrasse [153-156].
Patients with a pacemaker can be treated with SWL, provided that appropriate technical precautions are taken. Patients with implanted cardioverter defibrillators must be managed with special care (firing mode temporarily reprogrammed during SWL treatment). However, this might not be necessary with new-generation lithotripters [157].

**Shock wave rate**
Lowering shock wave frequency from 120 to 60-90 shock waves/min improves SFRs [158-166]. Ultraslow frequency 30 shock waves/min may increase SFR [167]. Tissue damage increases with shock wave frequency [168-171].

**Number of shock waves, energy setting and repeat treatment sessions**
The number of shock waves that can be delivered at each session depends on the type of lithotripter and shock wave power. There is no consensus on the maximum number of shock waves [172]. Starting SWL on a lower energy setting with stepwise power (and SWL sequence) ramping can achieve vasoconstriction during treatment [168], which prevents renal injury [173-175]. Animal studies [176] and a prospective randomised study [177] have shown better SFRs (96% vs. 72%) using stepwise power ramping, but no difference has been found for fragmentation or evidence of complications after SWL, irrespective of whether ramping was used [178, 179].

There are no conclusive data on the intervals required between repeated SWL sessions. However, clinical experience indicates that repeat sessions are feasible (within one day for ureteral stones) [180].

**Improvement of acoustic coupling**
Proper acoustic coupling between the cushion of the treatment head and the patient’s skin is important. Defects (air pockets) in the coupling gel deflect 99% of shock waves [181]. Ultrasound gel is probably the most widely-used agent available as a lithotripsy coupling agent [182].

**Procedural control**
Results of treatment are operator dependent, and experienced clinicians obtain better results. During the procedure, careful imaging control of localisation contributes to outcome quality [183].

**Pain Control**
Careful control of pain during treatment is necessary to limit pain-induced movements and excessive respiratory excursions [184-187].

**Antibiotic prophylaxis**
No standard antibiotic prophylaxis before SWL is recommended. However, prophylaxis is recommended in the case of internal stent placement ahead of anticipated treatments and in the presence of increased bacterial burden (e.g., indwelling catheter, nephrostomy tube, or infectious stones) [68, 188, 189].

**Medical therapy after extracorporeal shock wave lithotripsy**
Despite conflicting results, most RCTs and several MAs support MET after SWL for ureteral or renal stones as an adjunct to expedite expulsion and to increase SFRs. Medical expulsion therapy might also reduce analgesic requirements [190-199].

**Post-treatment management**
Mechanical percussion and diuretic therapy can significantly improve SFRs and accelerate stone passage after SWL [200-203].

**Complications of extracorporeal shock wave lithotripsy**
Compared to percutaneous nephrolithotomy (PNL) and ureteroscopy (URS), there are fewer overall complications with SWL [204, 205] (Table 3.8). The relationship between SWL and hypertension or diabetes is unclear. Published data are contradictory; however, no evidence exists supporting the hypothesis that SWL may cause long-term adverse effects [206-212].

3.4.6 Ureteroscopy (retrograde and antegrade)

The current standard for rigid ureteroscopes is a tip diameter of < 8 French (F). Rigid URS can be used for the whole ureter [206]. However, technical improvements, as well as the availability of digital scopes, also favour the use of flexible ureteroscopes in the ureter [228].

Percutaneous antegrade removal of ureteral stones is a consideration in selected cases, i.e. large (> 15 mm), impacted proximal ureteral calculi in a dilated renal collecting system [229-231], or when the ureter is not amenable to retrograde manipulation [231-235].

Ureteroscopy for renal stones (RIRS)

Technical improvements including endoscope miniaturisation, improved deflection mechanism, enhanced optical quality and tools, and introduction of disposables have led to an increased use of URS for both renal and ureteral stones. Major technological progress has been achieved for RIRS. A recent systematic review addressing renal stones > 2 cm showed a cumulative SFR of 91% with 1.45 procedures/patient; 4.5% of the complications were > Clavien 3 [228, 236, 237]. Digital scopes demonstrate shorter operation times due to the improvement in image quality [236].

Stones that cannot be extracted directly must be disintegrated. If it is difficult to access stones within the lower renal pole that need disintegration; it may help to displace them into a more accessible calyx [238].
**Best clinical practice in ureteroscopy**

**Access to the upper urinary tract**

Most interventions are performed under general anaesthesia, although local or spinal anaesthesia is possible [239]. Intravenous sedation is suitable for female patients with distal ureteral stones [240]. Antegrade URS is an option for large, impacted, proximal ureteral calculi [229-231, 241]. Reduction of flexible ureteroscope diameter may provide similar vision, deflection, and manoeuvrability to standard flexible ureteroscopes potentially with improved ureteric access [242]. Disposable ureteroscopes provides similar safety and clinical effectiveness to reusable scopes. Concerns regarding the cost effectiveness and environmental sustainability remain [243-245].

**Safety aspects**

Fluoroscopic equipment must be available in the operating room. The Panel recommend placement of a safety wire, even though some groups have demonstrated that URS can be performed without it [246-250]. Balloon and plastic dilators should be available, if necessary.

Prior rigid URS can be helpful for optical dilatation followed by flexible URS, if necessary. If ureteral access is not possible, insertion of a JJ stent followed by URS after seven to fourteen days offers an alternative [251]. Bilateral URS during the same session is feasible resulting in equivalent-to-lower SFRs, but slightly higher overall complication rates (mostly minor, Clavien 1 and 2) [252, 253].

Difficult lower pole anatomy such as steep infundibulopelvic angle predisposes to failure during RIRS [254]. Prolonged operative times are linked to increased complication rates in ureteroscopy, and efforts must be made to keep it below 90 minutes [255].

**Ureteral access sheaths**

Hydrophilic-coated ureteral access sheaths, which are available in different calibres (inner diameter from 9 F upwards), can be inserted (via a guide wire) with the tip placed in the proximal ureter.

Ureteral access sheaths allow easy, multiple, access to the UUT and therefore significantly facilitate URS. The use of ureteral access sheaths improves vision by establishing a continuous outflow, decreases intrarenal pressure, and potentially reduces operating time [256, 257].

The insertion of ureteral access sheaths may lead to ureteral damage, the risk is lowest in presented systems [258]. No data on long-term side effects are available [258, 259]. Whilst larger cohort series showed no difference in SFRs and ureteral damage (stricture rates of about 1.8%), they did show lower post-operative infectious complications [260, 261]. The use of ureteral access sheath is safe and can be useful for large and multiple renal stones or if long procedural time is expected [262].

**Stone extraction**

The aim of URS is complete stone removal. “Dust and go” strategies should be limited to the treatment of large (renal) stones [263]. Stones can be extracted by endoscopic forceps or baskets. Only baskets made of nitinol can be used for flexible URS [264].

**Intracorporeal lithotripsy**

The most effective lithotripsy system is the holmium: yttrium-aluminium-garnet (Ho:YAG) laser, which is currently the optimum standard for URS and flexible nephroscopy (Section 3.4.6), because it is effective in all stone types [265, 266]. Compared to low-power lasers, high-power laser reduces procedural time although the reported difference in clinical outcomes were non-significant [267]. J Pneumatic and US systems can be used with high disintegration efficacy in rigid URS [268, 269]. However, stone migration into the kidney is a common problem, which can be prevented by placement of special anti-migration tools proximal of the stone [270]. Medical expulsion therapy following Ho:YAG laser lithotripsy increases SFRs and reduces colic episodes [271]. Thulium fibre laser (TFL) for stone disease has a promising role, offers good clinical outcomes, which seem to be comparable to Ho:YAG laser (holmium) laser. More comparative clinical studies are however needed between these two modalities [272, 273].

**Stenting before and after URS**

Routine stenting is not necessary before URS. Despite a complete lack of RCTs on this subject, a meta-analysis has been performed, demonstrating that pre-stenting may improve the stone free rate of ureteroscopic treatment of renal stones, but not of ureteral stones [274]. Although it may facilitate ureteroscopic management of stones and increase success in access sheath placement, intra-operative complications were not significantly different [274, 275]. One should also take into account that pre-stenting also causes the patient to experience stent-related symptoms during the time the stent is indwelling, prior to a procedure.

Randomised prospective trials have found that routine stenting after uncomplicated URS (complete stone
removal) is not necessary; stenting might be associated with higher post-operative morbidity and costs [276-279]. A ureteral catheter with a shorter indwelling time (one day) may also be used, with similar results [280].

Stents should be inserted in patients who are at increased risk of complications (e.g., ureteral trauma, residual fragments, bleeding, perforation, UTIs, or pregnancy), and in all doubtful cases, to avoid stressful emergencies. The ideal duration of stenting is not known. Most urologists favour one to two weeks after URS. Alpha-blockers reduce the morbidity of ureteral stents and increase tolerability [281, 282].

**Medical expulsive therapy before and after ureteroscopy**

Medical expulsion therapy before URS might reduce the risk for intra-operative ureteral dilatation, protect against ureteral injury and increase stone free rates four weeks after URS [283]. Medical expulsion therapy following Ho:YAG laser lithotripsy accelerates the spontaneous passage of fragments and reduces episodes of colic [271].

**Complications of ureteroscopy**

The overall complication rate after URS is 9-25% [206, 284, 285]. Most complications are minor and do not require intervention. There is evidence suggesting a risk of post-operative urosepsis of up to 5% [286, 287]. Ureteral avulsion and strictures are rare (< 1%). Previous perforations, pre-operative positive urine cultures and longer operation time are the most important risk factor for complications [255, 288]. Infectious complications following URS can be minimised using prophylactic antibiotics, limiting stent dwell and procedural time, identification and treatment of UTI, and planning in patients with large stone burden and multiple comorbidities [289].

High intrarenal pressure (IRP) predisposes to URS complications, and measures should be used to reduce IRP. Currently there are no accurate ways to measure intra-operative IRP [290].

### 3.4.7 Percutaneous nephrolithotomy

Percutaneous nephrolithotomy remains the standard procedure for large renal calculi. Different rigid and flexible endoscopes are available, and the selection is mainly based on the surgeon’s own reference. Standard access tracts are 24-30 F. Smaller access sheaths, < 18 F, were initially introduced for paediatric use, but are now increasingly utilised in the adult population [291, 292].
Contraindications

Patients receiving anti-coagulant therapy must be monitored carefully pre- and post-operatively. Anti-coagulant therapy must be discontinued before PNL [293].

Other important contraindications include:
- untreated UTI;
- tumour in the presumptive access tract area;
- potential malignant kidney tumour;
- pregnancy (Section 3.4.14.1).

Best clinical practice

Intracorporeal lithotripsy

Several methods for intracorporeal lithotripsy during PNL are available. Ultrasonic and pneumatic systems are most commonly used for rigid nephroscopy, whilst laser is increasingly used for miniaturised instruments [294]. Flexible endoscopes also require laser lithotripsy to maintain tip deflection, with the Ho:YAG laser having become the standard.

Pre-operative imaging

Pre-procedural imaging evaluations are summarised in Section 3.3.1. In particular, US or CT of the kidney and the surrounding structures can provide information regarding interposed organs within the planned percutaneous path (e.g., spleen, liver, large bowel, pleura, and lung).

Positioning of the patient

Both prone and supine positions are equally safe, although the supine position confers some advantages, it depends on appropriate equipment being available to position the patient correctly, for example, X-ray devices and an operating table. A meta-analysis including 12 studies and a total of 1,290 patients treated, showed a similar SFR but a lower operative time for supine PNL [295]. Prone position offers more options for puncture and is therefore preferred for upper pole or multiple accesses [296, 297]. On the other hand, supine position allows simultaneous retrograde access to the collecting system, using flexible ureteroscope [298]. The combination of PNL and RIRS may be a good alternative for the treatment of complex renal stones compared to standard PNL; however, the existing evidence is of low quality [295].

Puncture

Although fluoroscopy is the most common intra-operative imaging method, the (additional) use of US reduces radiation exposure [299-301]. Pre-operative CT or intra-operative US allows identification of the tissue between the skin and kidney and lowers the incidence of visceral injury. The calyceal puncture may be done under direct visualisation using simultaneous flexible URS [300, 302, 303].

Dilatation

Dilatation of the percutaneous access tract can be achieved using a metallic telescope, single (one-shot or serial) dilators, or a balloon dilatator. During PNL, safety and effectiveness are similar for different tract dilatation methods [304]. Although there are papers demonstrating that single step dilation is equally effective as other methods and that US only can be used for the dilatation, the difference in outcomes is most likely related to surgeon experience rather than to the technology used [304, 305]. A meta-analysis on the most commonly used tract dilation methods suggested that one-step dilatation would allow for a shorter operative time and reduced complication rate, including haemoglobin loss and transfusion rate [306].

Choice of instruments

Several meta-analyses on mPNL (12-22 F) vs. standard PNL (> 22 F) have identified that both techniques allow for a similar SFR. Patients treated with mPNL had reduced blood loss and transfusion rates, as well as shorter hospital stays, without a significant difference in overall complication rates [292, 307-309]. However, it is important to note that the level of evidence was downgraded due to heterogeneity of data related to tract sizes used and types of stones treated. There is some evidence for using suction during PNL to reduce IRP and increase SFR [310].

Nephrostomy and stents

The decision on whether, or not, to place a nephrostomy tube at the conclusion of the PNL procedure depends on several factors, including:
- presence of residual stones;
- likelihood of a second-look procedure;
• significant intra-operative blood loss;
• urine extravasation;
• ureteral obstruction;
• potential persistent bacteriuria due to infected stones;
• solitary kidney;
• bleeding diathesis;
• planned percutaneous chemolitholysis.

Small-bore nephrostomies seem to have advantages in terms of post-operative pain [292, 311, 312]. Tubeless PNL is performed without a nephrostomy tube and is associated with reduced post-operative pain and hospital stay [313]. When neither a nephrostomy tube nor a ureteral stent is introduced, the procedure is known as totally tubeless PNL [314]. In uncomplicated cases, the latter procedure results in a shorter hospital stay, with no disadvantages reported [315].

Complications of percutaneous nephrolithotomy
A systematic review of almost 12,000 patients shows the incidence of complications associated with PNL; fever 10.8%, transfusion 7%, thoracic complication 1.5%, sepsis 0.5%, organ injury 0.4%, embolisation 0.4%, urinoma 0.2%, and death 0.05% [316].

Peri-operative fever can occur, even with a sterile pre-operative urinary culture and peri-operative antibiotic prophylaxis, because the renal stones themselves may be a source of infection. The evidence demonstrates that a stone culture or urine culture taken directly from the renal pelvis is more predictive of post-operative systemic inflammatory response syndrome (SIRS) or sepsis. Whenever possible a urine culture from the renal pelvis and/or stone culture should be taken at time of percutaneous cystolithotripsy [317].

Intra-operative renal stone or renal pelvic urine culture may be more indicative of the causative organism for sepsis; therefore, helping to select the most suitable post-operative antibiotics [317-319]. Intra-operative irrigation pressure < 30 mmHg and unobstructed post-operative urinary drainage may be important factors in preventing post-operative sepsis [320]. Bleeding after PNL may be treated by briefly clamping the nephrostomy tube. Super-selective embolic occlusion of the arterial branch may become necessary in the case of severe bleeding. The use of tranexamic acid seems to reduce bleeding complications and transfusion rate of PNL; however, more evidence is needed before it can be introduced in routine clinical practice [321, 322].

