European Association of Urology Guidelines 2022

Introduction

Over the course of the past year, we have continued to face a truly unprecedented healthcare crisis. The COVID-19 pandemic has continued to test the resources and capacity of health systems around the world and our normal working patterns have been radically altered. Despite these challenges, the EAU Guidelines Office has continued to function and we are honoured to present the 2022 edition of the European Association of Urology (EAU) Guidelines. We would like to take this opportunity to thank all members of the Guidelines Office who have worked tirelessly over the course of the past twelve months to make this update possible. The EAU Guidelines remain the most comprehensive, continuously updated, guidelines available for urologists and clinicians from related specialties.

For the 2022 edition of the EAU Guidelines, a number of Guidelines have expanded with the addition of new sections or completed comprehensive updates of specific sections resulting in new and updated recommendations. Highlights from this year’s Guidelines include new sections on: urinary incontinence in males in the Management of Non-neurogenic Male LUTS Guidelines; bladder tumours in eosinophilic cystitis and nephrogenic adenoma in the Paediatric Urology Guidelines; follow-up with supporting algorithms in the Urolithiasis Guidelines; and paratesticular tumours in the Testicular Cancer Guidelines. In addition, major updates have been made to the recurrent UTI section in the Urological Infections Guidelines as well as the metastatic disease sections of the EAU Oncology Guidelines.

The impact of the EAU Guidelines is underpinned not only by a stringent methodology, but also by the multidisciplinary nature of the panels including the involvement of patient representatives. The EAU Guidelines Office is committed to ensuring that patient engagement is meaningful and that patients receive training and are equipped with the necessary skills to allow them to effectively contribute to guidelines development. To realise this ambition the Guidelines Office has defined a model for patient participation in guidelines development supported by a number of recommendations to guide the panels in how they can achieve effective patient engagement. To support the panels in this initiative the Guidelines Office has also produced a patient role description, patient-specific handbook and patient-dedicated training module. The first two patient training sessions were held last year and we continue to actively recruiting patient representatives across all panels.

Last year also saw the continued growth of a number of Guidelines Office coordinated projects. The IMAGINE project aimed at measuring baseline adherence to EAU Guidelines recommendations across Europe with the support of the European National Urological Societies concluded its pilot study collecting adherence data on more than 6,500 patients across 196 centres. The Big Data for better outcomes for prostate cancer project PIONEER entered its fourth year with harmonised data on more than 3.5 million prostate cancer patients available in the PIONEER platform. Last year also saw the successful launch of OPTIMA an EAU Guidelines Office Coordinated Innovative Medicines Initiative project aimed at building a state-of-the-art Big Data analytic platform for the development of dynamic computer-interpretable guidelines for breast, lung & prostate cancer.

The yearly publication of the EAU Guidelines would not be possible without the unwavering support of the EAU Executive Committee and Management team, our highly valued Guidelines Panels and young Guidelines Associates, the Guidelines Office staff members, our EAU membership and every user of the Guidelines globally. So, on behalf of the EAU Guidelines Office Board, thank you for your support and inspiration.

We hope you enjoy using the 2022 update of the EAU Guidelines!

Prof. Dr. Maria Ribal
Chair EAU Guidelines Office
The EAU Guidelines Office has set up dedicated Committees responsible for critical aspects of guidelines development.

**EAU Guidelines Office Methods Committee**

Ms. C. Bezuidenhout, Arnhem (NL)
Mrs. S. Lina, Arnhem (NL)
**Methodology section**

Clinical guidelines development is one of the core activities of the European Association of Urology (EAU), with the 2022 Guidelines covering the majority of the urological field. The EAU clinical guidelines, which are updated based on systematic reviews (SRs) of the available clinical evidence, are developed to support clinicians in making informed choices in their care of patients within a shared decision-making framework with patients.

The Guidelines Office (GO), consisting of more than 300 clinicians, is responsible for the production of these documents. Their efforts are supported by a number of expert Committees, each with specific tasks and responsibilities.

The EAU GO unified production methodology aims to:
- ensure scientific quality, accuracy and currency of information;
- promote sustainable quality improvement;
- contribute to the dissemination and effective implementation of all EAU Guidelines publications.

All EAU Guidelines can be accessed online through the Association website: www.uroweb.org/guidelines/. The EAU Guidelines Office Methodology Handbook is also available online: https://uroweb.org/guidelines/policies-and-methodological-documents/. A mobile app containing the Pocket guidelines is available for download for both iOS and Android devices.

**Systematic Review development**

The EAU GO have set up a management structure to support development of SRs involving young clinicians (Guidelines Associates) who are supported by methodologists and statisticians. These SRs are based on clinical questions prioritised by the Guideline Panel responsible for each topic and their findings are incorporated into the EAU guidelines as they become available. Benefits and harms of interventions are addressed in detail, both in the development stage of the clinical question and when review findings are being incorporated, and treatment recommendations formulated. Whenever possible, patient input is sought at both the development stage of the SR questions as well as when guidelines recommendations are being drafted. Patient organisations are invited to take part in review of the EAU Guidelines documents prior to publication. This is an ongoing programme, with the ambition to address the majority of key clinical questions covered by the EAU guidelines.

All SRs are performed using standard Cochrane SR methodology: (http://www.cochranelibrary.com/about/about-cochrane-systematic-reviews.html). Two independent reviewers screen abstracts and full texts, carry out data abstraction, assess risk of bias and do a GRADING exercise [1-4]. The results are presented in tables showing baseline characteristics and summaries of findings. Meta-analyses are performed only as part of a SR when several randomised controlled trials have addressed the same question and outcomes are reported homogenously. For lower-level data, narrative syntheses of the evidence are provided. The Preferred Reporting Items for SRs and Meta-Analyses (PRISMA) guidance is followed [5].

Independently of these SRs, each Guideline Panel has undertaken a separate systematic search, tailored to their individual guideline. These are broad searches (Scope/Horizon searches) which are developed to:
- ensure that the available clinical evidence is identified in a structured unbiased fashion;
- ensure that significant data are not missed;
- inform on the need to update guidelines documents;
- identify gaps in the literature and prioritise future systematic review activities.

The results of these searches are selected and assessed in a structured fashion by Guideline Associates and Guideline Panel members, although no detailed evidence summaries are produced. The search histories are available online in the Appendices and Publications sections of each guideline topic (www.uroweb.org/guidelines/).
Level of evidence and grading systems

For each recommendation within the guidelines there is an accompanying online strength rating form, the basis of which is a modified GRADE methodology [3, 4]. Each strength rating form addresses a number of key elements namely:

1. the overall quality of the evidence which exists for the recommendation, references used in this text are graded according to a classification system modified from the Oxford Centre for Evidence-Based Medicine Levels of Evidence [6];
2. the magnitude of the effect (individual or combined effects);
3. the certainty of the results (precision, consistency, heterogeneity and other statistical or study related factors);
4. the balance between desirable and undesirable outcomes;
5. the impact of patient values and preferences on the intervention;
6. the certainty of those patient values and preferences.

These key elements are the basis which panels use to define the strength rating of each recommendation. The strength of each recommendation is determined by the balance between desirable and undesirable consequences of alternative management strategies, the quality of the evidence (including certainty of estimates), and nature and variability of patient values and preferences.

Table 1: Level of evidence*

<table>
<thead>
<tr>
<th>Level</th>
<th>Type of evidence</th>
</tr>
</thead>
<tbody>
<tr>
<td>1a</td>
<td>Evidence obtained from meta-analysis of randomised trials.</td>
</tr>
<tr>
<td>1b</td>
<td>Evidence obtained from at least one randomised trial.</td>
</tr>
<tr>
<td>2a</td>
<td>Evidence obtained from one well-designed controlled study without randomisation.</td>
</tr>
<tr>
<td>2b</td>
<td>Evidence obtained from at least one other type of well-designed quasi-experimental study.</td>
</tr>
<tr>
<td>3</td>
<td>Evidence obtained from well-designed non-experimental studies, such as comparative studies, correlation studies and case reports.</td>
</tr>
<tr>
<td>4</td>
<td>Evidence obtained from expert committee reports or opinions or clinical experience of respected authorities.</td>
</tr>
</tbody>
</table>

The EAU Guidelines Office is most grateful for the continued support of the European Board of Urology.
Acknowledgement of reviewers – 2022 edition of the EAU Guidelines

Reviewers were identified based on their expert knowledge within the urological field and bordering specialities. The EAU Guidelines Board is most grateful for their time and diligence in providing complete and extensive reviews of the individual EAU Guidelines. Whenever feasible, feedback from lay reviewers and patient advocacy groups has been sought.

11. CITATION INFORMATION
1. INTRODUCTION

1.1 Aim and scope
This overview represents the updated European Association of Urology (EAU) Guidelines for Non-muscle-invasive Bladder Cancer (NMIBC), TaT1 and carcinoma in situ (CIS). The information presented is limited to urothelial carcinoma, unless specified otherwise. The aim is to provide practical recommendations on the clinical management of NMIBC with a focus on clinical presentation and recommendations.

Separate EAU Guidelines documents are available addressing upper tract urothelial carcinoma (UTUC) [1], muscle-invasive and metastatic bladder cancer (MIBC) [2] and primary urethral carcinoma [3]. It must be emphasised that clinical guidelines present the best evidence available to the experts, but following guideline recommendations will not necessarily result in the best outcome. Guidelines can never replace clinical expertise when making treatment decisions for individual patients, but rather help to focus decisions - also taking personal values and references/individual circumstances of patients into account. Guidelines are not mandates and do not purport to be a legal standard of care.

1.2 Panel composition
The EAU Guidelines Panel on NMIBC consists of an international multidisciplinary group of clinicians, including urologists, uro-oncologists, a pathologist, and a statistician. Members of this Panel have been selected based on their expertise and to represent the professionals treating patients suspected of suffering from bladder cancer. In the course of 2021 two patient representatives have formally joined the NMIBC Panel. All experts involved in the production of this document have submitted potential conflict of interest statements which can be viewed on the EAU website Uroweb: https://uroweb.org/guideline/non-muscle-invasive-bladder-cancer/.

1.3 Available publications
A quick reference document (Pocket guidelines) is available, both in print and as an app for iOS and Android devices. These are abridged versions which may require consultation together with the full text version. Several scientific publications are available, the latest publication dating to 2022 [4], as are a number of translations of all versions of the EAU NMIBC Guidelines. All documents are accessible through the EAU website Uroweb: https://uroweb.org/guideline/non-muscle-invasive-bladder-cancer/.

1.4 Publication history and summary of changes

1.4.1 Publication history
The EAU Guidelines on Bladder Cancer were first published in 2000. This 2022 NMIBC Guidelines document presents a limited update of the 2021 publication.

1.4.2 Summary of changes
Additional data has been included throughout this document text. In particular in Chapters/Sections:

- 5.4 Imaging – with the introduction of Vesical Imaging-Reporting and Data System [VI-RADS].
- 5.7.3 Surveillance of non-muscle-invasive bladder cancer – inclusion of urine biomarkers in a surveillance strategy of an individual patient.
- 5.8 Cystoscopy – inclusion of the procedural chance (‘bag squeeze’). The recommendation was amended accordingly.

<table>

2. METHODS

2.1 Data Identification

For the 2022 NMIBC Guidelines, new and relevant evidence has been identified, collated, and appraised through a structured assessment of the literature.

A broad and comprehensive scoping exercise covering all areas of the NMIBC Guidelines was performed. Excluded from the search were basic research studies, case series, reports, and editorial comments. Only articles published in the English language, addressing adults, were included. The search was restricted to articles published between May 29th 2020 and June 3rd 2021. Databases covered by the search included PubMed, Ovid, EMBASE and the Cochrane Central Register of Controlled Trials and the Cochrane Database of Systematic Reviews. After deduplication, a total of 1,463 unique records were identified, retrieved, and screened for relevance.

A total of 40 new references were added to the 2022 NMIBC Guidelines. A detailed search strategy is available online: https://uroweb.org/guideline/non-muscle-invasive-bladder-cancer/?type=appendices-publications.

For Chapters 3 through 6 (Epidemiology, Aetiology and Pathology, Staging and Classification systems, Diagnosis, Predicting disease recurrence and progression) the references used in this text were assessed according to their level of evidence (LE) based on the 2009 Oxford Centre for Evidence-Based Medicine (CEBM) Levels of Evidence [5]. For the Disease Management and Follow-up chapters (Chapters 7 and 8) a system modified from the 2009 CEBM levels of evidence was used [5].

For each recommendation within the guidelines there is an accompanying online strength rating form based on a modified GRADE methodology [6, 7]. Each strength rating form addresses a number of key elements namely:

1. the overall quality of the evidence which exists for the recommendation [5];
2. the magnitude of the effect (individual or combined effects);
3. the certainty of the results (precision, consistency, heterogeneity and other statistical or study related factors);
4. the balance between desirable and undesirable outcomes;
5. the impact of patient values and preferences on the intervention;
6. the certainty of those patient values and preferences.
These key elements are the basis which panels use to define the strength rating of each recommendation. The strength of each recommendation is represented by the words ‘strong’ or ‘weak’ [8]. The strength of each recommendation is determined by the balance between desirable and undesirable consequences of alternative management strategies, the quality of the evidence (including certainty of estimates), and nature and variability of patient values and preferences.

Additional information can be found in the general Methodology section of this print, and online at the EAU website; http://www.uroweb.org/guideline/. A list of associations endorsing the EAU Guidelines can also be viewed online at the above address.

2.2 Review
The 2021 publication was peer reviewed prior to print.

2.3 Future goals
The findings of the ongoing ‘Individual Patient Data Validation of the Definition of bacillus Calmette-Guérin (BCG) Failure/BCG Unresponsive in Patients with Non-muscle Invasive Urothelial Carcinoma of the Bladder: an international multicentre retrospective study’ will be included in the future update of the NMIBC Guidelines.

3. EPIDEMIOLOGY, AETIOLOGY AND PATHOLOGY

3.1 Epidemiology
Bladder cancer (BC) is the seventh most commonly diagnosed cancer in the male population worldwide, while it drops to tenth when both genders are considered [9]. The worldwide age-standardised incidence rate (per 100,000 person/years) is 9.5 in men and 2.4 in women [9]. In the European Union the age-standardised incidence rate is 20 for men and 4.6 for women [9].

Worldwide, the BC age-standardised mortality rate (per 100,000 person/years) was 3.3 for men vs. 0.86 for women [9]. Bladder cancer incidence and mortality rates vary across countries due to differences in risk factors, detection and diagnostic practices, and availability of treatments. The variations are, however, partly caused by the different methodologies used and the quality of data collection [10]. The incidence and mortality of BC has decreased in some registries, possibly reflecting the decreased impact of causative agents [11].

Approximately 75% of patients with BC present with a disease confined to the mucosa (stage Ta, CIS) or submucosa (stage T1); in younger patients (< 40 years of age) this percentage is even higher [12]. Patients with TaT1 and CIS have a high prevalence due to long-term survival in many cases and lower risk of cancer-specific mortality compared to T2-4 tumours [9, 10].

3.2 Aetiology
Tobacco smoking is the most important risk factor for BC, accounting for approximately 50% of cases [10, 11, 13-15] (LE: 3). The risk of BC increases with smoking duration and smoking intensity [14]. Low-tar cigarettes are not associated with a lower risk of developing BC [14]. The risk associated with electronic cigarettes is not adequately assessed; however, carcinogens have been identified in urine [16]. Environmental exposure to tobacco smoke is also associated with an increased risk of BC [10]. Tobacco smoke contains aromatic amines and polycyclic aromatic hydrocarbons, which are renally excreted.