To reduce post-operative pain after PNL, a peripheral nerve block can be performed at the intercostal nerve, paravertebral region, erector spinae or quadratus lumborum. Such a block may significantly reduce the need for post-operative opioid analgesics [323].

High IRP predisposes to PNL complications, and measures should be taken to reduce IRP. Currently there are no accurate ways to measure IRP [290].

### 3.4.8 General recommendations and precautions for stone removal

#### 3.4.8.1 Antibiotic therapy

Urinary tract infections should always be treated if stone removal is planned. In patients with clinically significant infection and obstruction, drainage should be performed for several days before starting stone removal. A urine culture or urinary microscopy should be performed before treatment [324].

**Peri-operative antibiotic prophylaxis**

For prevention of infection following URS and percutaneous stone removal, no clear-cut evidence exists [289, 325]. In a review of a large database of patients undergoing PNL, it was found that in patients with negative baseline urine culture, antibiotic prophylaxis significantly reduced the rate of post-operative fever and other complications [326]. Single dose administration prior to ureteroscopy was found to be sufficient [327]. Based on a meta-analysis by Yu et al., an extended course of pre-operative prophylactic antibiotics prior to PNL compared to single dose before anaesthesia significantly reduced post-operative sepsis and fever [318]. In an RCT including only moderate to high-risk of infection patients (patients with pre-operative stents/nephrostomy or positive urine culture), a seven-day course of pre-operative antibiotics reduced the risk of post-PNL sepsis threefold in comparison to a two-day course. In studies that did not specify the risk of the patient population, a single dose of antibiotic prophylaxis administered at induction was equivalent to an extended pre-operative course [328]. In contrast to this, a prolonged course of post-operative antibiotics was not superior to a single dose pre-operatively [318, 329].

As national and regional antibiotic resistance patterns can differ significantly, the choice of antibiotic prophylaxis should be tailored to institutional or regional antimicrobial susceptibility [330].

#### 3.4.8.2 Antithrombotic therapy and stone treatment

Patients with a bleeding disorder, or receiving antithrombotic therapy, should be referred to an internist for appropriate therapeutic measures before deciding on stone management [331-335]. In patients with an uncorrected bleeding disorder, the following are at elevated risk of haemorrhage or perinephric haematoma (PNH) (high-risk procedures):

- SWL (hazard ratio of PNH up to 4.2 during anti-coagulant/anti-platelet medication [336-338]);
- PNL;
- percutaneous nephrostomy;
- laparoscopic surgery;
- open surgery [331].

Shock wave lithotripsy is feasible and safe after correction of the underlying coagulopathy [339-343]. In the case of an uncorrected bleeding disorder or continued antithrombotic therapy, URS, in contrast to SWL and PNL, might offer an alternative approach since it is associated with less morbidity [344-346]. Despite appropriate cessation of anti-platelet agents, following standardised protocols, prolonged haematuria in tube drainage after PNL has been reported [347]. Only data on flexible URS are available which support the superiority of URS in the treatment of proximal ureteral stones [348, 349]. Although URS is safe in patients with bleeding disorders or anticoagulation, an individualised patient-approach is necessary [346].

3.4.8.3 Obesity

A high BMI can pose a higher anaesthetic risk and a lower success rate after SWL and PNL and may influence the choice of treatment [351].

3.4.8.4 Stone composition

Stones composed of brushite, calcium oxalate monohydrate, or cystine are particularly hard, as well as homogeneous stones with a high density on NCCT [46, 352]. Percutaneous nephrolithotomy or RIRS and URS are alternatives for removal of large SWL-resistant stones.

3.4.8.5 Contraindications of procedures

Contraindications of extracorporeal SWL

There are several contraindications to the use of extracorporeal SWL, including:
- pregnancy, due to the potential effects on the foetus [353];
- bleeding disorders, which should be compensated for at least 24 hours before and 48 hours after treatment [354];
- uncontrolled UTIs;
- severe skeletal malformations and severe obesity, which prevent targeting of the stone;
- arterial aneurism in the vicinity of the stone [355];
- anatomical obstruction distal to the stone.

Contraindications of URS

Apart from general problems, for example with general anaesthesia or untreated UTIs, URS can be performed in all patients without any specific contraindications.

Contraindications of PNL

Patients receiving anti-coagulant therapy must be monitored carefully pre- and post-operatively. Anti-coagulant therapy must be discontinued before PNL [346]. Other important contraindications include:
- untreated UTI;
- tumour in the presumptive access tract area;
- potential malignant kidney tumour;
- pregnancy (Section 3.4.14.1).
General contraindication for endourological procedures
Endourological interventions do not adversely affect renal function although care must be taken in those with poor pre-operative renal function, diabetes and hypertension [356]. However, a meta-analysis, based on low-quality evidence, suggests that patients with impaired renal function and stone disease, may in fact benefit from the procedure to preserve or increase their renal function [357].

3.4.9 Specific stone management of ureteral stones
3.4.9.1 Conservative treatment/observation
There are only limited data regarding spontaneous stone passage according to stone size [358]. It is estimated that 95% of stones up to 4 mm pass within 40 days [206].

Based on an analysis of available evidence, an exact cut-off size for stones that are likely to pass spontaneously cannot be provided [206].

Spontaneous stone passage was reported for 49% of upper ureteral stones, 58% of mid ureteral stones and 68% of distal ureteral stones. Considering stone size almost 75% of stones < 5 mm and 62% of stones ≥ 5 mm passed spontaneously, with an average time to stone expulsion about 17 days (range 6-29 days) [359]. The Panel is aware of the fact that spontaneous stone expulsion decreases with increasing stone size and that there are differences between individual patients.

According to a number of RCT based meta-analysis sexual intercourse has been reported to be beneficial in facilitating stone expulsion in men with distal ureteral stones and be comparable to MET [360-362].

3.4.9.2 Pharmacological treatment, medical expulsive therapy
Medical expulsive therapy should only be used in informed patients if active stone removal is not indicated. Treatment should be discontinued if complications develop (infection, refractory pain, deterioration of renal function). In case of known uric acid stones in the distal ureter, a combination of alkalinisation with tamsulosin can increase the frequency of spontaneous passage. For details see Sections 3.4.3 and 3.4.4.

3.4.9.3 Indications for active removal of ureteral stones
Indications for active removal of ureteral stones are [206, 358, 363]:
- stones with a low likelihood of spontaneous passage;
- persistent pain despite adequate analgesic medication;
- persistent obstruction;
- renal insufficiency (renal failure, bilateral obstruction, or single kidney).

3.4.9.4 Selection of procedure for active removal of ureteral stones
Overall, SFRs after URS or SWL for ureteral stones are comparable. However, larger stones achieve earlier stone-free status with URS.

A large multi-center non-inferiority trial compared URS to ESWL for ureteral stones. When excluding patients that had spontaneously passed their stone prior to treatment, ESWL could not be considered non-inferior to URS with only 12% of patients needing further intervention after URS in comparison to 26% in the SWL arm [364]. In the current endourological era, the complication rate and morbidity of URS has been significantly reduced [365]. It has been demonstrated that URS is a safe option in obese patients (BMI > 30 kg/m²) with comparable SFRs and complication rates. However, in morbidly obese patients (BMI > 35 kg/m²) the overall complication rates double [366].

The Panel performed a systematic review to assess the benefits and harms of URS compared to SWL [367]. Compared with SWL, URS was associated with a significantly greater SFR of up to four weeks, but the difference was not significant at three months in the included studies. Ureteroscopy was associated with fewer retreatments and need for secondary procedures, but with a higher need for adjunctive procedures, greater complication rates and longer hospital stay. Counterbalancing for URS's higher SFRs, SWL is associated with lower morbidity. Success rates and complications of URS are not impacted by previous unsuccessful SWL [368]. Clavien-Dindo grade complications were, if reported, less frequent in patients treated with SWL [369].

Bleeding disorder
Ureteroscopy can be performed in patients with bleeding disorders, with a moderate increase in complications (see also Section 3.4.8.2) [346].

3.4.10 **Specific stone management of renal stones**

The natural history of small, non-obstructing asymptomatic calculi is not well defined, and the risk of progression is unclear. There is still no consensus on the follow-up duration, timing, and type of intervention. Treatment options are chemolysis or active stone removal.

3.4.10.1 **Conservative treatment (observation)**

Observation of renal stones, especially in calyces, depends on their natural history (Section 3.4.10.3). The recommendations provided are not supported by high-level literature [370]. There is a prospective trial supporting annual observation for asymptomatic inferior calyceal stones, < 10 mm. In case stone growth is detected, the follow-up interval should be lowered. Intervention is advised for growing stones > 5 mm [371]. In a systematic review of patients with asymptomatic renal stones on active surveillance spontaneous stone passage rates varied from 3-29%, symptom development from 7-77%, stone growth from 5-66%, surgical intervention from 7-26% [370], respective risk of symptomatic episodes ranged from 0-59.4% [372].

3.4.10.2 **Pharmacological treatment of renal stones**

Dissolution of stones through pharmacological treatment is an option for uric acid stones only, but information on the composition of the stone will need to guide the type of treatment selected. See sections 3.4.4. and 3.4.8.4.

3.4.10.3 **Indications for active stone removal of renal stones**

Indications for the removal of renal stones, include:

- stone growth;
- stones in high-risk patients for stone formation;
- obstruction caused by stones;
- infection;
- symptomatic stones (e.g., pain or haematuria) [373];
- stones > 15 mm;
- stones < 15 mm if observation is not the option of choice;
- patient preference;
- comorbidity;
- social situation of the patient (e.g., profession or travelling);
- choice of treatment.

The risk of a symptomatic episode or need for intervention in patients with asymptomatic renal stones seems to be ~10-25% per year, with a cumulative five-year event probability of 48.5% [371, 372, 374, 375]. A prospective RCT with more than two years clinical follow-up reported no significant difference between SWL and observation when comparing asymptomatic calyceal stones < 15 mm in terms of SFR, symptoms, requirement for additional treatment, quality of life (QoL), renal function, or hospital admission [376]. Although some have recommended prophylaxis for these stones to prevent renal colic, haematuria, infection, or stone growth, conflicting data have been reported [375, 377, 378]. In a follow-up period of almost five years after SWL, two series have demonstrated that up to 25% of patients with small residual fragments needed treatment [215, 379]. Although the question of whether calyceal stones should be treated is still unanswered, stone growth, de novo obstruction, associated infection, and acute and/or chronic pain are indications for treatment [373, 380, 381]. There is some evidence that external physical vibration lithocole (EPVL) after SWL and RIRS results in higher SFRs [203].

3.4.10.4 **Selection of procedure for active removal of renal stones**

For general recommendations and precautions see Section 3.4.8.

3.4.10.4.1 Stones in renal pelvis or upper/middle calyces

Shock wave lithotripsy, PNL and RIRS are available treatment modalities for renal calculi. While PNL efficacy is hardly affected by stone size, the SFRs after SWL or URS are inversely proportional to stone size [364, 382-388]. Although multiple treatments or sessions may be needed SWL achieves good SFRs for stones up to 20 mm, except for those at the lower pole [384, 389, 390]. Endourology is considered an alternative because of the reduced need for repeated procedures and consequently a shorter time until stone-free status is achieved. For stones > 10 mm, mini-PNL (mPNL) achieves a higher SFR than RIRS or ESWL, but carries a higher risk of bleeding and is associated with a longer hospital stay; however, there is a high degree of heterogeneity among the included studies [386, 388]. Stones > 20 mm should be treated primarily by PNL, because SWL often requires multiple treatments, and is associated with an increased risk of ureteral obstruction (colic or steinstrasse) with a need for adjunctive procedures (Figure 3.2) [204]. Retrograde renal surgery cannot be recommended as first-line treatment for stones > 20 mm in uncomplicated cases as SFRs decrease, and
staged procedures will be required [391-393]. However, it may be a first-line option in patients where PNL is not an option or contraindicated or in selected patients [394]. The combination of PNL and RIRS may be a good alternative for the treatment of complex renal stones compared to standard PNL; however, the level of the existing evidence is low [295].

3.4.10.4.2 Stones in the lower renal pole
The stone clearance rate after SWL seems to be lower for stones in the inferior calyx than for other intra-renal locations. Although the disintegration efficacy of SWL is not limited compared to other locations, the fragments often remain in the calyx and cause recurrent stone formation. The reported SFR of SWL for lower pole calculi is 25-95%. The preferential use of endoscopic procedures is supported by some current reports, even for stones < 1 cm [204, 382, 383, 385, 389, 393, 395-407].

The following can impair successful stone treatment by SWL [397, 408-413]:
- steep infundibular-pelvic angle;
- long calyx;
- long skin-to-stone distance;
- narrow infundibulum;
- shock wave-resistant stones (calcium oxalate monohydrate, brushite, or cystine).

Further anatomical parameters cannot yet be established. Supportive measures such as inversion, vibration or hydration may facilitate stone clearance (See 3.4.5 ESWL) [201, 203, 414]. If there are negative predictors for SWL, PNL and RIRS might be reasonable alternatives, even for smaller calculi [395]. Retrograde renal surgery seems to have comparable efficacy to SWL [204, 383, 389, 415]. Recent clinical experience has suggested a higher SFR of RIRS compared to SWL, but at the expense of greater invasiveness. Depending on operator skills, stones up to 3 cm can be treated by RIRS [237, 416-418]. However, staged procedures are frequently required. Although mPNL has the highest success rate for the treatment of lower pole stones up to 2 cm, it comes at the expense of a higher complication rate and longer hospital stay [388]. In complex stone cases, open or laparoscopic approaches are possible alternatives although they are infrequently used.

3.4.11 Laparoscopy and open surgery

Advances in SWL and endourological surgery (URS and PNL) have significantly decreased the indications for open or laparoscopic stone surgery [419-424]. There is a consensus that most complex stones, including partial and complete staghorn stones, should be approached primarily with PNL. Additionally, a combined approach with PNL and RIRS may also be an appropriate alternative. However, if percutaneous approaches are not likely to be successful, or if multiple endourological approaches have been performed unsuccessfully; open or laparoscopic surgery may be a valid treatment option [425-431].

Few studies have reported laparoscopic stone removal. These procedures are usually reserved for special cases. When expertise is available, laparoscopic ureterolithotomy can be performed for large proximal ureteral stones as an alternative to URS or SWL [432, 433]. These more invasive procedures have yielded high SFRs and lower auxiliary procedure rates [230, 241, 434]. A recent systematic review showed no difference in the post-operative phase for stented or unstented laparoscopic ureterolithotomy [434].

Laparoscopic pyelolithotomy could be offered for solitary stones > 2cm located in renal pelvis as an alternative to PNL [435]. In addition, in selected cases with an extrarenal and dilated pelvis, retroperitoneal laparoscopic pyelolithotomy (RLP) can be considered as an alternative management of staghorn calculi [436].

A few studies with limited numbers of patients have reported using robotic surgery in the treatment of urinary stones [437]. Open surgery should be considered as the last treatment option, after all other possibilities have been explored.

Studies on laparoscopy should be interpreted with caution due to their poor design and low quality of evidence.