Occupational exposure to aromatic amines, polycyclic aromatic hydrocarbons and chlorinated hydrocarbons is the second most important risk factor for BC, accounting for about 10% of all cases. This type of occupational exposure occurs mainly in industrial plants which process paint, dye, metal, and petroleum products [10, 11, 17, 18]. In developed industrial settings these risks have been reduced by work-safety guidelines; therefore, chemical workers no longer have a higher incidence of BC compared to the general population [10, 17, 18]. Recently, greater occupational exposure to diesel exhaust has been suggested as a significant risk factor (odds ratio [OR]: 1.61; 95% confidence interval [CI]: 1.08–2.40) [19].

While family history seems to have little impact [20] and, to date, no overt significance of any genetic variation for BC has been shown; genetic predisposition has an influence on the incidence of BC via its impact on susceptibility to other risk factors [10, 21-25]. This has been suggested to lead to familial clustering of BC with an increased risk for first- and second-degree relatives (hazard ratio [HR]: 1.69; 95% CI: 1.47–1.95) [26].

Although the impact of drinking habits is uncertain, the chlorination of drinking water and subsequent levels of trihalomethanes are potentially carcinogenic, also exposure to arsenic in drinking water
increases risk [10, 27] (LE: 3). Arsenic intake and smoking have a combined effect [28]. The association between personal hair dye use and risk remains uncertain; an increased risk has been suggested in users of permanent hair dyes with a slow NAT2 acetylation phenotype [10] but a large prospective cohort study could not identify an association between hair dye and risk of most cancer and cancer-related mortality [29]. Dietary habits seem to have limited impact, recently protective impact of flavonoids has been suggested and a Mediterranean diet, characterised by a high consumption of vegetables and non-saturated fat (olive oil) and moderate consumption of protein, was linked to some reduction of BC risk (HR: 0.85, 95% CI: 0.77–0.93) [30-35]. The impact of an increased consumption of fruits has been suggested to reduce the risk of BC; to date, this effect has been demonstrated to be significant in women only (HR: 0.92; 95% CI: 0.85–0.99) [36].

Exposure to ionizing radiation is connected with increased risk; a weak association was also suggested for cyclophosphamide and pioglitazone [10, 27, 37] (LE: 3). The impact of metabolic factors (body mass index, blood pressure, plasma glucose, cholesterol, and triglycerides) is uncertain [38]. Schistosomiasis, a chronic endemic cystitis based on recurrent infection with a parasitic trematode, is also a cause of BC [10] (LE: 3).

3.3 Pathology
The information presented in this text is limited to urothelial carcinoma, unless otherwise specified.

4. PATHOLOGICAL STAGING AND CLASSIFICATION SYSTEMS

4.1 Definition of non-muscle-invasive bladder cancer
Tumours confined to the mucosa and invading the lamina propria are classified as stage Ta and T1, respectively, according to the Tumour, Node, Metastasis (TNM) classification system [39]. Intra-epithelial, high-grade (HG) tumours confined to the mucosa are classified as CIS (Tis). All of these tumours can be treated by transurethral resection of the bladder (TURB), eventually in combination with intravesical instillations and are therefore grouped under the heading of NMIBC for therapeutic purposes. The term ‘Non-muscle-invasive BC’ represents a group definition and all tumours should be characterised according to their stage, grade, and further pathological characteristics (see Sections 4.5 and 4.7 and the International Collaboration on Cancer Reporting website: http://www.iccr-cancer.org/datasets/published-datasets/urinary-male-genital/bladder. The term ‘superficial BC’ should no longer be used as it is incorrect.

4.2 Tumour, Node, Metastasis Classification (TNM)
The latest TNM classification approved by the Union International Contre le Cancer (UICC) (8th Edn.) is referred to (Table 4.1) [39].

Table 4.1: 2017 TNM classification of urinary bladder cancer

</tbody>
</table>
T3 Tumour invades perivesical tissue
   T3a Microscopically
   T3b Macroscopically (extravesical mass)

T4 Tumour invades any of the following: prostate stroma, seminal vesicles, uterus, vagina pelvic wall, abdominal wall
   T4a Tumour invades prostate stroma, seminal vesicles, uterus or vagina
   T4b Tumour invades pelvic wall or abdominal wall

N – Regional lymph nodes
NX Regional lymph nodes cannot be assessed
N0 No regional lymph node metastasis
N1 Metastasis in a single lymph node in the true pelvis (hypogastric, obturator, external iliac, or presacral)
N2 Metastasis in multiple regional lymph nodes in the true pelvis (hypogastric, obturator, external iliac, or presacral)
N3 Metastasis in common iliac lymph node(s)

M - Distant metastasis
M0 No distant metastasis
M1a Non-regional lymph nodes
M1b Other distant metastases

4.3 T1 subclassification
The depth and extent of invasion into the lamina propria (T1 sub-staging) has been demonstrated to be of prognostic value in retrospective cohort studies [40, 41] (LE: 3). Its use is recommended by the most recent 2016 World Health Organization (WHO) classification [42]. T1 sub-staging methods are based either on micrometric (T1e and T1m) or histo-anatomic (T1a and T1b) principles; the optimal classification system, however, remains to be defined [42, 43].

4.4 Carcinoma in situ and its classification
Carcinoma in situ is a flat, HG, non-invasive urothelial carcinoma. It can be missed or misinterpreted as an inflammatory lesion during cystoscopy if not biopsied. Carcinoma in situ is often multifocal and can occur in the bladder, but also in the upper urinary tract (UUT), prostatic ducts, and prostatic urethra [44].

From a clinical point of view, CIS may be classified as [45]:
- Primary: isolated CIS with no previous or concurrent papillary tumours and no previous CIS;
- Secondary: CIS detected during follow-up of patients with a previous tumour that was not CIS;
- Concurrent: CIS in the presence of any other urothelial tumour in the bladder.

4.5 Histological grading of non-muscle-invasive bladder urothelial carcinomas

4.5.1 Types of histological grading systems
In 2004 the WHO published a histological classification system for urothelial carcinomas including papillary urothelial neoplasm of low malignant potential (PUNLMP), non-invasive papillary carcinoma low grade (LG) and HG. This system was also taken into the updated 2016 WHO classification and will be maintained in the upcoming WHO 2022. It provides a different patient stratification between individual categories compared to the older 1973 WHO classification, which distinguished between grade 1 (G1), grade 2 (G2) and grade 3 (G3) categories [42, 46].

There is a significant shift of patients between the categories of the WHO 1973 and the WHO 2004/2016 systems (see Figure 4.1), for example an increase in the number of HG patients (WHO 2004/2016) due to inclusion of a subset of G2 patients with a favourable prognosis compared to the G3 category (WHO 1973) [47]. According to a multi-institutional individual patient data (IPD) analysis, the proportion of tumours classified as PUNLMP (WHO 2004/2016) has decreased to very low levels in the last decade [48].

4.5.2 Prognostic value of histological grading
A systematic review and meta-analysis did not show that the 2004/2016 classification outperforms the 1973 classification in prediction of recurrence and progression [47] (LE: 2a).

To compare the prognostic value of both WHO classifications, an IPD analysis of 5,145 primary TaT1 NMIBC patients from 17 centres throughout Europe and Canada was conducted. Patients had a transurethral resection of bladder tumour (TURBT) followed by intravesical instillations at the physician’s discretion. In this large prognostic factor study, the WHO 1973 and the WHO 2004/2016 were both prognostic for progression but not for recurrence. When compared, the WHO 1973 was a stronger prognosticator of progression in TaT1 NMIBC than the WHO 2004/2016. However, a 4-tier combination LG/G1, LG/G2, HG/G2 and HG/G3 of both classification systems proved to be superior to either classification system alone, as it divides the large group of G2 patients into two subgroups (LG/HG) with different prognoses [49].
In a subgroup of 3,311 patients with primary Ta bladder tumours, a similar prognosis was found for PUNLMP and Ta LG carcinomas [50]. Hence, these results do not support the continued use of PUNLMP as a separate grade category in the WHO 2004/2016.

4.5.3 Clinical application of histological grading systems
- The WHO 2016 classification system is currently supported by the WHO for clinical application, nevertheless, the WHO 1973 is still being used by some pathologists.
- The most important parameters, which must be considered for clinical application of any grading system are its inter-observer reproducibility and prognostic value (see Sections 4.5.1 and 4.6).
- To facilitate the clinical utilisation in daily practice, these guidelines provide recommendations for tumours classified by both classification systems.

*1973 WHO G1 carcinomas have been reassigned to papillary urothelial neoplasm of low malignant potential (PUNLMP) and LG carcinomas in the 2004/2016 WHO classification, and G2 carcinomas to LG and HG carcinomas. All 1973 WHO G3 carcinomas have been reassigned to HG carcinomas.
PUNLMP is a non-invasive neoplasm and therefore considered stage pTa in the AJCC/UICC staging systems (Figure reproduced with permission from Elsevier).

4.6 Inter- and intra-observer variability in staging and grading
There is significant variability among pathologists for the diagnosis of CIS, for which agreement is achieved in only 70–78% of cases [52] (LE: 2a). There is also inter-observer variability in the classification of stage T1 vs. Ta tumours and tumour grading in both the 1973 and 2004/2016 classifications. The general conformity between pathologists in staging and grading is 50–60% [53-56] (LE: 2a). The WHO 2004/2016 classification provides slightly better reproducibility than the 1973 classification [47].

4.7 Subtypes of urothelial carcinoma and lymphovascular invasion
Currently the following differentiations of urothelial carcinoma are used [57, 58]:
1. urothelial carcinoma (more than 90% of all cases);
2. urothelial carcinomas with partial squamous and/or glandular or trophoblastic differentiation;
3. micropapillary urothelial carcinoma;
4. nested variant (including large nested variant) and micropapillary urothelial carcinoma;
5. plasmacytoid, giant cell, signet ring, diffuse, undifferentiated;
6. lymphoepithelioma-like;
7. small-cell carcinomas;
8. sarcomatoid urothelial carcinoma;
9. neuroendocrine variant of urothelial carcinoma;
10. some urothelial carcinomas with other rare differentiations.

Most variants of urothelial carcinoma have a worse prognosis than pure HG urothelial carcinoma [2, 59-66] (LE: 3).
The presence of lymphovascular invasion (LVI) in TURB specimens is associated with an increased risk of pathological upstaging and worse prognosis [67-71] (LE: 3).

4.8 Tumour markers and molecular classification
Tumour markers and their prognostic role have been investigated [72-76]. These methods, in particular complex approaches such as the stratification of patients based on molecular classification, are promising but are not yet suitable for routine application [43, 77, 78].

5. DIAGNOSIS

5.1 Patient history
A focused patient history is mandatory.

5.2 Signs and symptoms
Haematuria is the most common finding in NMIBC. Visible haematuria was found to be associated with higher-stage disease compared to nonvisible haematuria [79]. Carcinoma in situ might be suspected in patients with lower urinary tract symptoms, especially irritative voiding symptoms.

5.3 Physical examination
A focused urological examination is mandatory although it does not reveal NMIBC.

5.4 Imaging
5.4.1 Computed tomography urography and intravenous urography
Computed tomography (CT) urography is used to detect papillary tumours in the urinary tract, indicated by filling defects and/or hydronephrosis [80].

Intravenous urography (IVU) is an alternative if CT is not available [81] (LE: 2b), but particularly in muscle-invasive tumours of the bladder and in UTUCs, CT urography provides more information (including status of lymph nodes and neighbouring organs).

The necessity to perform a baseline CT urography once a bladder tumour has been detected is questionable due to the low incidence of significant findings which can be obtained [82-84] (LE: 2b). The incidence of UTUCs is low (1.8%), but increases to 7.5% in tumours located in the trigone [83] (LE: 2b). The risk of UTUC during follow-up increases in patients with multiple and high-risk tumours [85] (LE: 2b).

5.4.2 Ultrasound
Ultrasound (US) may be performed as an adjunct to physical examination as it has moderate sensitivity to a wide range of abnormalities in the upper- and lower urinary tract. It permits characterisation of renal masses, detection of hydronephrosis, and visualisation of intraluminal masses in the bladder, but cannot rule out all potential causes of haematuria [86, 87] (LE: 3). It cannot reliably exclude the presence of UTUC and cannot replace CT urography.
5.4.3 Multi-parametric magnetic resonance imaging

The role of multi-parametric magnetic resonance imaging (mpMRI) has not yet been established in BC diagnosis and staging. A standardised methodology of MRI reporting (Vesical Imaging-Reporting and Data System [VI-RADS]) in patients with BC has recently been published and requires further validation [88]. A first systematic review of 8 studies showed that the VI-RADS scoring system can accurately differentiate NMIBC from MIBC with high inter-observer agreement rates [89].

A diagnosis of CIS cannot be made with imaging methods alone (CT urography, IVU, US or MRI) (LE: 4).

5.5 Urinary cytology

The examination of voided urine or bladder-washing specimens for exfoliated cancer cells has high sensitivity in HG and G3 tumours (84%), but low sensitivity in LG/G1 tumours (16%) [90]. The sensitivity in CIS detection is 28–100% [91] (LE: 1b). Cytology is useful, particularly as an adjunct to cystoscopy, in patients with HG/G3 tumours. Positive voided urinary cytology can indicate an urothelial carcinoma anywhere in the urinary tract; negative cytology, however, does not exclude its presence.

Cytological interpretation is user-dependent [92, 93]. Evaluation can be hampered by low cellular yield, urinary tract infections, stones, or intravesical instillations, however, in experienced hands specificity exceeds 90% [92] (LE: 2b).

A standardised reporting system known as The Paris System published in 2016 redefined urinary cytology diagnostic categories as follows [94]:

- No adequate diagnosis possible (No diagnosis);
- Negative for urothelial carcinoma (Negative);
- Atypical urothelial cells (Atypia);
- Suspicious for HG urothelial carcinoma (Suspicious);
- High-grade/G3 urothelial carcinoma (Malignant).

The principle of the system and its terminology underlines the role of urinary cytology in detection of G3 and HG tumours. The Paris system for reporting urinary cytology has been validated in several retrospective studies [95, 96].

Urine collection should respect the recommendation provided in Section 5.9. One cytospin slide from the sample is usually sufficient [97]. In patients with suspicious cytology repeat investigation is advised [98] (LE: 2b).

5.6 Urinary molecular marker tests

Driven by the low sensitivity of urine cytology, numerous urinary tests have been developed [99]. None of these markers have been accepted as routine practice by any clinical guidelines for diagnosis or follow-up.

The following conclusions can be drawn regarding the existing tests:

- Sensitivity is usually higher at the cost of lower specificity compared to urine cytology [100-105] (LE: 3).
- Benign conditions and previous BCG instillations may influence the results of many urinary marker tests [100-102] (LE: 1b).
- Requirements for sensitivity and specificity of a urinary marker test largely depend on the clinical context of the patient (screening, primary detection, follow-up [high-risk, low/intermediate-risk]) [101, 102] (LE: 3).
- The wide range in performance of the markers and low reproducibility may be explained by patient selection and complicated laboratory methods required [102, 103, 106-113].
- Positive results of cytology, UroVysion (FISH), Nuclear Matrix Protein (NMP)22®, Fibroblast Growth Factor Receptor (FGFR)/3/Telomerase Reverse Transcriptase (TERT) and microsatellite analysis in patients with negative cystoscopy and upper tract work-up, may identify patients more likely to experience disease recurrence and possibly progression [107, 109, 112-117] (LE: 2b).
- Promising novel urinary biomarkers, assessing multiple targets, have been tested in prospective multicentre studies [106, 108, 112, 118-121].

5.7 Potential application of urinary cytology and markers

The following objectives of urinary cytology or molecular tests must be considered.