---

*The term ‘Endourology’ encompasses all PNL and URS interventions.
PNL = percutaneous nephrolithotomy; RIRS = retrograde intrarenal surgery; SWL = shock wave lithotripsy; URS = ureteroscopy.

3.4.12 Steinstrasse

Steinstrasse is an accumulation of stone fragments or stone gravel in the ureter and may interfere with the passage of urine [438]. Steinstrasse occurs in 4-7% cases of SWL [225], and the major factor in the development of steinstrasse formation is stone size [439].

A major problem of steinstrasse is ureteral obstruction, which may be silent in up to 23% of cases. A MA including eight RCTs (n = 876) suggested a benefit of stenting before SWL in terms of steinstrasse formation, but did not result in a benefit on SFRs or less auxiliary treatments [154]. When steinstrasse is asymptomatic, conservative treatment is an initial option. Medical expulsion therapy increases stone expulsion and reduces the need for endoscopic intervention [440, 441]. Ureteroscopy and SWL are effective in treatment of steinstrasse [227, 442]. In the event of UTI or fever, the urinary system should be decompressed, preferably by percutaneous nephrostomy [125, 129].

3.4.13 Management of patients with residual stones

Following initial treatment with SWL, URS or PNL, residual fragments may remain and require additional intervention [372, 379, 443-445]. Most of the studies indicate that initial imaging is performed on the first day or the first week after treatment. However, false positive results from dust or residual fragments, that will pass spontaneously without causing any stone-related event, might lead to over-treatment. Therefore, imaging at four weeks seems most appropriate [446-448]. Compared to US, KUB and IVU, NCCT scan has a higher sensitivity to detect small residual fragments after definitive treatment of ureteral or kidney stones [449, 450]. However, more than half of the patients with a residual fragment on NCCT images may not experience a stone-related event [451].

It is clear that NCCT has the highest sensitivity to detect residual fragments; however, this must be balanced against the increased detection of clinically insignificant fragments and the exposure to ionising radiation when compared with KUB and US. In the absence of high-level supporting evidence, the timing of follow-up imaging studies and need for secondary intervention is left to the discretion of the treating physician. Recurrence risk in patients with residual fragments after treatment of infection stones is higher than for other stones [452]. For all stone compositions, 21-59% of patients with residual stones required treatment within five years. Fragments > 5 mm are more likely than smaller ones to require intervention [215, 372, 445, 453, 454]. There is evidence that fragments > 2 mm are more likely to grow, although this is not associated with increased re-intervention rates at one year follow up [443].

3.4.14 Management of specific patient groups

3.4.14.1 Management of urinary stones and related problems during pregnancy

Clinical management of a pregnant urolithiasis patient is complex and demands close collaboration between patient, radiologist, obstetrician, and urologist [70]. For diagnostic imaging see Section 3.3.1. Patients with urolithiasis may be at increased risk of developing adverse maternal or neonatal outcomes [455].

If spontaneous passage does not occur, or if complications develop (e.g., intractable symptoms, severe hydronephrosis, spontaneous renal fornix rupture [456] or induction of premature labour), placement of a ureteral stent or a percutaneous nephrostomy tube is necessary as it is more effective than conservative treatment for symptom relief [127, 457, 458].

Unfortunately, these temporising therapies are often associated with poor tolerance, and they require multiple exchanges during pregnancy, due to the potential for rapid encrustation [459].

Ureteroscopy has become a reasonable alternative in these situations [448, 460]. When compared to temporary ureteral JJ stenting until after delivery, ureteroscopy resulted in reduced need for stent exchanges, less irritative lower urinary tract symptoms and better patient satisfaction [461, 462].

Non-urgent ureteroscopy in pregnant women is best performed during the second trimester, by an experienced urologist. Counselling of the patient should include access to neonatal and obstetric services [78].

Although feasible, percutaneous removal of renal stones during pregnancy remains an individual decision and should be performed only in experienced centres [463]. Pregnancy remains an absolute contraindication for SWL.

3.4.14.2 Management of stones in patients with urinary diversion

**Aetiology**

Patients with urinary diversion are at high risk for stone formation in the renal collecting system and ureter or in the conduit or continent reservoir [464, 465]. Metabolic factors (hypercalciuria, hyperoxaluria and hypocitraturia), infection with urease-producing bacteria, foreign bodies, mucus secretion, and urinary stasis are responsible for stone formation [466] (section 3.1.3). One study has shown that the risk for recurrent upper tract stones in patients with urinary diversion subjected to PNL was 63% at five years [467].
Management
Smaller upper-tract stones can be treated effectively with SWL [234, 468]. In the majority of cases, endourological techniques are necessary to achieve stone-free status [232]. In individuals with long, tortuous conduits or with invisible ureter orifices, a retrograde endoscopic approach might be difficult or impossible [469].

For stones in the conduit, a trans-stomal approach can be used to remove all stone material (along with the foreign body) using standard techniques, including intracorporeal lithotripsy and flexible endoscopes. Trans-stomal manipulations in continent urinary diversion must be performed carefully to avoid disturbance of the continence mechanism [470].

Before considering any percutaneous approach in these cases, CT should be undertaken to assess the presence of overlying bowel, which could make this approach unsafe [471], and if present, an open surgical approach should be considered.

Prevention
Recurrence risk is high in these patients [467]. Metabolic evaluation and close follow-up are necessary to obtain the risk parameters for effective long-term prevention. Preventive measures include medical management of metabolic abnormalities, appropriate therapy of urinary infections, and hyperdiuresis or regular irrigation of continent reservoirs [472].

3.4.14.3 Management of stones in patients with neurogenic bladder

Aetiology, clinical presentation and diagnosis
Patients with neurogenic bladder develop urinary calculi because of additional risk factors such as bacteriuria, hydronephrosis, VUR, renal scarring and lower urinary tract reconstruction [473]. The most common causes are urinary stasis and infection (Section 3.1.3). Indwelling catheters and surgical interposition of bowel segments for treatment of bladder dysfunction both facilitate UTI. Although calculi can form at any level of the urinary tract, they occur more frequently in the bladder; especially if bladder augmentation has been performed [474, 475].

Diagnosis of stones may be difficult and delayed in the absence of clinical symptoms due to sensory impairment and vesico-urethral dysfunction. Difficulties in self-catheterisation should lead to suspicion of bladder calculi. Imaging studies are needed (US, CT) to confirm the clinical diagnosis prior to surgical intervention.

Management
Management of calculi in patients with neurogenic bladder is similar to that described in Section 3.3.3. In myelomeningocele patients, latex allergy is common; therefore, appropriate measures need to be taken regardless of the treatment [476]. Any surgery in these patients must be performed under general anaesthesia because of the impossibility of using spinal anaesthesia. Bone deformities often complicate positioning on the operating table [477]. The risk of stone formation after augmentation cystoplasty in immobile patients with sensory impairment can be significantly reduced by irrigation protocols [472].

For efficient long-term stone prevention in patients with neurogenic bladder, correction of the metabolic disorder, appropriate infection control, and restoration of normal storing/voiding function of the bladder are needed.

3.4.14.4 Management of stones in patients with transplanted kidneys

Stones in transplanted kidneys can either be transplanted or present de novo allograft stones. Usually they are detected by routine US examination, followed by NCCT in cases of unclear diagnosis [478].

**Aetiology**

Transplant patients depend on their solitary kidney for renal function. Impairment causing urinary stasis/obstruction therefore requires immediate intervention or drainage of the transplanted kidney. Stones in kidney allografts have an incidence of 1% [479]. Risk factors for de novo stone formation in these patients are multi-fold:

- Immunosuppression increases the infection risk, resulting in recurrent UTIs.
- Hyper-filtration, excessively alkaline urine, renal tubular acidosis (RTA), and increased serum calcium caused by persistent tertiary hyperparathyroidism [480] are biochemical risk factors.

**Management**

Selecting the appropriate technique for stone removal in a transplanted kidney is difficult, although management principles are similar to those applied in other single renal units [481-483]. Additional factors such as transplant function, coagulative status, and anatomical obstacles due to the iliacal position of the organ, directly influence the surgical strategy.

For large or ureteral stones, careful percutaneous access and subsequent antegrade endoscopy are more favourable. The introduction of small flexible ureteroscopes and the holmium laser has made URS a valid treatment option for transplant calculi; however, one must be aware of potential injury to adjacent organs [482, 484, 485]. Retrograde access to transplanted kidneys is difficult due to the anterior location of the ureteral anastomosis, and ureteral tortuosity [486-488]. Treatment of donor stones may be needed pre-transplant and increases the pool available for renal transplants. Post-transplant stone disease may also need treatment to maintain the allograft function. A systematic review evaluating the outcomes of pre- vs. post-transplant URS demonstrated a 100% SFR with an overall 7.5% complication rate, compared to SFR of 60-100% with an overall complication rate of 12.9% for post-transplant URS; most complications were Clavien 1 [489].

### 3.4.15 Management of stones in children

The true incidence of nephrolithiasis in children remains unclear due to the global lack of large epidemiological studies. Data derived from nation-wide epidemiological studies, studies performed in different counties worldwide [504] and large-scale databases [505, 506] indicate that the incidence and prevalence of paediatric urinary stone disease has increased over the last few decades. Although boys are most commonly affected in the first decade of life [507] the greatest increase in incidence has been seen in older female adolescences [504].

Stone composition is similar in children as in adults, with a predominance of calcium oxalate stones. Compared to historical data, metabolic abnormalities responsible for stone formation are less commonly identified in children nowadays [508-510]. Hypocitraturia, low urine volume and hypercalciuria predominate [87, 508-510]. Age may affect the predominant metabolic abnormality with hypercalciuria and hypocitraturia being the most common disorder present in children < 10 and > 10 years old, respectively [510]. Genetic or systemic diseases (e.g., cystinuria or nephrocalcinosis) contributing to stone formation are relatively frequent in children accounting for less than 17% of the identifying causes [508, 511]. The role of diet remains unclear in children, although there is some evidence that children are drinking less water and taking greater daily amounts of sodium than is recommended [512-514].

For diagnostic procedures see Section 3.3.3.2, for acute decompression see Section 3.4.2. and for metabolic evaluation see Chapter 4.

#### 3.4.15.1 Clinical presentation

Children with urinary stones can be asymptomatic or present with non-specific symptoms that necessitate a high index of suspicion for proper diagnosis. Symptoms are age-dependent with infants presenting with crying, irritability and vomiting in 40% of cases [515] while in older children flank pain, micro or gross haematuria and recurrent UTIs are more common [516].

#### 3.4.15.2 Conservative management

There is a lack of evidence on conservative management of paediatric stones with evidence for ureteric calculi coming from the placebo arms of medical expulsive trials, while evidence for renal stones comes from small cohort studies, either on primary stones [517, 518] or residual fragments remained after SWL, RIRS or PNL [519]. Expectant management for single, asymptomatic lower-pole renal stones could be the initial approach with increased odds of stone passage, especially in patients with non-struvite, non-cystine stones < 7 mm, with no anatomic abnormalities [517]. Intervention may be needed for stones located elsewhere independently of their size [517-519].
3.4.15.3 Medical expulsive therapy in children

There are limited studies on MET as off-label expulsive therapy for children with stones which show conflicting outcomes. A systematic review of six placebo-controlled studies showed that α-blockers might increase SFR of distal ureteric stones (RR: 1.34, 95% CI: 1.16 - 1.54) [520]. A recent MA of MET for distal ureteric stones including nine RCTs found that α-blockers could significantly increase the rate of stone expulsion, reduce the stone expulsion time, decrease pain episodes and analgesia demand, but had a higher incidence of side effects [521].

3.4.15.4 Extracorporeal shock wave lithotripsy

Shock wave lithotripsy is still the first-line treatment for most ureteral stones in children. However, it is less likely to be successful for stones > 10 mm in diameter, impacted stones, calcium oxalate monohydrate or cystine stones, or for stones in children with unfavourable anatomy and in whom localisation is difficult [522].

Studies on ESWL in children suggest an overall SFR of 70-90%, retreatment rate of 4-50% and need for auxiliary procedures in 4-12.5% of cases [523-527]. A MA of fourteen studies reporting on 1,842 paediatric patients treated with SWL found significantly higher SFR for stones < 10 mm than for stones > 10 mm and higher retreatment rates as the stone size increased [522]. For best clinical practice see Section 3.4.5. A recent MA on slow SWL vs. rapid SWL for renal stones revealed very low-quality evidence about the effects of SWL on SFRs, serious adverse events or complications of treatment and secondary procedures for residual fragments [520]. Shock wave lithotripsy is well tolerated; however, good treatment outcomes are more likely to require the administration of general anaesthesia to children. With improvements in modern (second and third generation) lithotripters, successful treatment using intravenous sedation, patient-controlled analgesia or no medication at all has been increasingly performed in a select population of older, co-operative children [528].

Based on the results of a recent MA which compared SWL to dissolution therapy for intra-renal stones, and SWL to ureteroscopy with holmium laser or pneumatic lithotripsy for renal and distal ureteric stones, no firm conclusions can be drawn about the effects of SWL on SFR, serious adverse events or complications of treatment and secondary procedures for residual fragments [520]. When SWL was compared to mPNL for lower pole renal stones 1-2 cm in size SWL resulted in lower SFRs (RR: 0.88, 95% CI: 0.80 - 0.97; moderate-quality evidence) and higher rates of secondary procedures (RR: 2.50, 95% CI: 1.01 - 6.20; low-quality evidence); however, SWL showed less severe adverse events (RR: 0.13, 95% CI: 0.02 - 0.98; low quality evidence) [529].

3.4.15.5 Endourological procedures

Rigid/semi-rigid ureteroscopy

In recent years ureteroscopy is increasingly used in children with ureteral stones [530]. Ureteroscopy proved to be effective with SFR of 81-98% [531-533], retreatment rates of 6.3%-10% [534] and complication rates of 1.9-23% [531-533, 535]. Similar to adults, routine stenting is not necessary before URS. Pre-stenting may facilitate URS, increase SFR and decrease complication rates [536, 537].

Flexible ureteroscopy/retrograde intrarenal surgery

Retrograde intra-renal surgery with flexible ureteroscopes (FURS) has become an efficacious treatment modality for paediatric renal stones. Recent studies report SFRs of 76-100%, retreatment rates of 0-19% and complication rates of 0-28% [538-541]. Younger age, cystine composition [542], large stone diameter [541] and lack of pre-stenting predispose to FURS failure in children [536]. A large global study across eight centres show a SFR of 75.5%; although, complications were minor, they were higher in patients < 5 years of age [543].

Although high-level evidence is lacking to support a strong recommendation [520], FURS may be a particularly effective treatment option for lower calyceal stones in the presence of unfavourable factors for SWL [533, 539, 544].

For large and complex kidney stones RIRS has a significantly lower SFR compared to PNL (71% vs. 95%), but is associated with less radiation exposure, lower complication rates and a shorter hospital stay [545]. Similarly, retrospectively data indicate that RIRS may achieve lower SFRs compared to minor micropercutaneous surgery in favour of shorter operative time, shorter fluoroscopy time, and less hospitalisation time [546, 547]. A recently published MA confirmed these results [548].

Percutaneous nephrolithotomy

Indications for PNL in children are similar to those in adults, and include renal stones > 2 cm, or smaller stones resistant to SWL and ureteroscopic treatment. Reported SFRs with paediatric PNL are 71.4-95% after a single session [545-547, 549, 550] with an overall complication rate of 20% [551]. High degree of hydronephrosis, increased number of tracts and operative time [552] and large tract size [550, 553-555] are associated with
increased blood loss. Child age and stone burden predispose to the use of larger instruments during PNL in children. Miniaturisation of equipment increases the opportunity to perform tubeless PNL in appropriately selected children, which can reduce the length of hospital stay and post-operative pain, respectively, with no conversions to standard PNL, and a complication rate of 19%, with a mean transfusion rate of 3.3% [543].

Concerns have been raised regarding possible adverse effects of PNL on the renal parenchyma of the developing child. However, focal damage is only reported in 5% of cases [558]. Using pre- and post-PNL dimercaptosuccinic acid (DMSA) scans, Cicekbilek et al. demonstrated that PNL tracts between 12-24 Charrière in size did not cause significant harm to paediatric kidneys [549].

### 3.4.15.6 Open and laparoscopic/robot-assisted stone surgery

With the advances in ESWL, PNL and RIRS, very few cases of paediatric urolithiasis require open surgery. Data extracted from the National Inpatient Sample (NIS) databases for 2001-2014 showed that in the USA incisional procedures (mainly nephrolithotomy, pyelolithotomy and ureterotomy) were performed in 2.6% of hospitalised patients (52% aged 15-17 years) who required surgical intervention for urinary stones [559]. Laparoscopy for the management of paediatric renal and ureteric stones is a safe and effective procedure when specific indications are followed. Stone free rates of 100% were reported when laparoscopic pyelolithotomy was applied for a > 1cm single stone located in an extra-renal pelvis [560], or when laparoscopic ureterolithotomy was applied to impacted ureteric stones ≥1.5 cm, or to ureteric stones that were refractory to SWL or URS [561]. There are extremely limited data available on efficacy and complications of robot-assisted laparoscopic management of paediatric urolithiasis [562].

### 3.4.15.7 Special considerations on recurrence prevention

All paediatric stone formers need metabolic evaluation and recurrence prevention with respect to the detected stone type. Children are in the high-risk group for stone recurrence (See Chapter 4).

### 3.5 Radiation exposure and protection during endourology

The diagnosis and treatment of nephrolithiasis is associated with high levels of ionising radiation exposure to patients [563, 564]. Currently, there are no studies estimating the lifetime radiation exposure of stone formers or the subsequent risk of malignancy development. The radiation exposure of endourologists has been extensively studied. Still, there are no studies assessing the risk of radiation induced malignancies in urologists or operating theatre staff members [565-567].

Current evidence from atomic bomb patients [568, 569], retrospective epidemiological data on medical exposure [570, 571] and modelling studies [572, 573] suggest an age and dose dependent risk of secondary malignancy from ionising radiation.
The International Commission on Radiological Protection (ICRP) recommends a maximum annual occupational exposure of 50mSv [574]. However, the risk of radiation induced malignancy follows a stochastic model having no known safe threshold of exposure. Taking this into consideration as well as the length of a urologists career the upper limit of 50mSv is still highly concerning.

Table 3.12 shows the EAU Urolithiasis guidelines panel recommended protection methods to reduce radiation exposure to patients, surgical, anaesthesiologic and nursing staff.

<table>
<thead>
<tr>
<th>Table 3.12 Radiation protection measures</th>
</tr>
</thead>
<tbody>
<tr>
<td>• Limit studies or intervention involving radiation exposure to those that are strictly medically necessary.</td>
</tr>
<tr>
<td>• Implement a patient electronic record of medical imaging.</td>
</tr>
<tr>
<td>• Make use of imaging studies with lower radiation doses (US, KUB, digital tomosynthesis, low-dose and ultra-low dose CT scan).</td>
</tr>
<tr>
<td>• Create and follow a precise radiation exposure protection protocol in your department.</td>
</tr>
<tr>
<td>• Act in accordance with the as low as reasonably achievable (ALARA) principle.</td>
</tr>
<tr>
<td>• Measure and report fluoroscopy time to the operative surgeon (use dosimeters and perform monthly calculations).</td>
</tr>
</tbody>
</table>

- Technical measures to reduce radiation exposure include:
  - Reducing fluoroscopy time;
  - Limiting time adjacent to patient;
  - Using low-dose radiation;
  - Irradiating only to observe motion;
  - Intra-operative use of pulsed fluoroscopy;
  - Reduced fluoroscopy pulse rate;
  - Collimated fields;
  - Avoid digital image acquisition and rely on last image hold and instant replay technology.

- Use radiation protection instruments (chest, pelvic and thyroid shields, lead or lead-free gloves, protective glasses, lead protection under the operating table between the x-ray source and the surgeon).

- The radiation protection instruments must be cared for appropriately as any damage decreases effectiveness and increases exposure risk. They should be monitored and measured regularly to ensure integrity.

- Proper surgeon and operating room setup should be observed (follow the inverse square law, use the X-ray source underneath the patient’s body, decrease the X-ray source to patient distance, reduce magnification, avoid field overlap by not turning the C-arm in extreme angles, operate in the standing rather than the seated position).

Availability of fluoroscopy is mandatory for endourological procedures. There is an increasing interest on fluoroless and fluoroscopy-free operations in urology. Several RCTs have been published showing a good outcome in means of stone free and complication rates [183, 300, 575-577]. These trials have been limited to non-complex cases and they were not sufficiently powered to show non-inferiority of fluoroscopy in PNL [300, 565] or superiority of ultrasound in URS [249, 250].

4. METABOLIC EVALUATION AND RECURRENCE PREVENTION

4.1 General metabolic considerations for patient work-up

4.1.1 Evaluation of patient risk

After stone passage, every patient should be assigned to a low- or high-risk group for stone formation (Figure 4.1). For correct classification, two items are mandatory:

- reliable stone analysis by infrared spectroscopy or X-ray diffraction;
- basic analysis (Section 3.3.2).
Only high-risk stone formers require specific metabolic evaluation. Stone type is the deciding factor for further diagnostic tests. The different stone types include:

- calcium oxalate;
- calcium phosphate;
- uric acid;
- ammonium urate;
- struvite (and infection stones);
- cystine;
- xanthine;
- 2,8-Dihydroxyadenine;
- drug stones;
- stones of unknown composition.

Figure 4.1: Assignment of patients to low- or high-risk groups for stone formation

4.1.2 Urine sampling

Specific metabolic evaluation requires collection of two consecutive 24-hour urine samples [69, 578, 579]. The collecting bottles should be prepared with 1 g thymol per litre or stored at < 8°C during collection to reduce bacterial proliferation [69]. Pre-analytical errors can be minimised by carrying out urinalysis immediately after collection. Alternatively, boric acid (10 g powder per urine container) can also be used, but this prevents the correct determination of pH [69]. The collecting method should be chosen in close cooperation with the laboratory. A pH < 5.5 in a 24-hour urine indicates hyper acidic urine (acidic arrest) [580-582]. During therapy urine pH should be assessed during collection of freshly voided urine at different times throughout the day using sensitive pH-dipsticks or a pH-meter [27, 69, 583]. A urine pH on 24-hr collection > 6.2 is suspicious for
distal RTA [584]. A consensus statement from Gambaro et al., stated that RTA is suspected if 24-hr urine pH is > 6.2 and fasting second morning spot urine pH is > 5.8 [585].

Spot urine samples are an alternative method of sampling, particularly when 24-hour’s urine collection is difficult, for example, in non-toilet trained children [586]. Spot urine studies normally link the excretion rates to creatinine [587], but these are of limited use because the results may vary with collection time and patients’ sex, body weight and age.

4.1.3 **Timing of specific metabolic work-up**

For the initial specific metabolic work-up, the patient should stay on a self-determined diet under normal daily conditions and should ideally be stone free for at least twenty days [588]. Follow-up studies are necessary in patients taking medication for recurrence prevention [589]. The first follow-up 24-hour urine measurement is suggested eight to twelve weeks after starting pharmacological prevention of stone recurrence. This enables drug dosage to be adjusted if urinary risk factors have not normalised, with further 24-hour urine measurements, if necessary. Once urinary parameters have been normalised, it is sufficient to perform 24-hour urine evaluation every twelve months. On this issue the Panel realise that there is only very limited published evidence.

4.1.4 **Reference ranges of laboratory values**

Tables 4.1-4.4 provide the internationally accepted reference ranges for the different laboratory values in serum and urine.

**Table 4.1: Normal laboratory values for blood parameters in adults** [27, 589]

<table>
<thead>
<tr>

</tbody>
</table>

BE = base excess (loss of buffer base to neutralise acid); HCO₃ = bicarbonate; pCO₂ = partial pressure of carbon dioxide; pO₂ = partial pressure of oxygen.

4.1.5 **Risk indices and additional diagnostic tools**

Several risk indices have been developed to describe the crystallisation risk for calcium oxalate or calcium phosphate in urine [590-593]. However, clinical validation of these risk indices for recurrence prediction or therapy improvement is ongoing.

**Table 4.2: Laboratory values for urinary parameters in adults**

**4.2 General considerations for recurrence prevention**

All stone formers, independent of their individual risk, should follow the preventive measures in Table 4.5. The main focus is normalisation of dietary habits and lifestyle risks. Stone formers at high risk need specific prophylaxis for recurrence, which is usually pharmacological treatment based on stone analysis and urinary risk profile.

**Table 4.5: General preventive measures**

### Nutritional advice for a balanced diet

- **Balanced diet**:
  - Rich in vegetables and fibre
  - Normal calcium content: 1-1.2 g/day
  - Limited NaCl content: 4-5 g/day
  - Limited animal protein content: 0.8-1.0 g/kg/day

### Lifestyle advice to normalise general risk factors

- **BMI**: Retain a normal BMI level
- **Adequate physical activity**
- **Balancing of excessive fluid loss**
- **Reduce the intake of alcohol containing fluids**
- **Reduce the intake of sodas and calorie-containing fluids**

*Avoid excessive consumption of vitamin supplements.*

**4.2.1 Fluid intake**

An inverse relationship between high fluid intake and stone formation has been repeatedly demonstrated [596-600]. The beneficial effect of fruit juices is mainly determined by the presence of citrate or bicarbonate [601]. Citrus fruit juices seem to protect against stone disease either by increasing urinary citrate levels or by having an alkalinising effect on it [602]. However, if potassium is present, both pH and citrate are increased [603, 604]. One large moderate quality RCT randomly assigned men with more than one past renal stone of any type and soft drink consumption of at least 160 mL/day to reduced soft drink intake or no treatment. Although the intervention significantly reduced the risk for symptomatic recurrent stones (RR: 0.83; CI: 0.71-0.98), the level of evidence for this outcome is low because results were from only one trial [605]. An analysis on the 3 Channing’s cohorts (194,095 participants) over a median follow-up of more than eight years has shown that consumption of sugar-sweetened soda and punch is associated with a higher risk of stone formation, whereas consumption of coffee, tea, beer, wine, and orange juice is associated with a lower risk [606], whereas consumption of tea and coffee does not seem to increase the risk of stones disease [607]. However, the intake of fluids should be considered within a holistic approach to health. Some of them contain calories or alcohol that may be detrimental to health. Therefore, water should be the preferred fluid.

**4.2.2 Diet**

A common-sense approach to diet should be taken, that is, a mixed, balanced diet with contributions from all food groups, without any excesses [597, 608, 609]. Sufficient calcium intake is needed, especially in vegetarian and vegan diets [610].

**Fruit, vegetables and fibre:** Fruit and vegetable intake should be encouraged because of the beneficial effects of fibre, although the role of the latter in preventing stone recurrences is debatable [611-614]. The alkaline content of a vegetarian diet also increases urinary pH. In addition, fruit and vegetables have a high water content and can significantly contribute to fluid intake.

**Oxalate:** Excessive intake of oxalate-rich products should be limited or avoided to prevent high oxalate load [615], particularly in patients who have high oxalate excretion.

**Vitamin C:** Although vitamin C is a precursor of oxalate, its role as a risk factor in calcium oxalate stone formation remains controversial [616]. However, it seems wise to advise calcium oxalate stone formers to avoid excessive intake.

**Animal protein:** Animal protein should not be consumed in excess [617, 618] and limited to 0.8-1.0 g/kg body weight. Excessive consumption of animal protein has several effects that favour stone formation, including hypocitraturia, low urine pH, hyperoxaluria and hyperuricosuria.

**Calcium intake:** Calcium should not be restricted, unless there are strong reasons for doing so, due to the inverse relationship between dietary calcium and stone formation [612, 619]. The daily requirement for calcium is 1,000 to 1,200 mg [27]. Calcium supplements are not recommended except in enteric hyperoxaluria, when additional calcium should be taken with meals to bind intestinal oxalate [597, 615, 617, 620]. Older adults who do not have a history of renal stones but who take calcium supplements should ensure adequate fluid intake since it may prevent increases in urine calcium concentration, and thereby reduce or eliminate any increased risk of renal stones formation associated with calcium supplement use [621].
Sodium: Daily sodium (NaCl) intake should not exceed 3-5 g [27]. High intake adversely affects urine composition:
- calcium excretion is increased by reduced tubular re-absorption;
- urinary citrate is reduced due to loss of bicarbonate;
- increased risk of sodium urate crystal formation.

Calcium stone formation can be reduced by restricting sodium and animal protein [617, 618]. A positive correlation between sodium consumption and risk of first-time stone formation has been confirmed only in women [619]. There have been no prospective clinical trials on the role of sodium restriction as an independent variable in reducing the risk of stone formation.

Urate: Intake of purine-rich food should be restricted in patients with hyperuricosuric calcium oxalate [622, 623] and uric acid stones. Intake should not exceed 500 mg/day [27].

4.2.3 Lifestyle
Lifestyle factors may influence the risk of stone formation, for example, those causing obesity [624], diabetes mellitus [625], and metabolic syndrome [626].

4.3 Stone-specific metabolic evaluation and pharmacological recurrence prevention

4.3.1 Introduction
Pharmacological treatment is necessary in patients at high risk for stone formation or for associated systemic conditions. The ideal drug should halt stone formation, have no side effects, and be easy to administer. Each of these aspects is important to achieve good compliance. Table 4.6 highlights the most important characteristics of commonly used medication.

* Patients on hydrochlorothiazides should be advised to get their skin checked on a regular basis as they have a higher risk of developing a non-melanoma skin cancer (NMSC) and some forms of melanoma. In patients with history of skin cancer the indication for the intake of hydrochlorothiazides should be thoroughly reviewed [661-663].

** No information is available on maximum dose and patients may be initiated on a very low dose if they have had previously had reactions to tiopronin or penicillamine. For all patients, dosage should be titrated according to frequency of stone episodes, side effects and renal function under expert supervision with close monitoring.

### 4.4 Calcium oxalate stones

The criteria for identification of calcium oxalate stone formers with high recurrence risk are listed in section 3.1.3.