5.7.1 Screening of the population at risk of bladder cancer

The application of haematuria dipstick, followed by FGFR3, NMP22® or UroVysion tests if dipstick is positive has been reported in BC screening in high-risk populations [122, 123]. The low incidence of BC in the general population and the short lead-time impair feasibility and cost-effectiveness [115, 123]. Routine screening for BC is not recommended [115, 122, 123].
5.7.2 **Exploration of patients after haematuria or other symptoms suggestive of bladder cancer (primary detection)**

It is generally accepted that none of the currently available tests can replace cystoscopy. However, urinary cytology or biomarkers can be used as an adjunct to cystoscopy to detect missed tumours, particularly CIS. In this setting, specificity is particularly important.

5.7.3 **Surveillance of non-muscle-invasive bladder cancer**

Research has been carried out into the usefulness of urinary cytology vs. markers in the follow-up of NMIBC [106, 107, 119, 120, 124].

5.7.3.1 **Follow-up of high-risk non-muscle-invasive bladder cancer**

High-risk tumours should be detected early in follow-up and the percentage of tumours missed should be as low as possible. Therefore, the best surveillance strategy for these patients will continue to include cystoscopy and cytology (see Chapter 8).

5.7.3.2 **Follow-up of low/intermediate-risk non-muscle-invasive bladder cancer**

To reduce the number of cystoscopy procedures, urinary markers should be able to detect recurrence before the tumours are large, numerous and muscle invasive. The limitation of urinary cytology and current urinary markers is their low sensitivity for LG recurrences [101, 107] (LE: 1b).

According to current knowledge, no urinary marker can replace cystoscopy during follow-up or lower cystoscopy frequency in a routine fashion. One prospective randomised study (RCT) found that knowledge of positive test results (microsatellite analysis) can improve the quality of follow-up cystoscopy [125] (LE: 1b), supporting the adjunctive role of a non-invasive urine test performed prior to follow-up cystoscopy [125] (see Section 8.1).

Four of the promising and commercially available urine biomarkers, Cx-Bladder [106, 121], ADX-Bladder [118], Xpert Bladder [119] and EpiCheck [120], although not tested in RCTs, have such high sensitivities and negative predictive values in the referenced studies for HG disease that these biomarkers may approach the sensitivity of cystoscopy. These 4 tests might be used to replace and/or postpone cystoscopy as they may identify the rare HG recurrences occurring in low/intermediate NMIBC.

5.8 **Cystoscopy**

The diagnosis of papillary BC ultimately depends on cystoscopic examination of the bladder and histological evaluation of sampled tissue by either cold-cup biopsy or resection. Carcinoma in situ is diagnosed by a combination of cystoscopy, urine cytology, and histological evaluation of multiple bladder biopsies [126].

Cystoscopy is initially performed as an outpatient procedure. A flexible instrument with topical intraurethral anaesthetic lubricant instillation results in better compliance compared to a rigid instrument, especially in men [127, 128] (LE: 1b).

To temporary increase the urethral pressure by irrigation 'bag squeeze' when passing membranous and prostatic urethra with a flexible cystoscope in males also decreases pain during the procedure [129, 130].

5.10 Transurethral resection of TaT1 bladder tumours

5.10.1 Strategy of the procedure

The goal of TURB in TaT1 BC is to make the correct diagnosis and completely remove all visible lesions. It is a crucial procedure in the management of BC. Transurethral resection of the bladder should be performed systematically in individual steps [131, 132] (see Section 5.14).

The operative steps necessary to achieve a successful TURB include identifying the factors required to
assign disease risk (number of tumours, size, multifocality, characteristics, concern for the presence of CIS, recurrent vs. primary tumour), clinical stage (bimanual examination under anaesthesia, assignment of clinical tumour stage), adequacy of the resection (visually complete resection, visualisation of muscle at the resection base), and presence of complications (assessment for perforation) [132, 133]. To measure the size of the largest tumour, one can use the end of cutting loop, which is approximately 1 cm wide, as a reference. The characteristics of the tumour are described as sessile, nodular, papillary, or flat.

5.10.2 Surgical and technical aspects of tumour resection
5.10.2.1 Surgical strategy of resection (piecemeal/separate resection, en-bloc resection)
A complete resection, performed by either fractioned or en-bloc technique, is essential to achieve a good prognosis [131, 134].

- Piecemeal resection in fractions (separate resection of the exophytic part of the tumour, the underlying bladder wall and the edges of the resection area) provides good information about the vertical and horizontal extent of the tumour [135] (LE: 2b).
- En-bloc resection using monopolar or bipolar current, Thulium-YAG or Holmium-YAG laser is feasible in selected exophytic tumours. It provides high-quality resected specimens with the presence of detrusor muscle in 96–100% of cases [131, 136-139] (LE: 1b).

The technique selected is dependent on the size and location of the tumour and experience of the surgeon.

5.10.2.2 Evaluation of resection quality
The absence of detrusor muscle in the specimen is associated with a significantly higher risk of residual disease, early recurrence, and tumour under-staging [140] (LE: 1b). The presence of detrusor muscle in the specimen is considered as a surrogate criterion of the resection quality and is required (except in Ta LG/G1 tumours). Surgical checklists and a quality performance indicator programmes have shown to increase surgical quality (detrusor muscle presence) and decrease recurrence rates [132, 133, 141, 142].

It has been shown that surgical experience can improve TURB results, which supports the role of teaching programmes [143]. Virtual training on simulators is an emerging approach [144]. Its role in the teaching process still needs to be established [132]. Surgical experience and/or volume has been associated both with risk of complications [145], recurrence [146] and survival [147] in retrospective studies (LE: 3).

5.10.2.3 Monopolar and bipolar resection
Compared to monopolar resection, bipolar resection has been introduced to reduce the risk of complications (e.g., bladder perforation due to obturator nerve stimulation) and to produce better specimens. Currently, the results remain controversial [148-151] as a systematic review of 13 RCTs (2,379 patients) showed no benefit of bipolar vs. monopolar TURB for efficacy and safety [151].

5.10.2.4 Office-based fulguration and laser vaporisation
In patients with a history of small, Ta LG/G1 tumours, fulguration, or laser vaporisation of small papillary recurrences on an outpatient basis can reduce the therapeutic burden [152, 153] (LE: 3). There are no prospective comparative studies assessing the oncological outcomes.

5.10.2.5 Resection of small papillary bladder tumours at the time of transurethral resection of the prostate
It is not uncommon to detect bladder tumours in men with benign prostatic hyperplasia. Provided these tumours are papillary by aspect, rather small and not extensively multifocal, it seems feasible to resect these tumours and continue with the resection of the prostate [154, 155]. Although high-quality evidence is limited, simultaneous TURB and TUR of the prostate does not appear to lead to any increased risk of tumour recurrence or progression [156].

5.10.3 Bladder biopsies
Carcinoma in situ can present as a velvet-like, reddish area, indistinguishable from inflammation, or it may not be visible at all. For this reason, biopsies from suspicious urothelium should be taken. In patients with positive urine cytology (see Section 5.5), and normal-looking mucosa at cystoscopy, mapping biopsies are recommended [157, 158]. To obtain representative mapping of the bladder mucosa, biopsies should be taken from the trigone, bladder dome, right, left, anterior and posterior bladder wall [157, 158]. If the equipment is available, photodynamic diagnosis (PDD) is a useful tool to target the biopsy.

5.10.4 Prostatic urethral biopsies
Involvement of the prostatic urethra and ducts in men with NMIBC has been reported. Palou et al. showed that in 128 men with T1G3 BC, the incidence of CIS in the prostatic urethra was 11.7% [159] (LE: 2b). The risk
of prostatic urethra or duct involvement is higher if the tumour is located at the trigone or bladder neck, in the presence of bladder CIS and multiple tumours [160] (LE: 3b). Based on this observation, a biopsy from the prostatic urethra is necessary in some cases (see recommendation in Section 5.14) [159, 161, 162].

5.11 New methods of tumour visualisation
As a standard procedure, cystoscopy and TURB are performed using white light. However, the use of white light can lead to missing lesions that are present but not visible, which is why new technologies are being developed.

5.11.1 Photodynamic diagnosis (fluorescence cystoscopy)
Photodynamic diagnosis is performed using violet light after intravesical instillation of 5-aminolaevulinic acid (ALA) or hexaminolaevulinic acid (HAL). It has been confirmed that fluorescence-guided biopsy and resection are more sensitive than conventional procedures for the detection of malignant tumours, particularly CIS [163, 164] (LE: 1a). In a systematic review and meta-analysis, PDD had higher sensitivity than white light endoscopy in the pooled estimates for analyses at both the patient-level (92% vs. 71%) and biopsy-level (93% vs. 65%) [164]. A prospective RCT did not confirm a higher detection rate in patients with known positive cytology before TURB [165].

Photodynamic diagnosis had lower specificity than white-light endoscopy (63% vs. 81%) [164]. False-positivity can be induced by inflammation or recent TURB and during the first 3 months after BCG instillation [166, 167] (LE: 1a).

The beneficial effect of ALA or HAL fluorescence cystoscopy on recurrence rate in patients with TURB was evaluated. A systematic review and analysis of 14 RCTs including 2,906 patients, 6 using 5-ALA and 9 HAL, demonstrated a decreased risk of BC recurrence in the short and long term. There were, however, no differences in progression and mortality rates. The analysis demonstrated inconsistency between trials and potential susceptibility to performance and publication bias [168] (LE: 1a).

One RCT has shown a reduction in recurrence and progression with fluorescence-guided TURB as compared to white light TURB [169]. In another RCT flexible HAL-cystoscopy proved beneficial in the outpatient setting showing subsequent lower recurrence rates [170]. These results need to be validated by further studies.

5.11.2 Narrow-band imaging
In narrow-band imaging (NBI), the contrast between normal urothelium and hyper-vascular cancer tissue is enhanced. Improved cancer detection has been demonstrated by NBI flexible cystoscopy and NBI-guided biopsies and resection [171-174] (LE: 3b). A RCT assessed the reduction of recurrence rates if NBI is used during TURB. Although the overall results of the study were negative, a benefit after 3 and 12 months was observed for low-risk tumours (pTa LG, < 30 mm, no CIS) [175] (LE: 1b).

5.11.3 Additional technologies
Confocal laser micro-endoscopy is a high resolution imaging probe designed to provide endoscopic histological grading in real time but requires further validation [176]. The Storz professional image enhancement system (IMAGE1 S, formally called SPIES) is an image enhancement system using 4 different light spectra but prospective data using this system are still limited [177].

5.12 Second resection
5.12.1 Detection of residual disease and tumour upstaging
The significant risk of residual tumour after initial TURB of TaT1 lesions has been demonstrated [134] (LE: 1b).

A systematic review analysing data of 8,409 patients with Ta or T1 HG BC demonstrated a 51% risk of persistence and an 8% risk of under-staging in T1 tumours. The analysis also showed a high risk of residual disease in Ta tumours, but this observation was based only on a limited number of cases. Most of the residual lesions were detected at the original tumour location [178] (LE: 1a).

Another meta-analysis of 3,556 patients with T1 tumours showed that the prevalence rate of residual tumours and upstaging to invasive disease after TURB remained high in a subgroup with detrusor muscle in the resection specimen. In the subgroup of 1,565 T1 tumours with detrusor muscle present, persistent tumour was found in 58% and under-staging occurred in 11% of cases [179].

Prospective trials suggest that post-operative positive urine cytology [180] and Xpert-test (urine mRNA test) [181] independently are associated with residual disease at second resection and risk of future recurrences, respectively (LE: 2b). These data, however, need to be confirmed in further studies.
5.12.2 The impact of second resection on treatment outcomes

A second TURB can increase recurrence-free survival (RFS) [182, 183] (LE: 2a), improve outcomes after BCG treatment [184] (LE: 3) and provide prognostic information [185-188] (LE: 3).

In a retrospective evaluation of a large multi-institutional cohort of 2,451 patients with BCG-treated T1 G3/HG tumours (a second resection was performed in 935 patients), the second resection improved RFS, progression-free survival (PFS) and overall survival (OS) only in patients without detrusor muscle in the specimen of the initial resection [189] (LE: 3).

5.12.3 Timing of second resection

Retrospective evaluation showed that a second resection performed 14–42 days after initial resection provides longer RFS and PFS compared to second resection performed after 43–90 days [190] (LE: 3). Based on these arguments, a second TURB is recommended in selected cases 2 to 6 weeks after initial resection (for recommendations on patient selection, see Section 5.14).

5.12.4 Recording of results

The results of the second resection (residual tumours and under-staging) reflect the quality of the initial TURB. As the goal is to improve the quality of the initial TURB, the results of the second resection should be recorded.

5.13 Pathology report

Pathological investigation of the specimen(s) obtained by TURB and biopsies is an essential step in the decision-making process for BC [191]. Close co-operation between urologists and pathologists is required. A high quality of resected and submitted tissue and clinical information is essential for correct pathological assessment. To obtain all relevant information, the specimen collection, handling and evaluation, should respect the recommendations provided below (see Section 5.14) [192, 193]. In difficult cases, an additional review by an experienced genitourinary pathologist can be considered.

Take biopsies from abnormal-looking urothelium. Biopsies from normal-looking mucosa (mapping biopsies from the trigone, bladder dome, right, left, anterior and posterior bladder wall) are recommended if cytology or urinary molecular marker test is positive. If the equipment is available, perform fluorescence-guided (PDD) biopsies.

Take a biopsy of the prostatic urethra in cases of bladder neck tumour, if bladder carcinoma in situ is present or suspected, if there is positive cytology or urinary molecular marker test without evidence of tumour in the bladder, or if abnormalities of the prostatic urethra are visible. If biopsy is not performed during the initial procedure, it should be completed at the time of the second resection.

Take a prostatic urethral biopsy from the pre-collicular area (between the 5 and 7 o’clock position) using a resection loop. In case any abnormal-looking areas in the prostatic urethra are present at this time, these need to be biopsied as well.

Use methods to improve tumour visualisation (fluorescence cystoscopy, narrow-band imaging) during TURB, if available.

Refer the specimens from different biopsies and resection fractions to the pathologist in separately labelled containers.

The TURB record must describe tumour location, appearance, size and multifocality, all steps of the procedure, as well as extent and completeness of resection.

In patients with positive cytology, but negative cystoscopy, exclude an upper tract urothelial carcinoma, CIS in the bladder (by mapping biopsies or PDD-guided biopsies) and tumour in the prostatic urethra (by prostatic urethra biopsy).

Perform a second TURB in the following situations:
- after incomplete initial TURB, or in case of doubt about completeness of a TURB;
- if there is no detrusor muscle in the specimen after initial resection, with the exception of Ta LG/G1 tumours and primary CIS;
- in T1 tumours.

If indicated, perform a second TURB within 2–6 weeks after the initial resection. This second TURB should include resection of the primary tumour site.

Register the pathology results of a second TURB as it reflects the quality of the initial resection.

Inform the pathologist of prior treatments (intravesical therapy, radiotherapy, etc.).

The pathological report should specify tumour location, tumour grade and stage, lymphovascular invasion, subtypes of urothelial carcinoma (variant histologies), presence of CIS and detrusor muscle.

6. PREDICTING DISEASE RECURRENTENCE AND PROGRESSION

6.1 TaT1 tumours
Treatment should take into account a patient’s prognosis. In order to predict the risk of disease recurrence and/or progression, several prognostic models for specified patient populations have been introduced.

6.1.1 Scoring models using the WHO 1973 classification system
6.1.1.1 The 2006 European Organisation for Research and Treatment of Cancer (EORTC) scoring model
To be able to predict both the short- and long-term risks of disease recurrence and progression in individual patients, the EORTC Genito-Urinary Cancer Group (GUCG) published a scoring system and risk tables based on the WHO 1973 classification in 2006 [194]. The scoring system is based on the 6 most significant clinical and pathological factors in patients mainly treated by intravesical chemotherapy:
- Number of tumours;
- Tumour diameter;
- Prior recurrence rate;
- T category;
- Concurrent CIS;
- WHO 1973 tumour grade.