#### 4.4.1 Diagnosis

Blood analysis requires measurement of creatinine, sodium, potassium, chloride, ionised calcium (or total calcium + albumin), phosphate, uric acid; and, in the case of increased calcium levels, parathyroid hormone (PTH) and vitamin D. Urinalysis requires measurement of urine volume, urine pH profile, specific weight, calcium, oxalate, uric acid, citrate, sodium and magnesium. Figure 4.2 summarises the diagnostic steps for calcium oxalate stones.
Figure 4.2: Diagnostic algorithm for calcium oxalate stones
4.4.2 Interpretation of results and aetiology

The most common metabolic abnormalities associated with calcium stone formation are hypercalciuria, which affects 30-60% of adult stone formers, and hyperoxaluria (26-67%), followed by hyperuricosuria (15-46%), hypomagnesuria (7-23%), and hypocitraturia (5-29%). However, ranges tend to differ based on ethnicity [664].

- Elevated levels of ionised calcium in serum (or total calcium and albumin) require assessment of intact PTH to confirm or exclude suspected hyperparathyroidism (HPT).
- Consistently low pH (< 5.5) or 24-hr urine pH < 5.5 may promote co-crystallisation of uric acid and calcium oxalate.
- Similarly, increased uric acid excretion (> 4 mmol/day in adults or > 12 mg/kg/day in children) can act as a promoter.
- A pH > 6.2 in a 24-hr urine collection may indicate RTA provided UTI has been excluded. An ammonium chloride loading test confirms RTA and identifies RTA subtype (Section 4.6.5).
- Hypercalciuria may be associated with normocalcemia (idiopathic hypercalciuria, or granulomatous diseases) or hypercalcaemia (hyperparathyroidism, granulomatous diseases, vitamin D excess, or malignancy).
- Hypocitraturia (male < 1.7 mmol/d, female < 1.9 mmol/d) may be idiopathic or secondary to metabolic acidosis or hypokalaemia.
- Oxalate excretion > 0.5 mmol/day in adults confirms hyperoxaluria (see Table 4.3 for the values in children).
  - primary hyperoxaluria (oxalate excretion mostly > 1 mmol/day), appears in three genetically determined forms;
  - secondary hyperoxaluria (oxalate excretion > 0.5 mmol/day, usually < 1 mmol/day), occurs due to intestinal hyperabsorption of oxalate or extreme dietary oxalate intake;
  - mild hyperoxaluria (oxalate excretion 0.45-0.85 mmol/day), commonly found in idiopathic calcium oxalate stone formers.
- Hypomagnesuria (< 3.0 mmol/day) may be related to poor dietary intake or to reduced intestinal absorption (chronic diarrhoea).
Figure 4.3: Therapeutic algorithm for calcium oxalate stones

1. Be aware of excess calcium excretion.
2. tid = three times/day (24h).
3. No magnesium therapy for patients with renal insufficiency.
4. There is no evidence that combination therapy (thiazide + citrate) or (thiazide + allopurinol) is superior to thiazide therapy alone [628, 665].
5. Febuxostat 80 mg/day.

* low evidence (see text)
** Calciuria is a continuous variable and treatment may be adjusted to clinical need even when below the threshold indicated.
*** Patients on hydrochlorothiazides should be advised to get their skin checked on a regular basis as they have a higher risk of developing a NMSC and some forms of melanoma. In patients with history of skin cancer the indication for the intake of hydrochlorothiazides should be thoroughly reviewed [661-663].

Hypocitraturia

Hypomagnesemia
4.4.3 **Specific treatment**

General preventive measures are recommended for fluid intake and diet. Hyperoxaluric stone formers should consume foods with low oxalate content, whereas hyperuricosuric stone formers benefit from daily dietary reduction of purine. Figure 4.3 summarises the pharmacological treatment of calcium oxalate stones [597, 604, 627-630, 633, 634, 636, 640, 643-645, 649-656, 664, 666-669]. There is only low-level evidence for the efficacy of preventing stone recurrence based on pre-treatment stone composition examination and biochemistry measures, or on-treatment biochemistry measures [597].

4.4.4 **Summary of evidence and recommendations for pharmacological treatments for patients with specific abnormalities in urine composition (based on 24-hour urine samples)**

4.5 **Calcium phosphate stones** [597, 627, 636, 649, 650, 654, 670]

Some calcium phosphate stone formers are at high risk of recurrence. Further information on identifying high-risk patients is provided in section 3.1.3.

Calcium phosphate mainly appears in two completely different minerals: carbonate apatite and brushite. Carbonate apatite crystallisation occurs at a pH > 6.8 and may be associated with infection. Brushite crystallises at an optimum pH of 6.5-6.8 at high urinary concentrations of calcium (> 8 mmol/day) and phosphate (> 35 mmol/day). Its occurrence is not related to UTI. Possible causes of calcium phosphate stones include HPT, RTA and UTI; each of which requires different therapy.

4.5.1 **Diagnosis**

Diagnosis requires blood analysis for: creatinine, sodium, potassium, chloride, ionised calcium (or total calcium + albumin), phosphate, and PTH (in the case of increased calcium levels). Urinalysis includes measurement of: volume, urine pH profile, specific weight, calcium, phosphate and citrate.

4.5.2 **Interpretation of results and aetiology**

General preventative measures are recommended for fluid intake and diet. The diagnostic and therapeutic algorithm for calcium phosphate stones is shown in Figure 4.4.
4.5.3 Pharmacological therapy [597, 627, 636, 649, 650, 654, 670]

Hyperparathyroidism and RTA are common causes of calcium phosphate stone formation. Most patients with primary HPT require surgery. Renal tubular acidosis can be corrected pharmacologically including with bicarbonate or alkaline citrate therapy. If primary HPT and RTA have been excluded, pharmacotherapy for calcium phosphate calculi depends on effective reduction of urinary calcium levels using thiazides. For infection-associated calcium phosphate stones, it is important to consider the guidance given for infection stones.

4.6 Disorders and diseases related to calcium stones

4.6.1 Hyperparathyroidism [671-674]

Primary HPT is responsible for an estimated 5% of all calcium stone formation. Renal stones occur in approximately 20% of patients with primary HPT. Elevated levels of PTH significantly increase calcium turnover, leading to hypercalcaemia and hypercalciuria and bone disease. Serum calcium may be mildly elevated and serum PTH may be within the upper normal limits and, therefore, repeated measurements may be needed;
preferably with the patient fasting. Stones of HPT patients may contain both calcium oxalate and calcium phosphate. Nephrocalcinosis and CKD may also occur.

If HPT is suspected, neck exploration should be performed to confirm the diagnosis. If surgery is contraindicated, primary HPT can be treated with cinacalcet.

4.6.2 Granulomatous diseases [675]
Granulomatous diseases, such as sarcoidosis, may be complicated by hypercalcaemia and hypercalciuria secondary to increased calcitriol production. The latter is independent of PTH control, leading to increased calcium absorption in the gastrointestinal tract and suppression of PTH. Treatment focuses on the activity of the granulomatous diseases and may require steroids, hydroxychloroquine or ketoconazole. Treatment should be reserved for a specialist.

4.6.3 Primary hyperoxaluria [646]
Patients with primary hyperoxaluria (PH) should be referred to specialised centres, as successful management requires an experienced interdisciplinary team. The main therapeutic aim is to reduce endogenous oxalate production, which is increased in patients with PH. In approximately one-third of patients with PH type I, pyridoxine therapy normalises or significantly reduces urinary oxalate excretion. The goal of adequate urine dilution is achieved by adjusting fluid intake to 3.5-4.0 L/day in adults (children 1.5 L/m² body surface area) and following a circadian drinking regimen.

Therapeutic options for preventing calcium oxalate crystallisation include hyperdiuresis, alkaline citrates, magnesium and Lumasiran, an RNAi agent, which is a new treatment for reducing the synthesis of oxalate of PH type 1 [676].

Treatment regimens are:
- pyridoxine in PH type I: 5-20 mg/kg/day according to urinary oxalate excretion and patient tolerance;
- alkaline citrate: 9-12 g/day in adults, 0.1-0.15 mg/kg/day in children;
- magnesium: 200-400 mg/day (no magnesium in the case of renal insufficiency).
- Lumasiran: Subcutaneous injection with dose and timing adjusted according to body weight and duration of treatment:
  - Initial Dose: Bodyweight < 10 kg: 6 mg/kg; Bodyweight 10-20 kg: 6 mg/kg; Bodyweight > 20 kg: 3 mg/kg; once per month for 3 months subcutaneous injection.
  - Maintenance starting one month after initial doses: Bodyweight < 10 kg: 3 mg/kg 1-mal monthly; Bodyweight 10-20 kg: 6 mg/kg every 3 months, Bodyweight > 20 kg: 3 mg/kg.

4.6.4 Enteric hyperoxaluria [615, 620, 677-679]
Enteric hyperoxaluria is a particularly problematic condition in patients with intestinal malabsorption of fat. This abnormality is associated with a high risk of stone formation and is seen after intestinal resection and malabsorptive bariatric surgery, as well as in Crohn's disease and pancreas insufficiency. In addition to hyperoxaluria, these patients usually present with hypocitraturia due to loss of alkali. Urine pH is usually low, as are urinary calcium and urine volume. All these abnormalities contribute to high levels of supersaturation with calcium oxalate, crystalluria, stone formation, and less frequently to nephrocalcinosis and CKD. Specific preventive measures are:
- restricted intake of oxalate-rich foods [615];
- restricted fat intake [615];
- calcium supplementation at meal times to enable calcium oxalate complex formation in the intestine [620, 677-679];
- sufficient fluid intake to balance intestinal loss of water caused by diarrhoea;
- alkaline citrates to raise urinary pH and citrate.

4.6.5 Renal tubular acidosis [597, 636, 680, 681]

Renal tubular acidosis is caused by severe impairment of proton or bicarbonate handling along the nephron. Kidney stone formation most probably occurs in patients with distal RTA type I. Figure 4.5 outlines the diagnosis of RTA. Table 4.7 shows acquired and inherited causes of RTA.

**Figure 4.5: Diagnosis of renal tubular acidosis**

BGA = blood gas analysis; RTA = renal tubular acidosis.

** An alternative ammonium chloride loading test using NH₄Cl load with 0.05 g/kg body weight over three days might provide similar results and may be better tolerated by the patient [682]. A second alternative in these cases could be the furosemide/fludrocortisone acidification test [683].

Renal tubular acidosis can be acquired or inherited. Reasons for acquired RTA can be chronic obstructive uropathy, recurrent pyelonephritis, acute tubular necrosis, renal transplantation, analgesic nephropathy, sarcoidosis, Sjögren syndrome and other autoimmune diseases, medullary sponge kidney, liver cirrhosis, sickle cell anaemia, idiopathic hypercalciuria, and primary parathyroidism; it may also be drug-induced (e.g., amphotericin B, foscarin, lithium, zonisamide and other carbonic anhydrase inhibitors).

</tr>
</tbody>
</table>

More rarely biallelic causative variants in FOXI1 and WDR72 genes have also been identified. The main therapeutic aim of RTA treatment is restoring a normal acid-base equilibrium. Despite the alkaline pH of urine in RTA, alkalisation using alkaline citrates or sodium bicarbonate is important for normalising the metabolic changes (intracellular acidosis) responsible for stone formation (Table 4.8) and bone demineralisation. The alkali load reduces tubular re-absorption of citrate, which in turn normalises citrate excretion. Therapeutic success can be monitored by venous blood gas analysis (base excess: ± 2.0 mmol/L) in complete RTA. If excessive calcium excretion (> 8 mmol/day) persists after re-establishing acid-base equilibrium, thiazides may lower urinary calcium excretion.

4.6.6 Nephrocalcinosis [684]

Nephrocalcinosis (NC) refers to increased calcium crystal deposition within the renal cortex or medulla and occurs alone or in combination with renal stones. There are various metabolic causes. The main causes are: HPT, primary and enteric hyperoxalurias, genetic and acquired RTA, medullary sponge kidney, vitamin D metabolic disorders, sarcoidosis, idiopathic hypercalciuria and hypocitraturia, and genetic disorders, including Dent's disease, Bartter's syndrome. The many causes of NC mean there is no single standard therapy. Therapeutic attention must focus on the underlying metabolic or genetic disease, on the frequent association with CKD while minimising the biochemical risk factors.
4.6.1 **Diagnosis**
Diagnosis requires the following blood analysis: PTH (in the case of increased calcium levels), vitamin D and metabolites, vitamin A, sodium, potassium, magnesium, chloride, and bicarbonate. Urinalysis should investigate urine pH profile at different times of the day, daily urine volume, specific weight of urine, and levels of calcium, oxalate, phosphate, uric acid, magnesium, and citrate [585].

4.7 **Uric acid and ammonium urate stones**
All uric acid and ammonium urate stone formers are considered to be at high risk of recurrence [27]. Uric acid nephrolithiasis is responsible for approximately 10% of renal stones [685] and associated with hyperuricosuria or low urinary pH. Hyperuricosuria may be a result of dietary excess, endogenous overproduction (enzyme defects), myeloproliferative disorders, chemotherapy drugs, gout or catabolism [582]. Low urinary pH may be caused by decreased urinary ammonium excretion (insulin resistance or gout), increased endogenous acid production (insulin resistance, metabolic syndrome, or exercise-induced lactic acidosis), increased acid intake (high animal protein intake), or increased base loss (diarrhoea) [582].

Ammonium urate stones are extremely rare, comprising < 1% of all types of urinary stones. They are associated with UTI, malabsorption (inflammatory bowel disease and ileostomy diversion or laxative abuse), phosphate deficiency, hypokalemia and malnutrition. Suggestions on uric acid and ammonium urate nephrolithiasis are based on level 3 and 4 evidence. Chronic kidney disease is frequently observed.

4.7.1 **Diagnosis**
Figure 4.6 shows the diagnostic algorithm for uric acid stones and figure 4.7 shows the therapeutic algorithm for uric acid and ammonium urate stones. Blood analysis requires measurement of creatinine, potassium, and uric acid levels. Urinalysis requires measurement of urine volume, urine pH profile, specific weight of urine, and uric acid level. Urine culture is needed in the case of ammonium urate stones.

4.7.2 **Interpretation of results**
Uric acid and ammonium urate stones form under completely different biochemical conditions. Low urine pH promotes uric acid crystallisation.

Hyperuricosuria is defined as uric acid excretion > 4 mmol/day and day and > 5 mmol/day in adult females and males, respectively or > 0.12 mmol/kg/day in children. Hyperuricaemia may be present, but there is only weak evidence for its association with stone formation [686].

Hyperuricosuric calcium oxalate stone formation can be distinguished from uric acid stone formation by urinary pH, which is usually > 5.5 in calcium oxalate stone formation and < 5.5 in uric acid stone formation and occasional absence of hyperuricosuria in patients with pure uric acid stones [687, 688]. Ammonium urate crystals form in urine at pH > 6.5, high uric acid concentration when ammonium is present [689, 690].

4.7.3 **Specific treatment**
General preventive measures are recommended for fluid intake and diet. Hyperuricosuric stone formers benefit from purine reduction in their daily diet. Figure 4.6 describes pharmacological treatment [27, 685, 687-697]. For uric acid stones, allopurinol may change the stone composition distribution in patients with gout to a pattern similar to that in stone formers without gout [698].
ADPKD = autosomal dominant polycystic kidney disease; G6P = glucose-6 phosphate dehydrogenase; HGPT = hypoxanthine guanine phosphorybosyl transferase; PRPS = phosphoribosyl-pyrophosphate synthetase superactivity; XO = xanthine oxidase.

3 A higher pH may lead to calcium phosphate stone formation.
4 In patients with high uric acid excretion, allopurinol may be helpful.
4.8 Struvite and infection stones

All infection-stone formers are deemed at high risk of recurrence. Struvite stones represent 2-15% of the stones sent for analysis. Stones that contain struvite may originate \textit{de novo} or grow on pre-existing stones, which are infected with urea-splitting bacteria [699]. There are several factors predisposing patients to struvite stone formation (Table 4.9) [700]. A number of studies have reported that urinary metabolic alterations can be disclosed in 36-81% of patients with mixed struvite stones [701-706].

4.8.1 Diagnosis

Blood analysis requires measurement of creatinine, and urinalysis requires repeat urine pH measurements and urine culture. In cases of mixed struvite stones the search of metabolic abnormalities in 24 hour urine after stone removal and infection control is suggested.

4.8.2 Interpretation

Infection stones contain the following minerals: struvite and/or carbonate apatite and/or ammonium urate. Urine culture typically provides evidence for urease-producing bacteria, which increase ammonia ions and develop alkaline urine (Table 4.10). Carbonate apatite starts to crystallise at a urine pH level of 6.8. Struvite only precipitates at pH > 7.2 [707, 708]. A mixed struvite stones, i.e. containing a high percentage of calcium oxalate and carbonate apatite, suggests the over infection of a “metabolic” calcium oxalate or calcium phosphate stone [706]. \textit{Proteus mirabilis} accounts for more than half of all urease-positive UTIs [709, 710].

4.8.3 Specific treatment

General preventive measures are recommended for fluid intake and diet. Specific measures include complete surgical stone removal [700], short- or long-term antibiotic treatment [711], urinary acidification using methionine [642] or ammonium chloride [712], and advice to restrict intake of urease [713, 714]. For persistent infections/colonisation, acetohydroxamic acid may be an option [713, 714] (Figure 4.8); however, it is not licensed/available in all European countries.

Eradication of infection after complete stone removal is desirable. The evidence regarding the duration of post-operative antibiotic administration is inconclusive.

4.9 Cystine stones
Cystine stones account for 1-2% of all urinary stones in adults and 6-8% of the stones reported in paediatric studies [37, 715]. All cystine stone formers are deemed at high risk of recurrence and CKD [716, 717].

4.9.1 Diagnosis
Blood analysis includes measurement of creatinine, and urinalysis includes measurement of urine volume, pH profile, specific weight, and cystine. Since the disease may be asymptomatic, siblings of cystinuric patients should be investigated for cystinuria [718].

Interpretation
• Cystine is poorly soluble in urine and crystallises spontaneously within the physiological urinary pH range.
• Cystine solubility depends strongly on urine pH: at pH 6.0, the limit of solubility is 1.33 mmol/L.
• Routine analysis of cystine is not suitable for therapeutic monitoring.
• Regardless of phenotype or genotype of the cystinuric patient, the clinical manifestations are the same [719].
• There is no role for genotyping patients in the routine management of cystinuria [720, 721].
• Reductive therapy targets the disulphide binding in the cystine molecule. For therapy monitoring, it is important to differentiate between cystine, cysteine and drug-cysteine complexes. However, available methods to monitor cystinuria treatment are cumbersome [722, 723], or inaccurate including high-performance liquid chromatography (HPLC) which may be able to differentiate between the different complexes formed by therapy [69].
• Quantitative 24-hour urinary cystine excretion confirms the diagnosis in the absence of stone analysis.
• Levels above 0.125 mmol/day (30 mg/day) are considered abnormal [724, 725].

4.9.2 Specific treatment
General preventative measures for fluid intake and diet are recommended. A diet low in methionine may theoretically reduce urinary excretion of cystine; however, patients are unlikely to comply sufficiently with such a diet. A restricted intake of sodium is more easily achieved and is more effective in reducing urinary cystine. Patients are usually advised to avoid sodium consumption > 2 g/day (5 g NaCl) [726]. A high level of diuresis is of fundamental importance, aiming for a 24-hour urine volume of > 3 L [719, 726-728]. A considerable fluid intake evenly distributed throughout the day is necessary.

4.9.2.1 Pharmacological treatment of cystine stones
The main therapeutic option for avoiding cystine crystallisation is to maintain urine pH > 7.5, to improve cysteine solubility and ensure appropriate hydration with a minimum of 3.5 L/day in adults, or 1.5 L/m² body surface area in children [719, 726-728]. Home monitoring of the urine pH is suggested because of the possibility to self-adjust alkaline treatment keeping the urine pH in range [69].

Free cystine concentration can be decreased by reductive substances, which act by splitting the disulphide binding of cystine.

Tiopronin is currently the best choice for cystine reduction. However, side effects often lead to treatment termination, for example when nephrotic syndrome develops or when there is poor compliance, especially with long-term use. After carefully considering the risk of early tachyphylaxis, put into place a dose-escape phenomenon for long-term use, and recurrence risk. Tiopronin is recommended at cystine levels > 3.0 mmol/day (720 mg/day) or in the case of recurring stone formation, notwithstanding other preventive measures [719, 726-728]. Spot measurement of urine protein should be performed at baseline and during follow-up.

4.10 2,8-Dihydroxyadenine stones and xanthine stones
All 2,8-Dihydroxyadenine and xanthine stone formers are considered to be at high risk of recurrence. Both stone types are rare. Diagnosis and specific prevention are similar to those for uric acid stones [27].

4.10.1 2,8-Dihydroxyadenine stones
A genetically determined defect of adenine phosphoribosyl transferase causes high urinary excretion of poorly soluble 2,8-Dihydroxyadenine [730]. High-dose allopurinol or febuxostat are important options but should be given with regular monitoring [731].

4.10.2 Xanthine stones
Patients who form xanthine stones usually show decreased levels of serum uric acid. There is no available pharmacological intervention.

4.10.3 Fluid intake and diet
Recommendations for general preventive measures apply. Pharmacological intervention is difficult; therefore, high fluid intake ensures optimal specific weight levels of urine < 1.010 (urine specific gravity). A purine-reduced diet decreases the risk of spontaneous crystallisation in urine.

4.11 Drug-induced stones
Drug stones are induced by pharmacological treatment [627, 732] (Table 4.10). Two types exist:
• stones formed by crystallised compounds of the drug;
• stones formed due to unfavourable changes in urine composition under drug therapy.

4.12 Matrix Stones
Pure matrix stones are extremely rare with less than 70 cases described in the literature. They are more prevalent in females. The main risk factors are recurrent UTIs, especially due to P. mirabilis or E. coli, previous surgery for stone disease, chronic renal failure, and haemodialysis. Complete endourological removal, frequently via the percutaneous approach, is critical. Given the rarity of matrix calculi a specific prophylactic regimen to minimise recurrence cannot be recommended. Eliminating infections and prophylactic use of antibiotics are most commonly proposed [733].

4.13 Unknown stone composition [20]
An accurate medical history is the first step towards identifying risk factors as summarised in sections 3.1.3 and 4.13.1 and Fig. 4.1.

Diagnostic imaging begins with US examination of both kidneys to establish whether the patient is stone free. Stone detection by US should be followed by KUB and unenhanced multislice CT in adults to differentiate between calcium-containing and non-calcium stones.

Blood analysis demonstrates severe metabolic and organic disorders, such as renal insufficiency, HPT or other hypercalcaemic states and hyperuricaemia. In children, hyper with low GFR oxalaemia should additionally be screened for.

Urinalysis is performed routinely with a dipstick test as described above. Urine culture is required if there are signs of infection. Urine pH < 5.5 in 24-hr urine collection indicates hyper acidic urine, which could
promote uric acid crystallisation. Urine pH > 6.2 in 24-hr urine collection may indicate RTA, if UTI is excluded [679, 681].

Microscopy of urinary sediment can help to discover rare stone types because crystals of 2,8-Dihydroxyadenine, cystine and xanthine are pathognomonic for the corresponding disease. In cases in which the presence of cystine is doubtful, a cyanide nitroprusside colorimetric qualitative test can be used to detect the presence of cystine in urine, with a sensitivity of 72% and specificity of 95%. False-positive results are possible in patients with Fanconi’s syndrome or homocystinuria, or in those taking various drugs, including ampicillin or sulfa-containing medication [734, 735].

Following this programme, the most probable stone type can be assumed, and specific patient evaluation can follow. Further metabolic investigations will depend on the presence of risk factors (see section 3.1.3) and on the results of previous investigations. However, if any expelled stone material is available, it should be analysed by diagnostic confirmation or correction.

5. FOLLOW-UP OF URINARY STONES

Patients suffering from urinary tract lithiasis have a predisposition to develop symptoms, complications, and recurrence of stones. Despite the rich literature published on urinary lithiasis very little has been written about how lithiasis patients should be monitored after their treatment.

There is no general agreement on whether and when stone patients should be released from their follow-up, nor when and how follow-up should occur for patients who need it. The main reason for this lack of agreement is the great clinical heterogeneity of stone disease among patients.

The EAU Urolithiasis Guidelines Panel performed a systematic review questioning the benefits and harms of scheduled follow-up for patients who underwent definitive treatment (extracorporeal shock wave lithotripsy, ureteroscopy, percutaneous nephrolithotripsy, medical chemoprophylaxis) for upper urinary tract stone disease [736].

The Panel aimed to answer three main questions regarding urolithiasis follow-up: a) In patients with no residual fragments, does imaging follow-up after treatment for upper urinary tract stones offer more clinical benefits
than harms compared with no scheduled follow-up? b) In patients with residual fragments, does imaging follow-up after treatment for upper urinary tract stones offer more clinical benefits than harms compared with no scheduled follow-up? and c) Does biochemical urine analysis follow-up after treatment for upper urinary tract stones offer more clinical benefits than harms compared with no scheduled follow-up? There was a lack of comparative studies regarding follow-up versus no follow-up, so the primary endpoints were not reached. The panel used the data from the eligible observational and randomised studies included in the systematic review to identify the time of patient discharge after follow-up according to stone disease status (stone-free patients, patients with residual stones, patients with metabolic abnormalities), and to come to a consensus on frequency of follow-up and use of investigations.

From a pooled analysis of 5,467 stone-free patients, the Panel estimated that for a safety margin of 80%, patients should be followed-up using imaging, for at least two years (radiopaque stones), or at least three years (radiolucent stones) before discharge, while for a safety margin of 90% patients should be discharged after five years of no recurrence. Regarding residual disease, patients with fragments ≤ 4mm could be offered either surveillance for up to four years, since intervention rates range between 17-29%, disease progression between 9-34% and spontaneous passage between 21-34% at 49 months. Patients with larger residual fragments should be offered further definitive intervention, since intervention rates are high (24-100%). Insufficient data exist for high-risk patients, but current literature dictates that patients who are adherent to targeted medical treatment seem to experience less stone growth or re-growth of residual fragments and may be discharged after 36-48 months of non-progressive disease on imaging (Figure 5.1).

A Panel consensus was reached after extensive discussion of data regarding frequency of follow-up. In stone-free general population, the vast majority of patients remained stone-free during the 1st year, in contrast with patients with metabolic abnormalities not under targeted medical treatment, < 40% were stone-free after three years of follow-up. Therefore, a more extensive follow-up is proposed for patients with metabolic abnormalities. Patients with small residual fragments ≤ 4mm, showed a spontaneous expulsion at 17.9-46.5% and growth rate at 10.1-40.7% during the 1st year, while patients with larger fragments (> 4 mm) had only 9% of spontaneous expulsion at three years. Therefore, patients with small ≤ 4mm, asymptomatic fragments should be followed-up or scheduled for an intervention according to patient preference, while those with larger stones should primarily be offered re-intervention. Proposed imaging consists of plain X-ray KUB and/or US, based on stone characteristics and clinicians’ preferences. Computed tomography scan should be reserved for symptomatic disease or pre-operative imaging, in order to avoid extensive radiation exposure (Figure 5.2) [736].

The information on stone composition can be used to counsel patients to set expectations and help plan the need for follow up and medical stone management [737].
Figure 5.1: Follow-up duration of Urinary stone patients after treatment

- **High-risk patients**
  - On medical treatment
  - Follow-up for 4 years
  - Follow-up for at least 14 years
  - Strongly consider follow-up until 10 years due to high-risk of recurrence

- **Stone Free Patients**
  - 80% "safety margin" 2 years X-ray follow-up for radiopaque stones
  - 90% "safety margin" Follow-up for 5 years
  - ≤ 4 mm or dust
  - Follow-up for 4 years or intervention

- **Patients with residual fragments**
  - 80% "safety margin" 3 years X-ray +/- US follow-up for radiolucent stones
  - > 4 mm
  - Schedule re-intervention

- **Follow-up of stone-disease patients after treatment**

* Not enough data about subgroup analysis of radiolucent and radiopaque stones.
** According to patient preference or symptomatic disease.
*** Patients with diagnosed metabolic abnormalities.
**** Lifelong follow-up is advised but data are available up to 10 years.
Figure 5.2: Consensus on follow-up frequency and imaging modality to use after treatment

Stone free = No stone fragments on post-operative imaging (i.e. no stone fragments on CT/KUB/US).
High-Risk = Known biochemical abnormality (i.e.: hypercalciuria, hypocitraturia, hyperuricosuria, RTA or high-risk stone type such as struvite). Imaging = plain film KUB &/or kidney ultrasonography (KUS) based on clinicians’ preference and stone characteristics. Consider CT if patient is symptomatic or if intervention is planned.

* Clinicians may choose the imaging-only pathway in patients with fragments ≤ 2 mm.
* Treatment monitoring for side effects, intolerance, and compliance.
* Panel recommends reintervention however close follow up may be considered for some patients at high risk for reintervention based on clinicians’ preference.
6. BLADDER STONES

6.1 Prevalence, aetiology, and risk factors of bladder stones
Bladder stones constitute only approximately 5% of all urinary tract stones [738] yet are responsible for 8% of urolithiasis-related mortalities in developed nations [739]. The incidence is higher in developing countries [740]. The prevalence of bladder stones is higher in males, with a reported male: female ratio between 10:1 and 4:1 [741, 742]. The age distribution is bimodal: incidence peaks at three years in children in developing countries [741, 743], and 60 years in adulthood [742].

The aetiology of bladder stones is typically multi-factorial [742]. Bladder stones can be classified as primary, secondary, or migratory [744].

Primary or endemic bladder stones occur in the absence of other urinary tract pathology, typically seen in children in areas with poor hydration, recurrent diarrhoea, and a diet deficient in animal protein [745].

Secondary bladder stones occur in the presence of other urinary tract abnormalities, which include bladder outlet obstruction (BOO), neurogenic bladder dysfunction, chronic bacteriuria, foreign bodies (including catheters), bladder diverticula and bladder augmentation or urinary diversion. In adults, BOO is the most common predisposing factor for bladder stone formation and accounts for 45-79% of vesical calculi [742, 746-749].

Migratory bladder stones are those which have passed from the upper urinary tract where they formed and may then serve as a nidus for bladder stone growth. Patients with bladder calculi are more likely to have a history of upper tract stones and risk factors for their formation [750].

A wide range of metabolic urinary abnormalities can pre-dispose to calculi anywhere in the urinary tract, which is covered in more detailed in Section 4. Metabolic Evaluation and Recurrence Prevention. There is a paucity of studies on the specific metabolic abnormalities which predispose to bladder stones.