Using the 2006 EORTC scoring model, individual probabilities of recurrence and progression at 1 and 5 years may be calculated (https://www.omnicalculator.com/health/eortc-bladder-cancer).
6.1.1.2 **The model for patients with Ta G1/G2 (WHO 1973) tumours treated with chemotherapy**

Patients with Ta G1/G2 tumours receiving chemotherapy were stratified into 3 risk groups for recurrence, taking into account the history of recurrences, history of intravesical treatment, tumour grade (WHO 1973), number of tumours and adjuvant chemotherapy [195].

6.1.1.3 **Club Urologico Español de Tratamiento Oncologico (CUETO) scoring model for BCG-treated patients**

A model that predicts the risk of recurrence and progression, based on 12 doses of intravesical BCG over a 5 to 6 months period following TURB, has been published by the CUETO (Spanish Urological Oncology Group). It is based on an analysis of 1,062 patients from 4 CUETO trials that compared different intravesical BCG treatments. No immediate post-operative instillation or second TURB was performed in these patients. The scoring system is based on the evaluation of seven prognostic factors:

- gender;
- age;
- prior recurrence status;
- number of tumours;
- T category;
- associated CIS;
- WHO 1973 tumour grade.

Using this model, the calculated risk of recurrence is lower than that obtained by the EORTC tables. For progression, probability is lower only in high-risk patients [196] (LE: 2a). The lower risks in the CUETO tables may be attributed to the use of BCG in this study. The prognostic value of the EORTC scoring system has been confirmed by data from the CUETO patients treated with BCG and by long-term follow-up in an independent patient population [197, 198] (LE: 2a).

6.1.1.4 **The 2016 EORTC scoring model for patients treated with maintenance BCG**

In 1,812 intermediate- and high-risk patients without CIS treated with 1 to 3 years of maintenance BCG, the EORTC found that the prior disease-recurrence rate and number of tumours were the most important prognostic factors for disease recurrence, stage and WHO 1973 grade for disease progression and disease-specific survival, while age and WHO 1973 grade were the most important prognostic factors for OS. T1 G3 patients did poorly, with 1- and 5-year disease-progression rates of 11.4% and 19.8%, respectively. Using these data, EORTC risk groups and nomograms for BCG-treated patients were developed [199] (LE: 2a).

6.1.2 **Scoring model using the WHO 2004/2016 and WHO 1973 classification systems**

6.1.2.1 **EAU NMIBC 2021 scoring model**

To update the risk of disease progression and create new prognostic factor risk groups using both the WHO 1973 and WHO 2004/2016 classification systems (without central pathology review), individual patient data from 3,401 primary patients treated from 1990 to 2018 were used [50] (see Section 4.5). Only patients treated with TURB ± intravesical chemotherapy were included, those treated with adjuvant intravesical BCG were excluded because BCG may reduce the risk of disease progression. From the multivariate analysis, tumour stage, WHO 1973 grade, WHO 2004/2016 grade, concomitant CIS, number of tumours, tumour size and age were independent predictors of disease progression [50].

This is the only available model where the WHO 2004/2016 classification system is included as one of the parameters to calculate an individual patient’s risk group and probability of progression. As the WHO 2004/2016 classification system is the main grading classification system used by pathologists, the Guidelines Panel recommends to use the 2021 EAU NMIBC scoring model for risk groups definition (see Section 6.3).

As the 2021 EAU NMIBC scoring model determines the risk of tumour progression, but not recurrence, any of models mentioned in Section 6.1.1 may be used for calculation of an individual’s risk of disease recurrence.

6.1.3 **Further prognostic factors**

Further prognostic factors have been described in selected patient populations:

- In T1G3 tumours, important prognostic factors were female sex, CIS in the prostatic urethra in men treated with an induction course of BCG, and age, tumour size and concurrent CIS in BCG-treated patients (62% with an induction course only) [159, 200] (LE: 2b).
- Attention must be given to patients with T1G3 tumours in bladder (pseudo) diverticulum because of the absence of muscle layer in the diverticular wall [201] (LE: 3).
- In patients with T1 tumours, the finding of residual T1 disease at second TURB is an unfavourable prognostic factor [186-188] (LE: 3).
• In patients with T1G2 tumours treated with TURB, recurrence at 3 months was the most important predictor of progression [202] (LE: 2b).
• The prognostic value of pathological factors has been discussed elsewhere (see Section 4.6). More research is needed to determine the role of molecular markers in improving the predictive accuracy of currently available risk tables [197, 203].
• Pre-operative neutrophil-to-lymphocyte ratio may have prognostic value in NMIBC. This data, however, needs further validation [204].

6.2 Carcinoma in situ
Without any treatment, approximately 54% of patients with CIS progress to muscle-invasive disease [205] (LE: 3). There are no reliable prognostic factors, but some studies, however, have reported a worse prognosis in concurrent CIS and T1 tumours compared to primary CIS [206, 207], in extended CIS [208] and in CIS in the prostatic urethra [159] (LE: 3).

The response to intravesical treatment with BCG or chemotherapy is an important prognostic factor for subsequent progression and death caused by BC [196-198, 202]. Approximately 10 to 20% of complete responders eventually progress to muscle-invasive disease, compared with 66% of non-responders [209, 210] (LE: 2a).

6.3 Patient stratification into risk groups
To be able to facilitate treatment recommendations, the Guidelines Panel recommends the stratification of patients into risk groups based on their probability of progression to muscle-invasive disease. The new risk group definitions provided in these EAU Guidelines are based on an IPD analysis in primary patients and the calculation of their progression scores (2021 EAU NMIBC scoring model) as presented in Sections 4.5 and 6.1.2) [50].

For calculation of the risk group in individual patients, either one, or both, of the WHO 1973 and WHO 2004/2016 classification systems may be used. The probability of progression at 5 years varies from less than 1% to more than 40% between the risk groups.

For factors where IPD were not collected such as subtypes of urothelial carcinoma (variant histologies), LVI, primary CIS and CIS in the prostatic urethra; literature data have been used to classify patients into risk groups.

The clinical compositions of the new EAU NMIBC prognostic factor risk groups based on the WHO 2004/2016 or WHO 1973 classification systems are provided in Table 6.1. Apps for the web (www.nmibc.net), iOS and Android (iOS / https://apps.apple.com/us/app/eau-nmibc-risk-calculator/id1578482687 and Android / https://play.google.com/store/apps/details?id=net.ydeal.nmibc) have been developed to facilitate determining a patient's risk group in daily clinical practice. The individual probability of disease progression at 1, 5 and 10 years for the new EAU NMIBC risk groups is presented in Table 6.2.

Table 6.1: Clinical composition of the new EAU NMIBC prognostic factor risk groups based on the WHO 2004/2016 or the WHO 1973 grading classification systems [50]

<table>
<thead>

<tr>
<td>Stage, grade with additional clinical risk factors:</td>
<td></td>
</tr>
<tr>
<td></td>
<td>Ta LG/G2 or T1G1, no CIS with all 3 risk factors</td>
</tr>
<tr>
<td></td>
<td>Ta HG/G3 or T1 LG, no CIS with at least 2 risk factors</td>
</tr>
<tr>
<td></td>
<td>T1G2 no CIS with at least 1 risk factor</td>
</tr>
</tbody>
</table>
Very High Risk  
Stage, grade with additional clinical risk factors:  
- Ta HG/G3 and CIS with all 3 risk factors  
- T1G2 and CIS with at least 2 risk factors  
- T1 HG/G3 and CIS with at least 1 risk factor  
- T1 HG/G3 no CIS with all 3 risk factors

The scoring model is based on IPD, but does not consider patients with primary CIS (high risk) or with recurrent tumours, as well as some pathologic parameters like subtypes of urothelial carcinoma (variant histologies, see Section 4.7) and LVI. Nevertheless:

- Based on data from the literature, all patients with CIS in the prostatic urethra, with subtypes of urothelial carcinoma (see Section 4.7) or with LVI should be included in the very high-risk group.
- Patients with recurrent tumours should be included in the intermediate-, high-, or very high-risk groups according to their other prognostic factors.

6.4 Summary of evidence and guidelines for stratification of non-muscle-invasive bladder cancer

Summary of evidence LE

The EAU NMIBC 2021 scoring model and risk tables predict the short- and long-term risks of disease progression in individual patients with primary NMIBC using either the WHO 1973 or the WHO 2004/2016 classification system (see Section 6.1.2.1). 2b

The 2006 EORTC scoring model and risk tables predict the short- and long-term risks of disease recurrence and progression in individual patients with NMIBC using the WHO 1973 classification system (see Section 6.1.1.1). 1b

Patients with Ta G1/G2 tumours receiving chemotherapy have been further stratified into 3 risk groups for recurrence, taking into account the history of recurrences, history of intravesical treatment, tumour grade (WHO 1973), number of tumours and adjuvant chemotherapy (see Section 6.1.1.2). 2b

In patients treated with 5 to 6 months of BCG, the CUETO scoring model predicts the short- and long-term risks of disease recurrence and progression using the WHO 1973 classification system (see Section 6.1.1.3). 1b

In patients receiving at least 1 year of BCG maintenance; prior recurrence rate and number of tumours are the most important prognostic factors for disease recurrence. Stage and grade are the most important prognostic factors for disease progression and disease-specific survival; patient age and grade (WHO 1973) are the most important prognostic factors for OS (see Section 6.1.1.4). 1b

Recommendations Strength rating

Stratify patients into 4 risk groups according to Table 6.1. A patient’s risk group can be determined using the EAU risk group calculator available at www.nmibc.net. Strong

For information about the risk of disease progression in a patient with primary TaT1 tumours not treated with BCG, use the data from Table 6.2. Strong
Use the 2006 EORTC scoring model to predict the risk of tumour recurrence in individual patients not treated with bacillus Calmette-Guérin (BCG).

Use the 2016 EORTC scoring model or the CUETO risk scoring model to predict the risk of tumour recurrence in individual patients treated with BCG intravesical immunotherapy (the 2016 EORTC model is calculated for 1 to 3 years of maintenance, the CUETO model for 5 to 6 months of BCG).

7. DISEASE MANAGEMENT

7.1 Counselling of smoking cessation
It has been confirmed that smoking increases the risk of tumour recurrence and progression [211, 212] (LE: 3). While it is still controversial whether smoking cessation in BC will favourably influence the outcome of BC treatment, patients should be counselled to stop smoking due to the general risks connected with tobacco smoking [201, 213-215] (LE: 3).

7.2 Adjuvant treatment
Although TURB by itself can eradicate a TaT1 tumour completely, these tumours commonly recur and can progress to MIBC. The high variability in the 3-month recurrence rate indicates that the TURB was incomplete or provokes recurrences in a high percentage of patients [134]. It is therefore necessary to consider adjuvant therapy in all patients.

7.2.1 Intravesical chemotherapy
7.2.1.1 A single, immediate, post-operative intravesical instillation of chemotherapy
Immediate single instillation (SI) has been shown to act by destroying circulating tumour cells after TURB, and by an ablative effect on residual tumour cells at the resection site and on small overlooked tumours [216-219] (LE: 3).

Four large meta-analyses comprising 1,476 to 3,103 patients have consistently shown that after TURB, SI significantly reduces the recurrence rate compared to TURB alone [220-223] (LE: 1a). In a systematic review and IPD meta-analysis of 2,278 eligible patients [220], SI reduced the 5-year recurrence rate by 14%, from 59% to 45%. Only patients with primary tumours or intermediate-risk recurrent tumours with a prior recurrence rate of ≤ 1 recurrence/year and those with a 2006 EORTC recurrence score < 5 benefited from SI. In patients with a 2006 EORTC recurrence score ≥ 5 and/or patients with a prior recurrence rate of > 1 recurrence per year, SI was not effective as a single adjuvant treatment. No randomised comparisons of individual drugs have been conducted [220-223].

Single instillation with mitomycin C (MMC), epirubicin or pirarubicin, have all shown a beneficial effect [220]. Single instillation with gemcitabine was superior to placebo control (saline) in a RCT with approximately 200 patients per arm with remarkably low toxicity rates [224]. These findings are in contrast with a previous study, which, however, used a shorter instillation time [225]. In the Böhle et al. study, continuous saline irrigation was used for 24 hours post-operatively in both arms, which could explain the low recurrence rate in the control arm [225]. Two meta-analyses suggest efficacy of continuous saline irrigation in the prevention of early recurrences [226, 227].

Prevention of tumour cell implantation should be initiated within the first few hours after TURB. After that, tumour cells are firmly implanted and are covered by the extracellular matrix [216, 228-230] (LE: 3). In all SI studies, the instillation was administered within 24 hours. Two RCTs found no overall impact of SI with apaziquone; in contrast, a post-hoc analysis did find a reduction of recurrence risk in patients receiving apaziquone within 90 minutes following TURB [231]. To maximise the efficacy of SI, one should devise flexible practices that allow the instillation to be given as soon as possible after TURB, preferably within the first two hours in the recovery room or even in the operating theatre. As severe complications have been reported in patients with drug extravasation [232, 233] safety measures should be maintained (see Section 7.7).

7.2.1.2 Additional adjuvant intravesical chemotherapy instillations
The need for further adjuvant intravesical therapy depends on prognosis. In low-risk patients (Tables 6.1 and 6.2), a SI reduces the risk of recurrence and is considered to be the standard and complete treatment [220, 221] (LE: 1a). For other patients, however, a SI remains an incomplete treatment because of the considerable likelihood of recurrence and/or progression (Tables 6.1 and 6.2). Efficacy data for the following comparisons of application schemes were published:
Single installation only vs. SI and further repeat instillations
In one study, further chemotherapy instillations after SI improved RFS in intermediate-risk patients [234] (LE: 2a).

Repeat chemotherapy instillations vs. no adjuvant treatment
A large meta-analysis of 3,703 patients from 11 RCTs showed a highly significant (44%) reduction in the odds of recurrence at one year in favour of chemotherapy over TURB alone [235]. This corresponds to an absolute difference of 13–14% in the number of patients with recurrence. Contrary to these findings, two meta-analyses have demonstrated that BCG therapy may reduce the risk of tumour progression [236, 237] (see Section 7.2.2.1) (LE: 1a). Moreover, BCG maintenance therapy appears to be significantly better in preventing recurrences than chemotherapy [238-240] (see Section 7.2.2.1) (LE: 1a). However, BCG causes significantly more side effects than chemotherapy [240] (LE: 1a).

Single instillation + further repeat instillations vs. later repeat instillations only
There is evidence from several studies in intermediate-risk patients that SI might have an impact on recurrence even when further adjuvant instillations are given [241-244]. A RCT including 2,243 NMIBC patients, which compared SI of MMC with an instillation of MMC delayed two weeks after TURB (followed by further repeat instillations in both treatment arms), showed a significant reduction of 9% in the risk of recurrence at 3 years in favour of SI, from 38% to 27%. The effect was significant in the intermediate- and high-risk groups of patients receiving additional adjuvant MMC instillations [241] (LE: 2a). Since the author's definition of the risk groups differed significantly in the initial publication, they adapted their patient stratification in the second analysis and consistently showed improved efficacy of SI followed by repeat MMC instillations [245]. The results of this study should be considered with caution since some patients did not receive adequate therapy. Another RCT found no impact of SI with epirubicin followed by further chemotherapy or BCG instillations in a cohort of predominant HR BC [246].

The optimal schedule of intravesical chemotherapy instillations
The length and frequency of repeat chemotherapy instillations is still controversial; however, it should not exceed one year [244] (LE: 3).