Bladder stones will form in 3-4.7% of men undergoing surgery for benign prostatic obstruction (BPO) [751, 752], 19-39% and 36-67% of motor-incomplete and motor-complete spinal cord injury patients, respectively [753], and 2.2% of patients with long-term catheters [754]. In men with chronic urinary retention secondary to BPO, the 24-hr urine of 27 men with bladder stones had a higher uric acid supersaturation (2.2 vs. 0.6 mmol/L, p < 0.01), lower magnesium (106 vs. 167 mmol/L, p = 0.01) and lower pH (5.9 vs. 6.4, p = 0.02) than the 21 men without bladder stones [750]. It is therefore likely that patients with these conditions who form bladder stones also have an abnormal urine composition which pre-disposes them to bladder stone formation.

The metabolic abnormalities which pre-dispose patients to form secondary bladder stones are poorly understood. Stone analysis of 86 men with a BPO-related bladder stone demonstrated 42% had calcium-based stones (oxalate, phosphate), 33% had magnesium ammonium phosphate, 10% had mixed stones and 14% had urate stones [742]. Similar findings were reported in more recent studies [755-757] and it is therefore likely that multiple metabolic factors pre-dispose patients to secondary bladder stone formation.

The exact metabolic basis for primary bladder stones is poorly understood and likely multi-factorial. Low urine volume (poor hydration) is the most consistently demonstrable abnormality [758-760]. Twenty-four hour urine analysis in children with endemic bladder stones is reported in two studies. Of 57 children in Pakistan, 89.5% had hypocitraturia, 49% had a low urine volume, 44% had hyperoxaluria and 42% had hypocalciuria [758]. Of 61 children in India, stone formers had higher urine calcium and uromucoid concentrations than controls [759]. One study from Thailand compared 24-hour urine analyses from children from a rural area with a high prevalence of bladder stones with those from an urban area: rural children had lower urine volumes and, despite equal calcium, oxalate, and uric acid concentrations, crystalluria with uric acid and calcium oxalate crystals was more prevalent in rural children [760].

BOO = Bladder Outlet Obstruction; BPO = Benign Prostatic Obstruction.

6.2 **Presentation**

The symptoms most commonly associated with bladder stones are urinary frequency, haematuria (which is typically terminal) and dysuria or suprapubic pain, which are worst towards the end of micturition. Sudden movement and exercise may exacerbate these symptoms. Detrusor over-activity is found in over two thirds of adult male patients with vesical calculi and is significantly more common in patients with larger stones (> 4 cm). However, recurrent urinary tract infections (UTIs) may be the only symptom [747, 748].

In children, symptoms may also include pulling of the penis, difficulties in micturition, urinary retention, enuresis and rectal prolapse (resulting from straining due to bladder spasms). Bladder stones may also be an incidental finding in 10% of cases [745, 761].

6.3 **Diagnostic evaluation**

6.3.1 **Diagnostic investigations for bladder stones**

Plain X-ray of KUB has a reported sensitivity of 21%-78% for cystoscopically detected bladder stones in adults [747, 762]. Larger (> 2.0 cm) stones are more likely to be radiopaque [762]. However, plain X-ray provides information on radio-opacity which may guide treatment and follow-up (see Section 3.2.3 X-ray characteristics, for further information).

Ultrasound has a reported sensitivity and specificity of 20-83% and 98-100%, respectively for the detection of bladder stones in adults [763, 764]. Computed tomography and cystoscopy have a higher sensitivity for detecting bladder stones than US or X-Ray in adults [763, 764]. No study compares cystoscopy and CT for the diagnosis of bladder stones. Cystoscopy has the advantage of detecting other potential causes for a patient’s symptoms (e.g., bladder cancer), whilst CT can also assess upper tract urolithiasis (see also section 3.2.3 X-ray characteristics) [765].

There is a paucity of evidence for the investigation of bladder stones, particularly in children [86, 766]. See also Section 3.3 Diagnostic evaluation, for further information on diagnostic imaging for urolithiasis. The principle of ALARA should be applied, especially in children [767].

6.3.2 **Diagnosing the cause of bladder stones**

The cause of the bladder stone should be considered prior to bladder stone treatment as eliminating the underlying cause will reduce recurrence rates [768]. The following should be performed where possible prior to (or at the time of) bladder stone treatment:

- physical examination of external genitalia, peripheral nervous system (including digital rectal examination, peri-anal tone, and sensation in men);
- uroflowmetry and post-void residual urine assessment;
- urine dipstick to include pH± culture;
- metabolic assessment (see also section 3.3.2.3) including: serum (creatinine, (ionised) calcium, uric acid, sodium, potassium, blood cell count);
- urine pH;
- stone analysis: in first-time formers using a valid procedure (X-ray diffraction or infrared spectroscopy).

The following investigations should also be considered for selected patients:

- upper tract imaging (in patients with a history of urolithiasis or loin pain);
- cysto-urethroscopy or urethrogram.
6.4 Disease Management
6.4.1 Conservative treatment and Indications for active stone removal
Migratory bladder stones in adults may typically be left untreated, especially asymptomatic small stones. Rates of spontaneous stone passage are unknown, but data on ureteric stones suggest stones < 1 cm are likely to pass in the absence of BOO, bladder dysfunction or long-term catheterisation (see section 3.4.9 Specific stone management of ureteral stones).

Primary and secondary bladder stones are usually symptomatic and are unlikely to pass spontaneously: active treatment of such stones is usually indicated.

6.4.2 Medical management of bladder stones
There is a paucity of evidence on chemolitholysis of bladder stones. However, guidance on the medical management of urinary tract stones in section 3.4.9 Specific stone management of ureteral stones, can be applied to urinary stones in all locations. Uric acid stones can be dissolved by oral urinary alkalinisation when a pH > 6.5 is consistently achieved, typically using an alkaline citrate or sodium bicarbonate. Regular monitoring is required during therapy (see section 3.4.4 Chemolysis). Irrigation chemolysis is also possible using a catheter; however, this is time consuming and may cause chemical cystitis and is therefore not commonly employed [148, 769].

6.4.3 Bladder stone interventions
Minimally invasive techniques for the removal of bladder stones have been widely adopted to reduce the risk of complications and shorten hospital stay and convalescence. Bladder stones can be treated with open, laparoscopic, robotic assisted laparoscopic, endoscopic (transurethral or percutaneous) surgery or ESWL [770].

6.4.3.1 Suprapubic cystolithotomy
Open suprapubic cystolithotomy is very effective but is associated with a need for catheterisation and longer hospital stay in both adults and children compared to all other stone removal modalities [393]. In children, a non-randomised study found that, if the bladder was closed meticulously in two layers, “tubeless” (drain-less and catheter-less) cystolithotomy was associated with a significantly shorter length of hospital stay compared with traditional cystolithotomy, without significant differences regarding late or intra-operative complications provided that children with prior UTI, recurrent stones, or with previous surgery for anorectal malformation (or other relevant surgery) were excluded [771].

6.4.3.2 Transurethral cystolithotripsy
In both adults and children, transurethral cystolithotripsy provides high SFRs and appears to be safe, with a very low-risk of unplanned procedures and major post-operative and late complications [770].

6.4.3.2.1 Transurethral cystolithotripsy in adults
In adults, meta-analysis of four RCTs including 409 patients demonstrated that transurethral cystolithotripsy has a shorter hospital stay and convalescence with less pain, but equivalent SFR and complications compared to percutaneous cystolithotripsy [770]. Transurethral cystolithotripsy with a nephroscope was quicker than percutaneous cystolithotripsy in three RCTs, although transurethral cystolithotripsy with a cystoscope was slower than percutaneous cystolithotripsy [770].

Rates of urethral strictures following transurethral procedures were not robustly reported: studies report rates between 2.9% and 19.6% during a follow up of 12 to 24 months [755, 770, 772].

One small RCT demonstrated a shorter duration of catheterisation, hospital stay and procedure with transurethral cystolithotripsy than open cystolithotripsy with similar SFR [770]. Meta-analysis of five RCTs found significantly shorter procedure duration for transurethral cystolithotripsy using a nephroscope vs. cystoscope with similar SFRs, hospital stay, convalescence, pain, and complications [773]. Two retrospective studies (n=188) reported that using a resectoscope or nephroscope was associated with a shorter procedure duration (p < 0.05) than a cystoscope for transurethral cystolithotripsy [774, 775]. This suggests that transurethral cystolithotripsy is quicker when using a continuous flow instrument.

6.4.3.2.1.1 Lithotripsy modalities used during transurethral cystolithotripsy in adults
When considering lithotripsy modalities for transurethral cystolithotripsy, the Panel’s systematic review found very low-quality evidence from five non-randomised studies (n=385) which found no difference in SFR between modalities (mechanical, laser, pneumatic, ultrasonic, electrohydraulic lithotripsy [EHL] or washout alone) [770]. Unplanned procedures and major post-operative complications were low-rate events and were not significantly different between lithotripsy modalities, although one non-randomised study (NRS) suggested these might be
higher with EHL or mechanical lithotripsy than pneumatic or ultrasonic lithotripsy [776]. All outcomes had very low-quality of evidence (GRADE) [770]. High-powered lasers seem to reduce lithotripsy time. Laser lithotripsy was faster than pneumatic lithotripsy (MD 16.6 minutes; CI: 23.51-9.69, p < 0.0001) in one NRS (n=62); however, a laser was used with a resectoscope and the pneumatic device with a cystoscope [777]. The same conclusion was stated in a meta-analysis of ten RCTs with high heterogeneity and small sample sizes in some of the included RCTs [778]. Continuous vs. intermittent irrigating instrument may affect the operation time more significantly than the choice of lithotripsy device [770].

6.4.3.2.1.2 Transurethral cystolithotripsy in children
In children, three NRS suggest that transurethral cystolithotripsy has a shorter hospital stay and catheterisation time than open cystolithotomy, but similar stone-free and complication rates [779]. One small quasi RCT found a shorter procedure time using laser vs. pneumatic lithotripsy for < 1.5 cm bladder stones with no difference in SFR or other outcomes [780]. Another RCT (n=73) found shorter procedure time using pneumatic vs. laser therapy for bladder stones ≤ 1.5 cm with similar SFRs and higher (minor) complication rates for pneumatic lithotripsy [781].

6.4.3.3 Percutaneous cystolithotripsy

6.4.3.3.1 Percutaneous cystolithotripsy in adults:
One NRS found a shorter duration of procedure and catheterisation and less blood loss for percutaneous, compared with open surgery in adult male patients with urethral strictures; all patients in both groups were rendered stone-free [757].

Meta-analysis of four RCTs comparing transurethral and percutaneous cystolithotripsy found a shorter hospital stay for transurethral cystolithotripsy over percutaneous surgery. Transurethral cystolithotripsy was quicker when using a nephroscope. There were no significant differences in SFRs, major post-operative complications or re-treatment [770].

6.4.3.3.2 Percutaneous cystolithotripsy in children:
In children, three NRS suggest that percutaneous cystolithotripsy has a shorter hospital stay and catheterisation time, but a longer procedure duration and more peri-operative complications than open cystolithotripsy; SFRs were similar [4, 761, 770, 779].

A systematic review identified four non-randomised studies comparing percutaneous and transurethral cystolithotripsy and found similar SFRs, but that transurethral surgery offers a shorter duration of catheterisation and hospital stay [4, 761, 779]. In contrast, a transurethral approach may need a longer operative time and shows a higher post-operative stricture rate [4]. One small NRS found a non-significant increased risk of unplanned procedures (within 30 days of primary procedure) and major post-operative complications for percutaneous operations compared with transurethral procedures; however, age and stone size determined which intervention children underwent and all patients were rendered stone-free [761]. One RCT compared 48 boys < 14 years undergoing transurethral lithotripsy vs. 49 boys undergoing percutaneous lithotripsy with comparable success and complications rates; however, PCCL had a shorter operative time and less need for stone disintegration [782].

6.4.3.4 Extracorporeal shock wave lithotripsy
Extracorporeal SWL is the least invasive therapeutic procedure [770].

6.4.3.4.1 Shock wave lithotripsy in adults
In adults, one RCT compared SWL with transurethral cystolithotripsy in 100 patients with ≤ 2 cm bladder stones presenting with acute urinary retention. Stone free rate after one SWL session favoured transurethral cystolithotripsy (86% vs. 98%, p = 0.03); however, following up to three sessions of SWL, there was no significant difference in SFR (94% vs. 98%, p = 0.3) [770, 783].

Two NRS compared transurethral cystolithotripsy vs. SWL and found no significant difference in SFR (97.0% vs. 93.9%, p=0.99, 97.7% vs. 89.7% p=0.07) despite larger stones in transurethral cystolithotripsy patients (4.2 vs. 2.5 cm, p=0.014; and 3.6 vs. 2.6 cm [p value not reported]) [784, 785].

Length of hospital stay appeared to favour SWL in all three studies (0 vs. 1 day, 4.8 vs. 0 days, p=0.02, 0.8 vs. 2.4 days, respectively) [783-785]. No significant differences in major post-operative or intra-operative complications were reported in any study [783-785].
One NRS compared SWL vs. open cystolithotomy in just 43 patients. Stone sizes were not comparable (2.5 vs. 7.4 cm, \( p < 0.001 \)). Stone-free rates were not significantly different (93.9% vs. 100%, \( p=0.50 \)). Length of stay favoured SWL. There was no significant difference in intra-operative or major post-operative complications [784].

6.4.3.4.2 Shock wave lithotripsy in children
One large NRS found lower SFR for SWL than both transurethral cystolithotripsy and open cystolithotomy, despite treating smaller stones with SWL. However, the length of stay stays favoured SWL over open cystolithotomy, although this appeared to be comparable between SWL and transurethral cystolithotripsy [786].

6.4.3.5 Laparoscopic cystolithotomy
Laparoscopic cystolithotomy has been described in adults and is typically performed in combination with simple prostatectomy using either traditional laparoscopy or with robotic assistance [787, 788]. A SR found no studies comparing laparoscopic surgery with other procedures [770].

6.4.4 Treatment for bladder stones secondary to bladder outlet obstruction in adult men
Bladder stones in men aged over 40 years may be caused by BPO, the management of which should also be considered. Bladder stones were traditionally an indication for a surgical intervention for BPO: a doctrine which has been questioned by recent studies. One prospective study reports urodynamics (cystometrogram) findings in 46 men aged > 60 years before and after bladder stone treatment [748]. Only 51% of men had BOO while 10% had detrusor under-activity. Eighteen percent of men had a completely normal urodynamic study and 68% had detrusor over-activity. There was no significant difference between pre- and post-bladder stone removal urodynamic findings [748].

One NRS compared 64 men undergoing transurethral cystolithotripsy with either transurethral resection of prostate (TURP) or medical management for BPO (\( \alpha \)-blocker with or without 5-alpha reductase inhibitor). After 28 months follow-up, no men on medication had had a recurrence, but 34% underwent TURP: a high post-void residual urine volume predicted the need for subsequent TURP [789]. Another observational study of 23 men undergoing cystolithotripsy and commencing medical management for BPO found 22% developed a BPO related complication, including 17% who had recurrent stones [768]. One RCT comparing cystolithotripsy with concomitant TURP to cystolithotripsy with medical management of bladder outlet obstruction with Tamsulosin and finasteride, demonstrated that both groups had a significantly improved Q\( \text{max} \), IPSS and PVR at follow-up, although the TURP group had a longer procedure and catheterisation time [790]. Large prostates and a high PVR (> 190 ml) were predictive of needing a TURP over time in the medical management cohort, although this was based on only a small number of patients.