7.2.1.3 Options for improving efficacy of intravesical chemotherapy
7.2.1.3.1 Adjustment of pH, duration of instillation, and drug concentration
A prospective randomised, multi-institutional RCT showed that intravesical solution reduced the recurrence rate [247] (LE: 1b). Another trial reported that duration of a one hour instillation of MMC was more effective compared to a 30-minute instillation, but no efficacy comparisons are available for one- vs. two-hour durations of instillation [248] (LE: 3). Another RCT using epirubicin has documented that concentration is more important than treatment duration [249] (LE: 1b). In view of these data, instructions are provided (see Section 7.7).

It has been suggested that the efficacy of MMC may be improved by optimising application through the adjustment of urine pH, in addition to the use of alternative maintenance schedules. Neither aspect is reflected in the literature quoted above since most published studies do not support this approach.

7.2.1.3.2 Device-assisted intravesical chemotherapy
Microwave-induced hyperthermia effect (RITE)
Promising data have been presented on enhancing the efficacy of MMC using microwave-induced hyperthermia in patients with high-risk tumours [250]. In one RCT comparing one year of BCG with one year MMC and microwave-induced hyperthermia in patients with intermediate- and high-risk BC, increased RFS at 24 months in the MMC group was demonstrated [251] (LE: 1b).

Hyperthermic intravesical chemotherapy
Different technologies which increase the temperature of instilled MMC are available, however, data about their efficacy are still lacking.

Electromotive drug administration
The efficacy of MMC using electromotive drug administration (EMDA) sequentially combined with BCG in patients with high-risk tumours has been demonstrated in one small RCT [252]. The definitive conclusion, however, needs further confirmation.

For application of device-assisted instillations in patients recurring after BCG treatment, see Section 7.6.3.

7.2.2 Intravesical bacillus Calmette-Guérin (BCG) immunotherapy

7.2.2.1 Efficacy of BCG

7.2.2.1.1 Recurrence rate

Five meta-analyses have confirmed that BCG after TURB is superior to TURB alone or TURB plus chemotherapy for preventing the recurrence of NMIBC [238, 253-256] (LE: 1a). Three RCTs of intermediate- and high-risk tumours have compared BCG with epirubicin and interferon (INF) [257], MMC [258], or epirubicin alone [239] and have confirmed the superiority of BCG for prevention of tumour recurrence (LE: 1a). The effect is long lasting [239, 258] and was also observed in a separate analysis of patients with intermediate-risk tumours [239]. One meta-analysis [238] has evaluated the individual data from 2,820 patients enrolled in 9 RCTs that have compared MMC vs. BCG. In the trials with BCG maintenance, there was a 32% reduction in the risk of recurrence for BCG compared to MMC, but a 28% increase in the risk of recurrence for patients treated with BCG in the trials without BCG maintenance. A Cochrane systematic review confirmed that BCG is more effective in reducing the recurrence rate over MMC [259].

7.2.2.1.2 Progression rate

Two meta-analyses have demonstrated that BCG therapy delays and potentially lowers the risk of tumour progression [236, 237, 256] (LE: 1a). A meta-analysis carried out by the EORTC Genito-Urinary Cancers Group (GUGC) has evaluated data from 4,863 patients enrolled in 24 RCTs. In 20 of the trials, some form of BCG maintenance was used. Based on a median follow-up of 2.5 years, tumours progressed in 9.8% of the patients treated with BCG compared to 13.8% in the control groups (TURB alone, TURB and intravesical chemotherapy, or TURB with the addition of other immunotherapy). This shows a reduction of 27% in the odds of progression with BCG maintenance treatment. The size of the reduction was similar in patients with TaT1 papillary tumours and in those with CIS [237]. A RCT with long-term follow-up has demonstrated significantly fewer distant metastases and better overall- and disease-specific survival in patients treated with BCG compared to epirubicin [239] (LE: 1b). In contrast, an IPD meta-analysis and Cochrane review were not able to confirm any statistically significant difference between MMC and BCG for progression, survival, and cause of death [238, 259].

The conflicting results in the outcomes of these studies can be explained by different patient characteristics, duration of follow-up, methodology and statistical power. However, most studies showed a reduction in the risk of progression in high-and intermediate-risk tumours if a BCG maintenance schedule was applied.

7.2.2.1.3 Influence of further factors

Two other meta-analyses have suggested a possible bias in favour of BCG arising from the inclusion of patients previously treated with intravesical chemotherapy [260]. In the IPD meta-analysis, however, BCG maintenance was more effective than MMC in reduction of recurrence rate, both in patients previously treated and not previously treated with chemotherapy [238] (LE: 1a). It was demonstrated that BCG was less effective in patients > 70 years of age, but still more effective than epirubicin in a cohort of elderly patients [261] (LE: 1a). According to a cohort analysis, the risk of tumour recurrence after BCG was shown to be higher in patients with a previous history of UTUC [262].

7.2.2.2 BCG strain

Although smaller studies without maintenance demonstrated some differences between strains [262-264], a network meta-analysis identified ten different BCG strains used for intravesical treatment in the published literature but was not able to confirm superiority of any BCG strain over another [265]. Similarly, a published meta-analysis of prospective RCTs [237], published data from a prospective registry [266] as well as from a post-hoc analysis of a large phase II prospective trial assessing BCG and INF-α in both BCG-naive and BCG-failure patients did not suggest any clear difference in efficacy between the different BCG strains [267] (LE: 2a). The quality of data, however, does not allow definitive conclusions.
7.2.2.3 BCG toxicity

Bacillus Calmette-Guérin intravesical treatment is associated with more side effects compared to intravesical chemotherapy [237, 259] (LE: 1a). However, serious side effects are encountered in < 5% of patients and can be treated effectively in almost all cases [268] (LE: 1b). The incidence of BCG infections after BCG instillations was 1% in a registry-based cohort analysis [269]. It has been shown that a maintenance schedule is not associated with an increased risk of side effects compared to an induction course [268]. Side effects requiring treatment stoppage were seen more often in the first year of therapy [270]. Elderly patients do not seem to experience more side effects leading to treatment discontinuation [271] (LE: 2a). No significant difference in toxicity between different BCG strains was demonstrated [266]. Symptoms may be the result of side effects of the BCG treatment or caused by bladder disease (widespread CIS) itself. Consequently, the burden of symptoms is reduced after completion of the treatment in a significant number of patients [272].

Major complications can appear after systemic absorption of the drug. Thus, contraindications of BCG intravesical instillation should be respected (see Section 7.7). The presence of leukocyturia, nonvisible haematuria or asymptomatic bacteriuria is not a contraindication for BCG application, and antibiotic prophylaxis is not necessary in these cases [109, 273, 274] (LE: 3).

Bacillus Calmette-Guérin should be used with caution in immunocompromised patients; e.g., immunosuppression, human immunodeficiency virus (HIV) infection poses relative contraindications [275], although some small studies have shown similar efficacy and no increase in complications compared to non-immunocompromised patients. The role of prophylactic anti-tuberculosis medication in these patients remains unclear [276-278] (LE: 3). The management of side effects after BCG should reflect their type and grade according to the recommendations provided by the International Bladder Cancer Group (IBCG) and by a Spanish group [279, 280] (Table 7.1).

### BCG sepsis

- Prevention: initiate BCG at least 2 weeks post-transurethral resection of the bladder (if no signs and symptoms of haematuria).
- Cessation of BCG.
- For severe infection:
  - High-dose quinolones or isoniazid, rifampicin and ethambutol daily for 6 months.
  - Early, high-dose corticosteroids as long as symptoms persist.
  - Consider an empirical non-specific antibiotic to cover Gram-negative bacteria and/or Enterococcus.

### Allergic reactions

- Antihistamines and anti-inflammatory agents.
- Consider high-dose quinolones or isoniazid and rifampicin for persistent symptoms.
- Delay therapy until reactions resolve.

### Optimal BCG Schedule

- **Induction BCG instillations** are given according to the empirical 6-weekly schedule introduced by Morales et al. [284]. For optimal efficacy, BCG must be given in a maintenance schedule [236-238, 256] (LE: 1a). Many different maintenance schedules have been used, ranging from a total of 10 instillations given in 18 to 27 weeks over 3 years [285].

#### Optimal number of induction instillations and frequency of instillations during maintenance

The optimal number of induction instillations and frequency of maintenance instillations were evaluated by NIMBUS, a prospective phase III RCT. Safety analysis after 345 randomised patients demonstrated that a reduced number of instillations (3 instillations in induction and 2 instillations at 3, 6 and 12 months) proved inferior to the standard schedule (6 instillation in induction and 3 instillations at 3, 6 and 12 months) regarding the time to first recurrence [286] (LE: 1b). In a RCT including 397 patients CUETO showed that in high-risk tumours a maintenance schedule with only one instillation every 3 months for 3 years was not superior to induction therapy only, which suggested that one instillation may be suboptimal to 3 instillations in each maintenance cycle [287] (LE: 1b).

#### Optimal length of maintenance

In their meta-analysis, Böhle et al. concluded that at least one year of maintenance BCG is required to obtain superiority of BCG over MMC for prevention of recurrence or progression [236] (LE: 1a). In a RCT of 1,355 patients, the EORTC has shown that when BCG is given at full dose, 3 years’ maintenance (3-weekly instillations 3, 6, 12, 18, 24, 30 and 36 months) reduces the recurrence rate compared to one year in high- but not in intermediate-risk patients. There were no differences in progression or OS. In the 3-year arm, however, 36.1% of patients did not complete the 3-year schedule [288] (LE: 1b). The main reason why these patients stopped treatment was treatment inefficacy, not toxicity.

#### Optimal dose of BCG

To reduce BCG toxicity, instillation of a reduced dose was proposed. However, it has been suggested that a full dose of BCG is more effective in multifocal tumours [289, 290] (LE: 1b). The CUETO study compared one-third dose to full-dose BCG and found no overall difference in efficacy. One-third of the standard dose of BCG might be the minimum effective dose for intermediate-risk tumours. A further reduction to one-sixth dose resulted in a decrease in efficacy with no decrease in toxicity [291] (LE: 1b). The EORTC did not find any difference in toxicity between one-third and full-dose BCG, but one-third dose BCG was associated with a higher recurrence rate, especially when it was given only for one year [270, 288] (LE: 1b). The routine use of one-third dose BCG is complicated by potential technical difficulties in preparing the reduced dose reliably.

### BCG shortage

</tr>
</tbody>
</table>

7.2.3 Combination therapy

7.2.3.1 Intravesical BCG plus chemotherapy versus BCG alone
In one RCT, a combination of MMC and BCG was shown to be more effective in reducing recurrences but more toxic compared to BCG monotherapy (LE: 1b). Using similar BCG schedules in both groups, each BCG instillation in the combination group was preceded a day before by one MMC instillation [292]. In a RCT using MMC with EMDA, a combination of BCG and MMC with EMDA showed an improved recurrence-free interval and reduced progression rate compared to BCG monotherapy [252, 293] (LE: 2). Two meta-analyses demonstrated improved disease-free survival (DFS), but no difference in PFS in patients treated with combination treatment comparing to BCG alone [293, 294].

7.2.3.2 Combination treatment using interferon
In a Cochrane meta-analysis of 4 RCTs, a combination of BCG and IFN-2α did not show a clear difference in recurrence and progression over BCG alone [295]. In one study, weekly MMC followed by monthly BCG alternating with IFN-2α showed a higher probability of recurrence compared to MMC followed by BCG alone [296]. Additionally, a RCT in a similar population of NMIBC comparing BCG monotherapy with a combination of epirubicin and INF for up to two years showed the latter was significantly inferior to BCG monotherapy in preventing recurrence [297] (LE: 1b).

7.2.4 Specific aspects of treatment of carcinoma in situ

7.2.4.1 Treatment strategy
The detection of concurrent CIS increases the risk of recurrence and progression of TaT1 tumours [194, 196]. In this case further treatment according to the criteria summarised in Sections 7.2.1, 7.2.2, 7.5 and 7.6 is mandatory. Carcinoma in situ cannot be cured by an endoscopic procedure alone. Histological diagnosis of CIS must be followed by further treatment, either intravesical BCG instillations or RC (LE: 4). Tumour-specific survival rates after immediate RC for CIS are excellent, but a large proportion of patients might be over-treated [205] (LE: 3).

7.2.4.2 Cohort studies on intravesical BCG or chemotherapy
In retrospective evaluations of patients with CIS, a complete response rate of 48% was achieved with intravesical chemotherapy and 72-93% with BCG [205-208, 298] (LE: 2a). Up to 50% of complete responders might eventually show recurrence with a risk of invasion and/or extravesical recurrence [208, 230, 285, 298] (LE: 3).

7.2.4.3 Prospective randomised trials on intravesical BCG or chemotherapy
Unfortunately, there have been few RCTs in patients with CIS only. A meta-analysis of clinical trials comparing intravesical BCG to intravesical chemotherapy in patients with CIS has shown a significantly increased response rate after BCG and a reduction of 59% in the odds of treatment failure with BCG [299] (LE: 1a).

In an EORTC-GUCG meta-analysis of tumour progression, in a subgroup of 403 patients with CIS, BCG reduced the risk of progression by 35% as compared to intravesical chemotherapy or immunotherapy [237] (LE: 1b). The combination of BCG and MMC was not superior to BCG alone [300]. In summary, compared to chemotherapy, BCG treatment of CIS increases the complete response rate, the overall percentage of patients who remain disease free, and reduces the risk of tumour progression (LE: 1b).

7.2.4.4 Treatment of CIS in the prostatic urethra and upper urinary tract
Patients with CIS are at high risk of extravesical involvement in the UUT and in the prostatic urethra. Solsona et al. found that 69% of 138 patients with CIS developed extravesical involvement initially or during follow-up [301]. Patients with extravesical involvement had worse survival than those with bladder CIS alone [301] (LE: 3). In the prostate, CIS might be present only in the epithelial lining of the prostatic urethra or in the prostatic ducts [302]. These situations should be distinguished from tumour invasion into the prostatic stroma (stage T4a in bladder tumours) and for which immediate radical cystoprostatectomy is mandatory. Patients with CIS in the epithelial lining of the prostatic urethra can be treated by intravesical instillation of BCG. Transurethral resection...
of the prostate can improve contact of BCG with the prostatic urethra [128, 303] (LE: 3). However, potential spread of CIS has to be considered; no suprapubic trocar-placed catheter should be used.

In patients with prostatic duct involvement there are promising results of BCG, but only from small series. The data are insufficient to provide clear treatment recommendations and radical surgery should be considered [303, 304] (LE: 3).

7.3 Intravesical chemoablation and neoadjuvant treatment

Older marker lesion studies have shown that chemoablation with a single intravesical chemotherapy instillation can achieve a complete response in a proportion of patients [305]. In addition, hypothesis-generating findings from an older RCT comparing immediate pre-operative device-assisted (EMDA) MMC with post-operative SI with MMC and TURB only, showed improved long-term RFS among patients treated prior to TURB [306], and thus even suggest a long-term effect after neoadjuvant instillations. While this has not been reproduced by other groups, additional neoadjuvant clinical trials were recently published. In recurrent low-risk [307] and recurrent Ta tumours [308], 4 and 6 intravesical MMC instillations achieved complete response in 37% and 57% of the patients, respectively. The former study prematurely stopped recruitment as the anticipated 45% complete response after chemoablation was not achieved. Compared to TURB, less dysuria and incontinence occurred in the intervention arm of the trial. Before routine clinical application, additional high-level evidence with RFS as an outcome measure is required.

7.4 Radical cystectomy for non-muscle-invasive bladder cancer

There are several reasons to consider immediate RC for selected patients with NMIBC:

- The staging accuracy for T1 tumours by TURB is low with 27–51% of patients being upstaged to muscle-invasive tumour at RC [162, 309-313] (LE: 3).
- Some patients with NMIBC experience disease progression to muscle-invasive disease (Table 6.2).
- Patients who experience disease progression to muscle-invasive stage have a worse prognosis than those who present with ‘primary’ muscle-invasive disease [314, 315].

The potential benefit of RC must be weighed against its risks, morbidity, and impact on quality of life (QoL) and discussed with patients, in a shared decision-making process. It is reasonable to propose immediate RC in those patients with NMIBC who are at very high risk of disease progression (see Section 6.3 and Tables 6.1 and 6.2) [66, 159, 194, 196, 316] (LE: 3).

Early RC is strongly recommended in patients with BCG-unresponsive tumours and should be considered in BCG relapsing HG tumours as mentioned in Section 7.7 and Table 7.3. A delay in RC may lead to decreased disease-specific survival [317] (LE: 3).

In patients in whom RC is performed before progression to MIBC, the 5-year DFS rate exceeds 80% [318-320] (LE: 3).

7.5 Individual treatment strategy in primary or recurrent tumours after TURB without previous BCG intravesical immunotherapy

The type of further therapy after TURB should be based on the risk groups shown in Section 6.3 and Table 6.1. The stratification and treatment recommendations are based on the risk of disease progression. In particular in intermediate-risk tumours, the 2006 EORTC scoring model may be used (Section 6.1.1.1) to determine a patient’s individual risk of disease recurrence as the basis to decide further treatment on.

Any decisions should reflect the following principles:

- Patients in the low-risk group have a negligible risk of disease progression. The single post-operative instillation of chemotherapy reduces the risk of recurrence and is considered as sufficient treatment in these patients.
Patients in the intermediate-risk group have a low risk of disease progression (7.4 and 8.5% after 10 years according to the 2021 EAU NMIBC scoring model). In these patients one-year full-dose BCG treatment (induction plus 3-weekly instillations at 3, 6 and 12 months), or instillations of chemotherapy (the optimal schedule is not known) for a maximum of one year, is recommended. The final choice should reflect the individual patient’s risk of recurrence and progression as well as the efficacy and side effects of each treatment modality.

Patients in the high-risk group have a high risk of disease progression (14.1 and 14.2% after 10 years according to the 2021 EAU NMIBC scoring model). In these patients full-dose intravesical BCG for one to 3 years (induction plus 3-weekly instillations at 3, 6, 12, 18, 24, 30 and 36 months), is indicated. The additional beneficial effect of the second and third years of maintenance should be weighed against its added costs, side effects and problems associated with BCG shortage. Because of the high risk of progression, immediate RC may also be discussed with the patient. Radical cystectomy is the safest approach from oncological point of view, it is, however, associated with the risk of complications and QoL impairment and represents overtreatment in some patients.

Patients in the very high-risk group have an extremely high risk of tumour progression (53.1 and 58.6% after 10 years according to the 2021 EAU NMIBC scoring model). Immediate RC should be discussed with these patients. In case RC is not feasible or refused by the patient, full-dose intravesical BCG for one to 3 years should be offered.

Figure 7.1 presents a treatment flow chart based on risk category, which may guide management of an individual patient.
Figure 7.1: Treatment strategy in primary or recurrent tumour(s) without previous BCG*
7.6 Treatment of failure of intravesical therapy

7.6.1 Recurrence during or after intravesical chemotherapy
Patients with NMIBC recurrence during or after a chemotherapy regimen can benefit from BCG instillations. Prior intravesical chemotherapy has no impact on the effect of BCG instillations [238] (LE: 1a).

7.6.2 Treatment failure after intravesical BCG immunotherapy
Several categories of BCG failures, broadly defined as any HG disease occurring during or after BCG therapy, have been proposed (see Table 7.2). Non-muscle-invasive BC may not respond at all (BCG refractory) or may relapse after initial response (BCG relapsing). Some evidence suggests that patients with BCG relapse have better outcomes than BCG refractory patients [321].

To be able to specify the subgroup of patients where additional BCG is unlikely to provide benefit, the category of BCG-unresponsive tumour was defined. Further BCG instillations in these patients are associated with an increased risk of progression [209, 322]. The category of BCG-unresponsive tumours comprises BCG-refractory and some of BCG-relapsing tumours (see Table 7.2) [323]. The definition was developed in consultation with the U.S. Food and Drug Administration (FDA), in particular to promote single-arm trials to provide primary evidence of effectiveness in this setting [324].

Non-HG recurrence after BCG is not considered as BCG failure.

| BCG-unresponsive tumours include all BCG refractory tumours and those who develop T1/Ta HG recurrence within 6 months of completion of adequate BCG exposure** or develop CIS within 12 months of completion of adequate BCG exposure [323] (LE: 4). |

| **BCG intolerance**                            |
| Severe side effects that prevent further BCG instillation before completing treatment [280]. |

* Patients with LG recurrence during or after BCG treatment are not considered to be a BCG failure.  
** Adequate BCG is defined as the completion of at least 5 of 6 doses of an initial induction course plus at least 2 out of 6 doses of a second induction course or 2 out of 3 doses of maintenance therapy.

7.6.3 Treatment of BCG-unresponsive tumours, late BCG-relapsing tumours, LG recurrences after BCG treatment and patients with BCG intolerance
Patients with BCG-unresponsive disease are unlikely to respond to further BCG therapy; RC is therefore the standard and preferred option. Currently, several bladder preservation strategies are being investigated such as cytotoxic intravesical therapies [327-330], device assisted instillations [331-333] intravesical immunotherapy [334, 335], systemic immunotherapy [336] or gene therapy [337-339].

A phase III RCT including predominantly high-risk NMIBC patients failing at least a previous induction course of BCG, MMC combined with microwave-induced hyperthermia provided 35% overall DFS at 2 years as compared to 41% in the control arm (treated with either BCG, MMC or MMC and electromotive drug administration at the discretion of the investigator). In the pre-planned sub-analysis, MMC and microwave-induced thermotherapy showed lower response rates in CIS recurrences but higher DFS in non-CIS papillary tumours (53% vs. 24%) [333].
Promising data on BCG-unresponsive cohorts of patients with CIS alone or concomitant to papillary tumours were recently reported following new immunotherapies. Systemic pembrolizumab achieved a 40% complete response rate in a prospective phase II study which was maintained in 48% of patients for up to 12 months (n = 101), resulting in FDA approval of the study drug for this patient population [340]. Promising data from a phase III multicentre RCT with intravesical nadofaragene firadenovec were published recently showing a complete response in 53.4% in patients with BCG-unresponsive CIS [341].

A systematic review and meta-analysis including 4 RCTs and 24 single-arm studies (all currently available prospective studies) assessed bladder-sparing treatments following BCG failure [342]. The significant heterogeneity of both trial designs and patient characteristics included in these studies, the different definitions of BCG failures used, and missing information on prior BCG courses may account for the variability in efficacy for the different compounds assessed across different trials. A higher number of previous BCG courses, BCG refractory/unresponsive or CIS predicted lower response rates. The pooled 12-month response rates were 24% for trials with ≥ 2 prior BCG courses and 36% for those with ≥ 1 BCG courses. Initial response rate did not predict durable responses highlighting the need for longer-term follow-up. More recently, a systematic review assessing 42 prospective trials on bladder preserving treatments after BCG showed that patients with papillary-only recurrences appeared more effectively treated (median recurrence free rates of 44% at 1 year, median progression-free rate 89% at a median follow-up of 19 months) than CIS-containing tumours (median complete response rate 17% at 1 year with a median progression-free rate of 95% at a median follow-up of 12 months), highlighting potential biological differences between these two tumour entities which should be analysed separately when reporting results of clinical trials [343].

At the present time, treatments other than RC are considered oncologically inferior in patients with BCG-unresponsive disease [209, 322, 325] (LE: 3). Various studies suggest that repeat-BCG therapy is appropriate for non-HG and even for some HG recurrent tumours; namely those relapsing beyond one year after BCG exposure (cases which do not meet the criteria of BCG-unresponsive disease) [344, 345] (LE: 3).

Treatment decisions in LG recurrences after BCG (which are not considered as any category of BCG failure) should be individualised according to tumour characteristics. Little is known about the optimal treatment in patients with high-risk tumours who could not complete BCG instillations because of intolerance.

<tr>
<td>In patients with tumours presumed to be at low risk and in those with small papillary recurrences (presumably Ta LG/G1) detected more than one year after previous TURB, offer one immediate chemotherapy instillation.</td>
<td>Strong</td>
</tr>
</tbody>
</table>
In patients with intermediate-risk tumours (with or without immediate instillation), one-year full-dose Bacillus Calmette-Guérin (BCG) treatment (induction plus 3-weekly instillations at 3, 6 and 12 months), or instillations of chemotherapy (the optimal schedule is not known) for a maximum of one year is recommended. The final choice should reflect the individual patient’s risk of recurrence and progression as well as the efficacy and side effects of each treatment modality.

In patients with high-risk tumours, full-dose intravesical BCG for one to 3 years (induction plus 3-weekly instillations at 3, 6, 12, 18, 24, 30 and 36 months), is indicated. The additional beneficial effect of the second and third years of maintenance should be weighed against its added costs, side effects and problems connected with BCG shortages. Immediate radical cystectomy (RC) may also be discussed with the patient.

In patients with very high-risk tumours discuss immediate RC. Offer intravesical full-dose BCG instillations for one to 3 years to those who refuse or are unfit for RC.

Offer transurethral resection of the prostate, followed by intravesical instillation of BCG to patients with CIS in the epithelial lining of the prostatic urethra.

The definition of ‘BCG-unresponsive’ should be respected as it most precisely defines the patients who are unlikely to respond to further BCG instillations.

Offer a RC to patients with BCG-unresponsive tumours.

Offer patients with BCG-unresponsive tumours, who are not candidates for RC due to comorbidities, preservation strategies (intravesical chemotherapy, chemotherapy and microwave-induced hyperthermia, electromotive administration of chemotherapy, intravesical- or systemic immunotherapy; preferably within clinical trials).

**Recommendations - technical aspects for treatment**

**Intravesical chemotherapy**
- If given, administer a single immediate instillation of chemotherapy within 24 hours after TURB.  
- Omit a single immediate instillation of chemotherapy in any case of overt or suspected bladder perforation or bleeding requiring bladder irrigation.
- Give clear instructions to the nursing staff to control the free flow of the bladder catheter at the end of the immediate instillation.
- The optimal schedule and duration of further intravesical chemotherapy instillation is not defined; however, it should not exceed one year.
- If intravesical chemotherapy is given, use the drug at its optimal pH and maintain the concentration of the drug by reducing fluid intake before and during instillation.
- The length of individual instillation should be one to two hours.

**BCG intravesical immunotherapy**

Absolute contraindications of BCG intravesical instillation are:
- during the first two weeks after TURB;
- in patients with visible haematuria;
- after traumatic catheterisation;
- in patients with symptomatic urinary tract infection.

<td></td>
</tr>
<tr>
<td>Offer one immediate instillation of intravesical chemotherapy after transurethral resection of the bladder (TURB).</td>
<td>Strong</td>
</tr>
</tbody>
</table>

**EAU Risk Group: Intermediate**

In all patients either one-year full-dose Bacillus Calmette-Guérin (BCG) treatment (induction plus 3-weekly instillations at 3, 6 and 12 months), or instillations of chemotherapy (the optimal schedule is not known) for a maximum of one year is recommended. The final choice should reflect the individual patient’s risk of recurrence and progression as well as the efficacy and side effects of each treatment modality. Offer one immediate chemotherapy instillation to patients with small papillary recurrences (presumably Ta LG/G1) detected more than one year after previous TURB.

**EAU risk group: High**

Offer intravesical full-dose BCG instillations for one to 3 years or discuss immediate radical cystectomy (RC).
**EAU risk group: Very High**

Offer RC or intravesical full-dose BCG instillations for one to 3 years to those who refuse or are unfit for RC.

### 8. FOLLOW-UP OF PATIENTS WITH NMIBC

As a result of the risk of recurrence and progression, patients with NMIBC need surveillance following therapy. However, the frequency and duration of cystoscopy and imaging follow-up should reflect the individual patient's degree of risk. Using the EAU NMIBC prognostic factor risk groups (see Section 6.3, Tables 6.1 and 6.2) or further prognostic models for specific patient populations (see Chapter 6), the short- and long-term risks of recurrence and progression in individual patients may be predicted and the follow-up schedule adapted accordingly (see Section 8.1) [194, 196]. However, recommendations for follow-up are mainly based on retrospective data and there is a lack of RCTs investigating the possibility of safely reducing the frequency of follow-up cystoscopy.

When planning the follow-up schedule and methods, the following aspects should be considered:

- The prompt detection of muscle-invasive and HG/G3 non-muscle-invasive recurrence is crucial and the percentage of tumours missed should be as low as possible because a delay in diagnosis and therapy can be life-threatening. Therefore, the best surveillance strategy for these patients will continue to include frequent cystoscopy and cytology.
- Tumour recurrence in the low-risk group is nearly always low stage and LG/G1. Small, Ta LG/G1 papillary recurrence does not present an immediate danger to the patient and early detection is not essential for successful therapy [346, 347] (LE: 2b). Fulguration of small papillary recurrences on an outpatient basis could be safe [348] (LE: 3). Multiple authors have suggested active surveillance in selected cases [349-351] (LE: 3/2a).
- The first cystoscopy after TURB at 3 months is an important prognostic indicator for recurrence and progression [202, 208, 352-354] (LE: 1a). Therefore, the first cystoscopy should always be performed 3 months after TURB in all patients with TaT1 tumours and CIS.
- In tumours at low risk, the risk of recurrence after 5 recurrence-free years is low [353] (LE: 3). Therefore, in low-risk tumours, after 5 years of follow-up, discontinuation of cystoscopy or its replacement with less-invasive methods can be considered [354].
- In tumours originally intermediate- to high risk, or very high risk treated conservatively, recurrences after ten years tumour-free are not unusual [355] (LE: 3). Therefore, life-long follow-up is recommended [354].
- The follow-up strategy must reflect the risk of extravesical recurrence (prostatic urethra in men and UUT in both genders).
- The risk of UUT recurrence increases in patients with multiple- and high-risk tumours [85] (LE: 3).
- There may be a role for newer methods of tumour visualisation in follow-up cystoscopy. In a prospective study of blue light flexible cystoscopy (BLFC) for surveillance of NMIBC, BLFC alone showed an abnormality in 8% of which half had biopsy-confirmed BC [356]. On the other hand, a prospective study of narrow-band imaging (NBI) for NMIBC surveillance failed to show any benefit for NBI over white light cystoscopy alone [357].
- The current status of urine cytology and urinary molecular marker tests is discussed in detail in Sections 5.5, 5.6 and 5.7. Non-muscle-invasive BC follow-up strategies include urine cytology and urinary molecular marker tests as adjunct (or companion) tests to improve detection at the time of flexible cystoscopy or as replacement tests to reduce the number of flexible cystoscopies.

- The role of urinary cytology or urinary molecular markers as an adjunct to cystoscopy (companion test) in the follow-up of NMIBC has been investigated [106, 107, 119, 120, 124]. One prospective RCT found that knowledge of positive test results (microsatellite analysis) can improve the quality of follow-up cystoscopy [125] (LE: 1b), supporting the adjunctive role of a non-invasive urine test performed prior to follow-up cystoscopy [125] (see Section 5.7.3).

- In order for urinary markers to reduce or replace cystoscopy altogether, they should be able to detect recurrence across all risk groups. However, currently the limitation of urinary cytology and current urinary markers is their low sensitivity for LG recurrences [101, 107] (see Section 5.7.3) (LE: 1b).

- In patients initially diagnosed with Ta LG/G1–2 BC, US of the bladder or a urinary marker may be a mode of surveillance in case cystoscopy is not possible or refused by the patient [123, 124, 358].