Large studies support the safety of performing BPO and bladder stone procedures during the same operation with no difference in major complications compared to a BPO procedure alone [791-793]. An observational study on 2,271 patients undergoing TURP found no difference in complications except UTIs, which occurred slightly more frequently in patients with simultaneously treated bladder stones: 0% vs. 0.6%, \( p=0.044 \) [791]. An observational study of 321 men undergoing Holmium laser enucleation of the prostate (HoLEP) found a higher rate of early post-operative incontinence (26.8% vs. 12.5%, \( p=0.03 \)) in men having concomitant transurethral cystolithotripsy, but no difference in long-term continence rates [793]. Another larger multicenter observational study of 963 patients undergoing HoLEP found no significant differences in frequency of complications in patients with (n=54 (5.6%)) or without concomitant transurethral cystolithotripsy [794].

6.4.5 Special situations
6.4.5.1 Neurogenic bladder and stone formation
Patients with a neurogenic bladder secondary to spinal cord injury or myelomeningocele are at increased risk of forming bladder stones. Within eight to ten years, 15-36% of patients with spinal cord injury will develop a bladder stone [795-797]. According to a systematic review, the prevalence of stone formation depends on the level of the spinal cord injury with 19-39% and 36-67% of respectively motor-incomplete and motor-complete spinal cord injury patients developing bladder stones over time [753]. The absolute annual risk of stone formation in spinal cord injury patients with an indwelling catheter is 4% compared with 0.2% for those voiding with clean intermittent self-catheterisation (CISC) [798].

A study of 2,825 spinal cord injury patients over eight years found a 3.3% incidence of bladder stones: 2% with CISC, 6.6% with indwelling urethral catheter, 11% with a suprapubic catheter and 1.1% in patients voiding using reflex micturition [799]. However, another study of 457 spinal cord injury patients for six months found no difference in bladder stones between urethral and suprapubic catheterisation [798]. Spinal cord injury patients
with an indwelling urethral catheter are six times more likely to develop bladder stones than patients with normal micturition [797, 799].

The risk of stone recurrence after complete removal in spinal cord injury patients is 16% per year [798]. A RCT of 78 spinal cord injury patients who perform CISC found a significant reduction in bladder stone formation when twice weekly manual bladder irrigations were performed for six months (49% vs. 0%, p = < 0.0001), as well as less symptomatic UTIs (41% vs. 8%; p = 0.001) [800]. However, this study excluded patients who developed autonomic dysreflexia during bladder irrigations. The irrigation volume used was not reported.

6.4.5.2 Bladder Augmentation
The incidence of vesical calculus formation after bladder augmentation is 2-44% in adults [801-810], and 4-53% in children [810-824]. Following cystoplasty, stones form after 24-31 months in adults [802, 804, 809], and after 25-68 months in children [815, 818, 819, 823, 825-827]. The reported cumulative incidence of bladder stone formation after ten years is 28-36% and after twenty years is 41% [810, 828].

Risk factors for bladder stone formation after augmentation include excess mucus production, incomplete bladder emptying, non-compliance with CIC or bladder irrigations, bacteriuria or urinary tract infections (due to urease-producing bacteria), foreign bodies (including staples, mesh, non-absorbable sutures), drainage by vesico-entero-cystostomy (Mitrofanoff or Monti) [472, 802, 805, 807, 808, 815, 819, 822, 828] and voiding by CISC compared with those voiding spontaneously [806]. Gastric segment augmentation confers a lower risk of bladder stones than ileal or colonic segment cystoplasty [811, 815, 819, 822].

In previous stone formers, the rate of recurrence is 15-44% in adults [802-804, 806, 809], and 19-56% in children [472, 810, 811, 815, 817-820, 822, 827]. The risk of recurrence is greatest during the first two years, at about 12% per patient per year, with the risk decreasing with time [827].

Daily, or three-times-weekly bladder irrigations reduce the incidence of bladder stones following bladder augmentation or continent urinary diversion [472, 805]. A randomised study found that daily bladder irrigation with 240 mL of saline reduced stone recurrences (p < 0.0002, p=0.0152) and symptomatic UTIs (p < 0.0001, p < 0.0001) compared to 60mL or 120mL [805]. The frequency of bladder irrigations required is unclear.

6.4.5.3 Urinary diversion
The incidence of stone formation after urinary diversion with an ileal or colon conduit is 0-3% [829, 830]. The incidence of stone formation is 0-34% in orthotopic ileal neobladders (Hautmann, hemi-Kock, Studer, T-pouch or w-neobladder) [470, 806, 830-838], and 4-6% in orthotopic sigmoid neobladders (Reddy) [835, 839]. The risk of pouch stone formation is 4-43% in adults with an ileocaecal continent cutaneous urinary diversion (Indiana, modified Indiana, Kock or Mainz I) [464, 806, 829, 830, 838, 840]. The average interval from construction of the urinary diversion to stone detection is 71-99 months [834, 841]. In children, the incidence of neobladder stone formation is 30% after Mainz II diversion (rectosigmoid reservoir) [812], and 27% after Kock ileal reservoir construction [824].

6.4.5.4 Treatment of stones in patients with bladder augmentation or urinary diversion
Stones may be removed by open or endoscopic surgery in patients with bladder augmentation or diversion [817]. However, often access cannot be obtained through a continent vesico-entero-cystostomy without damaging the continence apparatus; hence a percutaneous or open approach is typically preferred [817].

No studies comparing outcomes following procedures for stones in reconstructed or augmented bladders were found. Two observational studies indicate that percutaneous lithotomy can be safely performed with US or CT guidance in patients with reconstructed or augmented bladders [842, 843] and is proposed to offer similar advantages over open surgery to those for percutaneous native bladder surgery. Stone recurrence after successful removal has been reported to be 10-42% [842, 843], but appears to be unrelated to the modality used for stone removal [809, 815, 819, 820, 822, 827].
**Bladder stones follow-up**

There are no studies examining the merits of differing follow-up modalities or frequencies following conservative, medical, or operative treatment of bladder stones in adults or children. Identification and prevention of the cause of bladder stone formation will be crucial to prevent recurrence (see section 6.3.2 Diagnosing the cause of bladder stones).

In adults, there is a paucity of evidence on dietary modification or medical treatment for the prevention of bladder stone recurrence. Recommendations in the EAU Guideline on Urolithiasis, based on evidence from upper tract stones, constitutes the best available recommendations, especially for migratory bladder stones (see Section 4 Metabolic Evaluation and Recurrence Prevention).
Where it is possible to address the cause of secondary bladder stones (e.g., treatment of BPO), it is unclear whether metabolic intervention would offer any significant additional benefit in preventing stone recurrence. However, especially where the secondary cause cannot be addressed (e.g., indwelling catheter, neuropathic bladder, bladder augmentation or urinary diversion); metabolic interventions are likely to reduce bladder stone recurrence rates.

Regular bladder irrigation reduces the chances of bladder stone recurrence in adults and children with bladder augmentation or continent cutaneous urinary diversion and adults with spinal cord injury who perform CISC (see section 6.4.5 Special Situations) [800, 805, 830].

In children with primary (endemic) bladder stones maintenance of hydration, avoidance of diarrhoea and a mixed cereal diet with milk and Vitamins A and B supplements, with the addition of eggs, meat, and boiled cows’ milk after one year of age are recommended to prevent recurrence [758].

Finally, there are contradictory reports on a possible association between bladder calculi and future development of bladder cancer [844-846]. The need for follow-up with regular cystoscopy therefore remains controversial.

### 6.6 Summary of evidence and recommendations for the treatment of bladder stones

<table>
<thead>
<tr>
<th>Summary of evidence</th>
<th>LE</th>
</tr>
</thead>
<tbody>
<tr>
<td>The incidence of bladder stones peaks at three years in children (endemic/primary stones in developing countries) and 60 years in adults.</td>
<td>2c</td>
</tr>
<tr>
<td>The aetiology of bladder stones is typically multi-factorial. Bladder stones can be classified as primary (endemic), secondary (associated with lower urinary tract abnormalities e.g., BPO, neuropathic bladder, foreign body, chronic bacteriuria) or migratory (having formed in the upper tract).</td>
<td>4</td>
</tr>
<tr>
<td>In adults, BOO is the most common pre-disposing factor for bladder stone formation.</td>
<td>2c</td>
</tr>
<tr>
<td>Of men undergoing surgery for BPO, 3-4.7% form bladder stones.</td>
<td>2b</td>
</tr>
<tr>
<td>Metabolic abnormalities are also likely to contribute to bladder stone formation in patients with secondary bladder stones.</td>
<td>2b</td>
</tr>
<tr>
<td>Primary (endemic) bladder stones typically occur in children in areas with poor hydration, recurrent diarrhoea, and a diet deficient in animal protein. The following measures are proposed to reduce their incidence: maintenance of hydration, avoidance of diarrhoea, and a mixed cereal diet with milk and Vitamins A and B supplements; with the addition of eggs, meat, and boiled cows’ milk after one year of age.</td>
<td>5</td>
</tr>
<tr>
<td>In adults, US has a sensitivity of 20-83% for diagnosing bladder stones.</td>
<td>2b</td>
</tr>
<tr>
<td>In adults, X-ray-KUB has a sensitivity of 21-78%; sensitivity increases with stone size.</td>
<td>2b</td>
</tr>
<tr>
<td>Computed tomography has a higher sensitivity than US for the detection of bladder stones.</td>
<td>2b</td>
</tr>
<tr>
<td>Cystoscopy has a higher sensitivity than X-ray-KUB or US for the detection of bladder stones.</td>
<td>2b</td>
</tr>
<tr>
<td>Endoscopic bladder stone treatments (trans-urethral or percutaneous) are associated with comparable SFRs, but a shorter length of hospital stay, duration of procedure and duration of catheterisation compared to open cystolithotomy in adults.</td>
<td>1a</td>
</tr>
<tr>
<td>Stone-free rates are lower in patients treated with SWL than those treated with open or endoscopic procedures in both adults and children.</td>
<td>2a</td>
</tr>
<tr>
<td>Transurethral cystolithotripsy is associated with a shorter length of hospital stay, less pain and a shorter convalescence period than percutaneous cystolithotripsy in adults.</td>
<td>1b</td>
</tr>
<tr>
<td>Transurethral cystolithotripsy with a nephroscope is quicker than when using a cystoscope with no difference in SFR in adults.</td>
<td>1a</td>
</tr>
<tr>
<td>Transurethral cystolithotripsy with a resectoscope is quicker than when using a cystoscope with no difference in SFR in adults.</td>
<td>2a</td>
</tr>
<tr>
<td>Mechanical, pneumatic and laser appear equivalent lithotripsy modalities for use in endoscopic bladder stone treatments in adults and children.</td>
<td>2a</td>
</tr>
<tr>
<td>Open cystolithotomy without a retropubic drain or urethral catheter (“tubeless”) is associated with a shorter length of hospital stay than traditional cystolithotomy and can be performed safely in children with primary stones and no prior bladder surgery or infections.</td>
<td>2b</td>
</tr>
</tbody>
</table>
Bladder stone removal with concomitant treatment for BOO is associated with no significant difference in major post-operative complications when compared to BOO treatment alone in adults. However, concomitant bladder stone treatment does increase the rates of short-term post-operative incontinence and UTI.

The incidence of bladder stone formation in spinal cord injury patients is 19-67% over time. The absolute annual risk of stone formation in spinal cord injury patients is significantly higher with an indwelling catheter compared to those voiding with CISC or spontaneously.

The incidence of bladder stone formation after bladder augmentation or vesico-entero-cystostomy is between 2-53% in adults and children.

Urinary diversion including orthotopic ileal neobladders, ileocaecal continent cutaneous urinary diversion and rectosigmoid reservoirs is associated with urinary reservoir stone formation in 0-43%.

The risk of bladder stone formation in spinal cord injury, bladder augmentation or continent urinary diversion patients is reduced by performing regular bladder irrigation.

| All patients with bladder stones should be examined and investigated for the cause of bladder stone formation, including:  
  • uroflowmetry and post-void residual;  
  • urine dipstick, pH, ± culture;  
  • metabolic assessment and stone analysis (see sections 3.3.2.3 and 4.1 of the Urolithiasis guidelines for further details). In selected patients, consider:  
  • upper tract imaging (in patients with a history of urolithiasis or loin pain);  
  • cysto-urethroscopy or urethrogram. | Weak |
| Offer oral chemolitholysis for radiolucent or known uric acid bladder stones in adults. | Weak |
| Offer adults with bladder stones transurethral cystolithotripsy where possible. | Strong |
| Perform transurethral cystolithotripsy with a continuous flow instrument in adults (e.g., nephroscope or resectoscope) where possible. | Weak |
| Offer adults percutaneous cystolithotripsy where transurethral cystolithotripsy is not possible or advisable. | Strong |
| Suggest open cystolithotomy as an option for very large bladder stones in adults and children. | Weak |
| Offer children with bladder stones transurethral cystolithotripsy where possible. | Weak |
| Offer children percutaneous cystolithotripsy where transurethral cystolithotripsy is not possible or is associated with a high risk of urethral stricture (e.g., young children, previous urethral reconstruction, and spinal cord injury). | Weak |
| Open, laparoscopic, and extracorporeal shock wave lithotripsy are alternative treatments where endoscopic treatment is not advisable in adults and children. | Weak |
| Prefer “tubeless” procedure (without placing a catheter or drain) for children with primary bladder stones and no prior infection, surgery, or bladder dysfunction where open cystolithotomy is indicated. | Weak |
| Individualise imaging follow up for each patient as there is a paucity of evidence. Factors affecting follow up will include:  
  • whether the underlying functional predisposition to stone formation can be treated (e.g., TURP);  
  • metabolic risk. | Weak |
| Recommend regular irrigation therapy with saline solution to adults and children with bladder augmentation, continent cutaneous urinary reservoir or neuropathic bladder dysfunction, and no history of autonomic dysreflexia, to reduce the risk of stone recurrence. | Weak |

8. CONFLICT OF INTEREST

All members of the Urolithiasis Guidelines Panel have provided disclosure statements of all relationships that they have that might be perceived as a potential source of a conflict of interest. This information is publicly accessible through the European Association of Urology website: http://www.uroweb.org/guidelines/. This guidelines document was developed with the financial support of the European Association of Urology. No external sources of funding and support have been involved. The EAU is a non-profit organisation and funding is limited to administrative assistance and travel and meeting expenses. No honoraria or other reimbursements have been provided.
9. CITATION INFORMATION

The format in which to cite the EAU Guidelines will vary depending on the style guide of the journal in which the citation appears. Accordingly, the number of authors or whether, for instance, to include the publisher, location, or an ISBN number may vary.

The compilation of the complete Guidelines should be referenced as:

If a publisher and/or location is required, include:

References to individual guidelines should be structured in the following way:
Contributors’ names. Title of resource. Publication type. ISBN. Publisher and publisher location, year.