- According to current knowledge, no urinary marker can replace cystoscopy during follow-up or lower cystoscopy frequency in a routine fashion.

8.1 Summary of evidence and guidelines for the follow-up of UTUC

9. REFERENCES

10. CONFLICT OF INTEREST

11. CITATION INFORMATION
1. INTRODUCTION

1.1 Aim and scope
The European Association of Urology (EAU) Non-muscle-invasive Bladder Cancer (NMIBC) Guidelines Panel has compiled these clinical guidelines to provide urologists with evidence-based information and recommendations for the management of upper urinary tract urothelial carcinoma (UTUC). Separate EAU guidelines documents are available addressing non-muscle-invasive bladder cancer [1], muscle-invasive and metastatic bladder cancer (MIBC) [2], and primary urethral carcinoma [3].

It must be emphasised that clinical guidelines present the best evidence available to the experts but following guideline recommendations will not necessarily result in the best outcome. Guidelines can never replace clinical expertise when making treatment decisions for individual patients, but rather help to focus decisions - also taking personal values and preferences/individual circumstances of patients into account. Guidelines are not mandates and do not purport to be a legal standard of care.

1.2 Panel composition
The European Association of Urology (EAU) Guidelines Panel on NMIBC consists of an international multidisciplinary group of clinicians, including urologists, uro-oncologists, a radiologist, a pathologist, and a statistician. Members of this panel have been selected based on their expertise and to represent the professionals treating patients suspected of harbouring urothelial carcinoma (UC). In the course of 2021 two patient representatives have formally joined the NMIBC Panel. All involved in the production of this document have submitted potential conflict of interest statements, which can be viewed on the EAU website Uroweb: https://uroweb.org/guideline/upper-urinary-tract-urothelial-cell-carcinoma/.

1.3 Available publications
A quick reference document (Pocket guidelines) is available in print and as an app for iOS and Android devices, presenting the main findings of the UTUC Guidelines. These are abridged versions which may require consultation together with the full text version. Several scientific publications are available as are a number of translations of all versions of the EAU UTUC Guidelines, the most recent scientific summary was published in 2020 [4]. All documents are accessible through the EAU website Uroweb: https://uroweb.org/guideline/upper-urinary-tract-urothelial-cell-carcinoma/.

1.4 Publication history & summary of changes
The first EAU Guidelines on UTUC were published in 2011. This 2022 publication presents a limited update of the 2021 version.

1.4.1 Summary of changes
The literature for the complete document has been assessed and updated, whenever relevant. Conclusions and recommendations have been rephrased and added to throughout the current document.

Key changes for the 2022 print can be found in:
- Section 3.1 – Epidemiology, due to the inclusion of additional data on mismatch repair testing, Figure 3.1: Selection of patients with UTUC for Lynch syndrome screening during the first medical Interview, was revised.
- Chapter 6 – Prognosis, considerable data has been added;
- 7.1.2 Management of high-risk non-metastatic UTUC – New Section 7.1.3.2.2 Immunotherapy, was added.
- 7.2.3 Systemic treatments. This section has been completely restructured and updated, resulting in a number of changes to the Summary of changes and guidelines for the treatment of metastatic UTUC.

7.2.4 Summary of evidence and guidelines for the treatment of metastatic UTUC

### 2. METHODS

#### 2.1 Data identification

Standard procedure for EAU Guidelines includes an annual assessment of newly published literature in the field to guide future updates. For the 2022 UTUC Guidelines, new and relevant evidence has been identified, collated, and appraised through a structured assessment of the literature. The search was restricted to articles published between May 29th 2020 and June 8th 2021. Databases searched included Pubmed, Ovid, EMBASE and both the Cochrane Central Register of Controlled Trials and the Cochrane Database of Systematic Reviews. After deduplication, a total of 823 unique records were identified, retrieved, and screened for relevance. Excluded from the search were basic research studies, case series, reports, and editorial comments. Only articles published in the English language, addressing adults, were included. The publications identified were mainly retrospective, including some large multicentre studies. Owing to the scarcity of randomised data, articles were selected based on the following criteria: evolution of concepts, intermediate- and long-term clinical outcomes, study quality, and relevance. Older studies were only included if they were historically relevant. A total of 45 new publications were included in the 2022 UTUC Guidelines print. A detailed search strategy is available online: [https://uroweb.org/guideline/upper-urinary-tract-urothelial-cell-carcinoma/?type=appendicespublications](https://uroweb.org/guideline/upper-urinary-tract-urothelial-cell-carcinoma/?type=appendicespublications).

For Chapters 3-6 (Epidemiology, Aetiology and Pathology, Staging and Classification systems, Diagnosis and Prognosis) references used in this text are assessed according to their level of evidence (LE) based on the 2009 Oxford Centre for Evidence-Based Medicine (CEBM) Levels of Evidence [5]. For the Disease Management and Follow-up chapters (Chapters 7 and 8) a system modified from the 2009 CEBM LEs has been used [5]. For each recommendation within the guidelines there is an accompanying online strength rating form, based on a modified GRADE methodology [6, 7]. These forms address a number of key elements, namely:

1. The overall quality of the evidence which exists for the recommendation [5];
2. the magnitude of the effect (individual or combined effects);
3. the certainty of the results (precision, consistency, heterogeneity and other statistical or study-related factors);
4. the balance between desirable and undesirable outcomes;
5. the impact of patient values and preferences on the intervention;
6. the certainty of those patient values and preferences.

These key elements are the basis which panels use to define the strength rating of each recommendation. The strength of each recommendation is represented by the words ‘strong’ or ‘weak’. The strength of each recommendation is determined by the balance between desirable and undesirable consequences of alternative...
management strategies, the quality of the evidence (including certainty of estimates), and nature and variability of patient values and preferences [8].

Additional information can be found in the general Methodology section of this print, and online at the EAU website: https://uroweb.org/guidelines/policies-and-methodological-documents/.

A list of Associations endorsing the EAU Guidelines can also be viewed online at the above address.

2.2 Review
The 2021 UTUC Guidelines have been peer-reviewed prior to publication.

3. EPIDEMIOLOGY, AETIOLOGY AND PATHOLOGY

3.1 Epidemiology
Urothelial carcinomas are the sixth most common tumours in developed countries [9]. They can be located in the lower (bladder and urethra) and/or the upper (pyelocalyceal cavities and ureter) urinary tract. Bladder tumours account for 90–95% of UCs and are the most common urinary tract malignancy [1]. Upper urinary tract UCs are uncommon and account for only 5–10% of UCs [9] with an estimated annual incidence in Western countries of almost two cases per 100,000 inhabitants. This rate has risen in the past few decades as a result of improved detection and improved bladder cancer survival [10, 11]. Pyelocalyceal tumours are approximately twice as common as ureteral tumours and multifocal tumours are found in approximately 10–20% of cases [12]. The presence of concomitant carcinoma in situ of the upper tract is between 11% and 36% [10]. In 17% of cases, concurrent bladder cancer is present [13] whilst a prior history of bladder cancer is found in 41% of American men but in only 4% of Chinese men [14]. This, along with genetic and epigenetic factors, may explain why Asian patients present with more advanced and higher grade disease compared to other ethnic groups [10]. Following treatment, recurrence in the bladder occurs in 22–47% of UTUC patients, depending on initial tumour grade [15] compared with 2–5% in the contralateral upper tract [16].

With regards to UTUC occurring following an initial diagnosis of bladder cancer, a series of 82 patients treated with bacillus Calmette-Guérin (BCG) who had regular upper tract imaging between years 1 and 3 showed a 13% incidence of UTUC, all of which were asymptomatic [17], whilst in another series of 307 patients without routine upper tract imaging the incidence was 25% [18]. A multicentre cohort study (n = 402) with a 50 month follow-up has demonstrated a UTUC incidence of 7.5% in NMIBC receiving BCG with predictors being intravesical recurrence and non-papillary tumour at transurethral resection of the bladder [19]. Following radical cystectomy for MIBC, 3–5% of patients develop a metachronous UTUC [20, 21].

Approximately two-thirds of patients who present with UTUCs have invasive disease at diagnosis compared to 15–25% of patients presenting with muscle-invasive bladder tumours [22]. This is probably due to the absence of muscularis propria layer in the upper tract, so tumours are more likely to upstage at an earlier time-point. Approximately 9% of patients present with metastasis [10, 23, 24]. Upper urinary tract UCs have a peak incidence in individuals aged 70–90 years and are twice as common in men [25].

Upper tract UC and bladder cancer exhibit significant differences in the prevalence of common genomic alterations. In individual patients with a history of both tumours, bladder cancer and UTUC were always clonally related. Genomic characterisation of UTUC provides information regarding the risk of bladder recurrence and can identify tumours associated with Lynch syndrome [26].

The Amsterdam criteria are a set of diagnostic criteria used by doctors to help identify families which are likely to have Lynch syndrome [27]. In Lynch-related UTUC, immunohistochemistry (IHC) analysis showed loss of protein expression corresponding to the disease-predisposing MMR (mismatch repair) gene mutation in 98% of the samples (46% were microsatellite stable and 54% microsatellite unstable) [28]. The majority of tumours develop in MSH2 mutation carriers [28]. Patients identified at high risk for Lynch syndrome should undergo DNA sequencing for patient and family counselling [29, 30]. Germline mutations in DNA MMR genes defining Lynch syndrome, are found in 9% of patients with UTUC compared to 1% of patients with bladder cancer, linking UTUC to Lynch syndrome [31]. A study of 115 consecutive UTUC patients, reported that 13.9% screened positive for potential Lynch syndrome and 5.2% had confirmed Lynch syndrome [32]. This is one of the highest rates of undiagnosed genetic disease in urological cancers, which justifies screening of all patients under 60 presenting with UTUC and those with a family history of UTUC (see Figure 3.1) [33, 34] or positive reflexive MMR-test by IHC in sporadic UTUC [31, 35-37].
3.2 Risk factors
A number of environmental factors have been implicated in the development of UTUC [12, 38]. Published evidence in support of a causative role for these factors is not strong, with the exception of smoking and aristolochic acid. Tobacco exposure increases the relative risk of developing UTUC from 2.5 to 7.0 [39-41]. A large population-based study assessing familial clustering in relatives of UC patients, including 229,251 relatives of case subjects and 1,197,552 relatives of matched control subjects, has demonstrated genetic or environmental roots independent of smoking-related behaviours. With more than 9% of the cohort being UTUC patients, clustering was not seen in upper tract disease. This may suggest that the familial clustering of UC is specific to lower tract cancers [42].

In Taiwan and Chile, the presence of arsenic in drinking water has been tentatively linked to UTUC [43, 44]. Aristolochic acid, a nitrophenanthrene carboxylic acid produced by Aristolochia plants, which are used worldwide, especially in China and Taiwan [45], exerts multiple effects on the urinary system. Aristolochic acid irreversibly injures renal proximal tubules resulting in chronic tubulointerstitial disease, while the mutagenic properties of this chemical carcinogen lead predominantly to UTUC [45-47]. Aristolochic acid has been linked to bladder cancer, renal cell carcinoma, hepatocellular carcinoma, and intrahepatic cholangiocarcinoma [48]. Two routes of exposure to aristolochic acid are known: (i) environmental contamination of agricultural products by Aristolochia plants, as reported for Balkan endemic nephropathy [49]; and (ii) ingestion of Aristolochia-
Based herbal remedies [50, 51]. Following bioactivation, aristolochic acid reacts with genomic DNA to form aristolactam-deoxyadenosine adducts [52]; these lesions persist for decades in target tissues, serving as robust biomarkers of exposure [9]. These adducts generate a unique mutational spectrum, characterised by A>T transversions located predominately on the non-transcribed strand of DNA [48, 53]. However, fewer than 10% of individuals exposed to aristolochic acid develop UTUC [47].

Two retrospective series found that aristolochic acid-associated UTUC is more common in females [54, 55]. However, females with aristolochic acid UTUC have a better prognosis than their male counterparts. Consumption of arsenic in drinking water and aristolochia-based herbal remedies together appears to have an additive carcinogenic effect [56].

Alcohol consumption is associated with development of UTUC. A large case-control study (1,569 cases and 506,797 controls) has evidenced a significantly higher risk of UTUC in ever-drinkers compared to never-drinkers (OR: 1.23; 95% CI: 1.08–1.40, p = 0.001). Compared to never-drinkers, the risk threshold for UTUC was > 15 g of alcohol/day. A dose-response was observed [57].

Differences in the ability to counteract carcinogens may contribute to host susceptibility to UTUC. Some genetic polymorphisms are associated with an increased risk of cancer or faster disease progression that introduces variability in the inter-individual susceptibility to the risk factors previously mentioned. Upper urinary tract UCs may share some risk factors and described molecular pathways with bladder UC [26]. So far, two UTUC-specific polymorphisms have been reported [58].

A history of bladder cancer is associated with a higher risk of developing UTUCs (see Section 3.1). Patients who undergo ureteral stenting at the time of TURB, including prior to radical cystectomy are at higher risk for upper tract recurrence [59, 60].

3.3 Histology and classification

3.3.1 Histological types

Upper urinary tract tumours are almost always UCs and pure non-urothelial histology is rare [53, 54]. However, variants are present in approximately 25% of UTUCs [55, 56]. Pure squamous cell carcinoma of the urinary tract is often assumed to be associated with chronic inflammatory diseases and infections arising from urolithiasis [57, 58]. Urothelial carcinoma with divergent squamous differentiation is present in approximately 15% of cases [57]. Keratinising squamous metaplasia of urothelium is a risk factor for squamous cell cancers and therefore mandates surveillance. Upper urinary tract UCs with variant histology are high-grade and have a worse prognosis compared with pure UC [56, 59, 60]. Other variants, although rare, include sarcomatoid and UCs with inverted growth [60].

However, collecting duct carcinomas, which may seem to share similar characteristics with UCs, display a unique transcriptomic signature similar to renal cancer, with a putative cell of origin in the distal convoluted tubules. Therefore, collecting duct carcinomas are considered as renal tumours [61].

4. STAGING AND CLASSIFICATION SYSTEMS

4.1 Classification
The classification and morphology of UTUC and bladder carcinoma are similar [1]. However because of the difficulty in adequate sample acquisition, it is often difficult to distinguish between non-invasive papillary tumours [70], flat lesions (carcinoma in situ [CIS]), and invasive carcinoma. Therefore, histological grade is often used for clinical decision making as it is strongly associated with pathological stage [71].

4.2 Tumour Node Metastasis staging
The tumour, node, metastasis (TNM) classification is shown in Table 1 [72]. The regional lymph nodes (LN) are the hilar and retroperitoneal nodes and, for the mid- and distal ureter, the pelvic nodes. Laterality does not affect N classification.

4.3 Tumour grade
In 2004, the WHO and the International Society of Urological Pathology published a new histological classification of UCs which provides a different patient stratification between individual categories compared to the older 1973 WHO classification [73, 74]. In 2016, an update of the 2004 WHO grading classification was published without major changes [73]. These guidelines are still based on both the 1973 and 2004/2016 WHO classifications since most published data use the 1973 classification [70].

4.4 Molecular classification of UTUCs
A number of studies focussing on molecular classification have been able to demonstrate genetically distinct groups of UTUC by evaluating DNA, RNA and protein expression. Five molecular subtypes with different gene expression, tumour location and outcome have been identified, but, as yet, it is unclear whether these subtypes will respond differently to treatment [75].

5. DIAGNOSIS

5.1 Symptoms
The diagnosis of UTUC may be incidental or symptom related. The most common symptom is visible or nonvisible haematuria (70–80%) [76, 77]. Flank pain, due to clot or tumour tissue obstruction or less often due to local growth, occurs in approximately 20–32% of cases [78]. Systemic symptoms (including anorexia, weight loss, malaise, fatigue, fever, night sweats, or cough) associated with UTUC should prompt evaluation for metastases associated with a worse prognosis [78].
5.2 Imaging

5.2.1 Computed tomography urography
Computed tomography (CT) urography has the highest diagnostic accuracy of the available imaging techniques [79]. A meta-analysis of 13 studies comprising 1,233 patients revealed a pooled sensitivity of CT urography for UTUC of 92% (CI: 0.85–0.96) and a pooled specificity of 95% (CI: 0.88–0.98) [80]. Rapid acquisition of thin sections allows high-resolution isotropic images that can be viewed in multiple planes to assist with diagnosis without loss of resolution. Epithelial “flat lesions” without mass effect or urothelial thickening are generally not visible with CT.

The presence of enlarged LNs is highly predictive of metastases in UTUC [81, 82].

5.2.2 Magnetic resonance urography
Magnetic resonance (MR) urography is indicated in patients who cannot undergo CT urography, usually when radiation or iodinated contrast media are contraindicated [83]. The sensitivity of MR urography is 75% after contrast injection for tumours < 2 cm [83]. The use of MR urography with gadolinium-based contrast media should be limited in patients with severe renal impairment (< 30 mL/min creatinine clearance), due to the risk of nephrogenic systemic fibrosis. Computed tomography urography is more sensitive and specific for the diagnosis and staging of UTUC compared to MR urography [84].

5.3 Cystoscopy
Urethroscopy is an integral part of UTUC diagnosis to rule out concomitant bladder cancer [10, 13].

5.4 Cytology
Abnormal cytology may indicate high-grade UTUC when bladder cystoscopy is normal, and in the absence of CIS in the bladder and prostatic urethra [1, 85, 86]. Cytology is less sensitive for UTUC than bladder tumours and should be performed selectively for the affected upper tract [87]. In a recent study, barbotage cytology detected up to 91% of cancers [88]. Barbotage cytology taken from the renal cavities and ureteral lumina is preferred before application of a contrast agent for retrograde ureteropyelography as it may cause deterioration of cytological specimens [89]. Retrograde ureteropyelography remains an option to detect UTUCs [79, 90, 91].

The sensitivity of fluorescence in situ hybridisation (FISH) for molecular abnormalities characteristic of UTUCs is approximately 50% and therefore its use in clinical practice remains unproven [92, 93].

5.5 Diagnostic ureteroscopy
Flexible ureteroscopy (URS) is used to visualise the ureter, renal pelvis and collecting system and for biopsy of suspicious lesions. Presence, appearance and size of tumour can be determined using URS. In addition, ureteroscopic biopsies can determine tumour grade in more than 90% of cases with a low false-negative rate, regardless of sample size [94]. Undergrading may occur following diagnostic biopsy, making intensive follow-up necessary if kidney-sparing treatment is chosen [71, 95]. Ureteroscopy also facilitates selective ureteral sampling for cytology in situ [91, 96, 97]. Stage assessment using ureteroscopic biopsy is inaccurate. Combining ureteroscopic biopsy grade, imaging findings such as hydronephrosis, and urinary cytology may help in the decision-making process between radical nephroureterectomy (RNU) and kidney-sparing therapy [97, 98]. In a meta-analysis comparing URS vs. no URS prior to RNU, 8/12 studies found an increased risk for intravesical recurrence if URS was performed before RNU [99]. Performing a biopsy at URS was also identified as a risk factor for intravesical recurrence [99].

Technical developments in flexible ureteroscopes and the use of novel imaging techniques improve visualisation and diagnosis of flat lesions [100]. Narrow-band imaging is a promising technique, but results are preliminary [101]. Optical coherence tomography and confocal laser endomicroscopy (Cellvizio®) have been used in vivo to evaluate tumour grade and/or for staging purposes, with a promising correlation with definitive histology in high-grade UTUC [102, 103]. Recommendations for the diagnosis of UTUC are listed in Section 5.7.

5.6 Distant metastases
Prior to any treatment with curative intent, it is essential to rule out distant metastases. Computed tomography is the diagnostic technique of choice for lung- and abdominal staging for metastases [80]. A SEER analysis shows that approximately 9% of patients present with distant metastases [104].

5.6.1 18F-Fluorodeoxglucose positron emission tomography/computed tomography
A retrospective multi-centre publication on the use of 18F-Fluorodeoxglucose positron emission tomography/computed tomography (FDG-PET/CT) for the detection of nodal metastasis in 117 surgically-treated UTUC patients reported a promising sensitivity and specificity of 82% and 84%, respectively. Suspicious LNs on FDG-PET/CT were associated with worse recurrence-free survival [105]. These results warrant further validation and comparison with MR urography and CT.

6. PROGNOSIS

6.1 Prognostic factors

Many prognostic factors have been identified and can be used to risk-stratify patients in order to decide on the most appropriate local treatment (radical vs. conservative) and discuss peri-operative systemic therapy. Factors can be divided into patient-related factors and tumour-related factors.

6.1.1 Patient-related factors

6.1.1.1 Age and gender

Older age at the time of RNU is independently associated with decreased cancer-specific survival (CSS) [106, 107] (LE: 3). Gender has no impact on prognosis of UTUC [108].

6.1.1.2 Ethnicity

One multicentre study in academic centres did not show any difference in outcomes between races [109], but U.S. population-based studies have indicated that African-American patients have worse outcomes than other ethnicities (LE: 3). Whether this is related to access to care or biological and/or patterns of care remains unknown. Another study has demonstrated differences between Chinese and American patients at presentation (risk factor, disease characteristics and predictors of adverse oncologic outcomes) [14].

6.1.1.3 Tobacco consumption

Being a smoker at diagnosis increases the risk for disease recurrence, mortality [110, 111] and intravesical recurrence after RNU [112] (LE: 3). There is a close relationship between tobacco consumption and prognosis [113] (LE: 3); smoking cessation improves cancer control [111].

6.1.1.4 Surgical delay

A delay between diagnosis of an invasive tumour and its removal may increase the risk of disease progression. Once a decision regarding RNU has been made, the procedure should be carried out within twelve weeks, when possible [114-118] (LE: 3).

6.1.1.5 Other factors

Comorbidity and performance indices (e.g. American Society of Anesthesiologists [ASA], performance status [PS], and Charlson Comorbidity Index) are also associated with worse survival outcomes across disease stages [119-122].

A higher ASA score confers worse CSS after RNU [123] (LE: 3), as does poor PS [124]. Obesity and higher body mass index adversely affect cancer-specific outcomes in patients treated with RNU [125] (LE: 3), with potential differences between races [126]. Several blood-based biomarkers have been associated with locally advanced disease and cancer-specific mortality such as high pre-treatment-derived neutrophil-lymphocyte ratio [127-130], low albumin [129, 131], high C-reactive protein [129] or modified Glasgow score [132], high De Ritis ratio (aspartate transaminase/alanine transaminase) [133], altered renal function [129, 134] and high fibrinogen [129, 134] (LE: 3).
6.1.2 **Tumour-related factors**

6.1.2.1 **Tumour stage and grade**

The main prognostic factors are tumour stage and grade [22, 97, 107, 135]. Upper urinary tract UCs that invade the muscle wall have a poor prognosis. In a large Dutch series of UTUC, 5-year CSS was 86% for non-muscle-invasive tumours, 70% for muscle-invasive organ-confined tumours and 44% for locally-advanced tumours [136]. A SEER contemporary analysis of RNU for high-risk disease showed that 5-year CSS was 86% for T1N0, 77% for T2N0, 63% for T3N0 and 39% for T4N0/T any N1-3 [137].

6.1.2.2 **Tumour location, multifocality, size and hydronephrosis**

Initial location of the UTUC is a prognostic factor in some studies [138, 139] (LE: 3). After adjustment for the effect of tumour stage, patients with ureteral and/or multifocal tumours seem to have a worse prognosis than patients diagnosed with renal pelvic tumours [140-145]. Hydronephrosis is associated with advanced disease and poor oncological outcome [81, 89, 146]. Increasing tumour size is associated with a higher risk of muscle-invasive and/or non-organ-confined disease, both in ureteral and renal pelvis UTUC. A large multi-institutional retrospective study including 932 RNU performed for non-metastatic UTUC demonstrated that 2 cm appears to be the best cut-off in identifying patients at risk of harbouring $\geq$ pT2 UTUC [147]. In a SEER database analysis of 4,657 patients with renal pelvis UTUC, each gain of 1 cm in tumour size was associated with a 1.25-fold higher risk of pT2–T4 histology at RNU [104].

6.1.2.3 **Variant histology**

Pathological variants are associated with worse cancer-specific and overall survival (OS) [64] (LE: 3). Most studied variants are micropapillary [67], squamous [148] and sarcomatoid [67] which are consistently associated with locally-advanced disease and worse outcome.

6.1.2.4 **Lymph node involvement**

Patients with nodal metastasis experience very poor survival after surgery [149]. Lymph node density (cut-off 30%) and extranodal extension are powerful predictors of survival outcomes in N+ UTUC [150-152]. Lymph node dissection (LND) performed at the time of RNU allows for optimal tumour staging, although its curative role remains controversial [151, 153-155] (LE: 3).

6.1.2.5 **Lymphovascular invasion**

Lymphovascular invasion (LVI) is present in approximately 20% of invasive UTUCs and is an independent predictor of survival [156-158]. Lymphovascular invasion status should be specifically reported in the pathological reports of all UTUC specimens [156, 159, 160] (LE: 3).

6.1.2.6 **Surgical margins**

Positive soft tissue surgical margin is associated with a higher disease recurrence after RNU. Pathologists should look for and report positive margins at the level of ureteral transection, bladder cuff, and around the tumour [161] (LE: 3).

6.1.2.7 **Other pathological factors**

Extensive tumour necrosis (> 10% of the tumour area) is an independent prognostic predictor in patients who undergo RNU [162, 163] (LE: 3). In case neoadjuvant treatment was administered, pathological downstaging is associated with better OS [164, 165] (LE: 3). The architecture of UTUC, as determined from pathological examination of RNU specimens, is also a strong prognosticator with sessile growth pattern being associated with worse outcome [166-168] (LE: 3). Concomitant CIS in organ-confined UTUC and a history of bladder CIS are associated with a higher risk of recurrence and cancer-specific mortality [169, 170] (LE: 3). Macroscopic infiltration or invasion of peri-pelvic adipose tissue confers a higher risk of disease recurrence after RNU compared to microscopic infiltration of renal parenchyma [63, 171].

6.1.3 **Molecular markers**

Because of the rarity of UTUC, the main limitations of molecular studies are their retrospective design and, for most studies, small sample size. None of the investigated markers have been validated yet to support their introduction in daily clinical decision making [140, 172].

6.2 **Risk stratification for clinical decision making**

6.2.1 **Low- versus high-risk UTUC**

As tumour stage is difficult to assess clinically in UTUC, it is useful to “risk stratify” UTUC between low- and high risk of progression to identify those patients who are more likely to benefit from kidney-sparing treatment and those who should be treated radically [173, 174] (see Figure 6.2). The factors to consider for risk stratification are presented in Figure 6.1.
Several new risk stratification models have been assessed to improve upon the dichotomous EAU risk grouping, with the main aim to avoid overtreatment (i.e., better stratify patients eligible for kidney-sparing surgery). Examples include multivariable models with novel clinical characteristics [175] a tumour grade-and stage-based model [176] and a three-tier risk stratification model (i.e., low-, intermediate-, and high risk) [177]. These models need further validation.

**Figure 6.1: Risk stratification of non-metastatic UTUC**

CT = computed tomography; URS = ureteroscopy; UTUC = upper urinary tract urothelial carcinoma.

* All these factors need to be present.
**Any of these factors need to be present.

**6.2.2 Peri-operative predictive tools for high-risk disease**

There are several pre-RNU models aiming at predicting which patient has muscle-invasive/non-organ-confined disease [162, 178-181] (LE: 3). Prognostic nomograms based on pre-operative factors and post-operative pathological characteristics are available [153, 180, 182-187]. The main factors included in these models, which may be used when counselling patients regarding follow-up and administration of peri-operative chemotherapy, are detailed in Figure 6.2.

**Figure 6.2: UTUC prognostic factors included in prognostic models**

CT = computed tomography; URS = ureteroscopy; UTUC = upper urinary tract urothelial carcinoma.
6.3 Bladder recurrence
A meta-analysis of available data has identified significant predictors of bladder recurrence after RNU [188] (LE: 3). Three categories of predictors for increased risk of bladder recurrence were identified:

1. Patient-specific factors such as male gender, previous bladder cancer, smoking and pre-operative chronic kidney disease.
2. Tumour-specific factors such as positive pre-operative urinary cytology, tumour grade, ureteral location, multifocality, tumour diameter, invasive pT stage, and necrosis [189].
3. Treatment-specific factors such as laparoscopic approach, extravesical bladder cuff removal, and positive surgical margins [188].

In addition, the use of diagnostic URS has been associated with a higher risk of developing bladder recurrence after RNU [190, 191] (LE: 3). Based on low-level evidence only, a single dose of intravesical chemotherapy after diagnostic/therapeutic ureteroscopy of non-metastatic UTUC has been suggested to lower the rate of intravesical recurrence, similarly to that after RNU [188].

7. DISEASE MANAGEMENT

7.1 Localised non-metastatic disease

7.1.1 Kidney-sparing surgery

Kidney-sparing surgery for low-risk UTUC reduces the morbidity associated with radical surgery (e.g., loss of kidney function), without compromising oncological outcomes [192]. In low-risk cancers, it is the preferred approach as survival is similar to that after RNU [192]. This option should therefore be discussed in all low-risk cases, irrespective of the status of the contralateral kidney. In addition, it can also be considered in selected high-risk patients with a serious renal insufficiency or having a solitary kidney (LE: 3). Recommendations for kidney-sparing management of UTUC are listed in Section 7.1.1.5.

7.1.1.1 Ureteroscopy

Endoscopic ablation should be considered in patients with clinically low-risk cancer [193, 194]. A flexible ureteroscope is useful in the management of pelvicalyceal tumours [195]. The patient should be informed of the need and be willing to comply with an early second-look URS [196] and stringent surveillance; complete tumour resection or destruction is necessary [196]. Nevertheless, a risk of disease progression remains with endoscopic management due to the suboptimal performance of imaging and biopsy for risk stratification and tumour biology [197].

7.1.1.2 Percutaneous access

Percutaneous management can be considered for low-risk UTUC in the renal pelvis [193, 198] (LE: 3). This may also be offered for low-risk tumours in the lower caliceal system that are inaccessible or difficult to manage by flexible URS. However, this approach is being used less due to the availability of improved endoscopic tools such as distal-tip deflection of recent ureteroscopes [194, 198]. Moreover, a risk of tumour seeding remains with a percutaneous access [198].
7.1.1.3 Ureteral resection
Segmental ureteral resection with wide margins provides adequate pathological specimens for staging and grading while preserving the ipsilateral kidney. Lymphadenectomy can also be performed during segmental ureteral resection [192]. Segmental resection of the proximal two-thirds of ureter is associated with higher failure rates than for the distal ureter [199, 200] (LE: 3).

Distal ureterectomy with ureteroneocystostomy are indicated for low-risk tumours in the distal ureter that cannot be removed completely endoscopically and for high-risk tumours when kidney-sparing surgery for renal function preservation is desired (in case of an imperative indication) [183, 199, 201] (LE: 3). A total ureterectomy with an ileal-ureteral substitution is technically feasible, but only in selected cases when a renal-sparing procedure is mandatory and the tumour is low risk [202].

7.1.1.4 Upper urinary tract instillation of topical agents
The antegrade instillation of BCG or mitomycin C in the upper urinary tract via percutaneous nephrostomy after complete tumour eradication has been studied for CIS after kidney-sparing management [170, 203] (LE: 3). Retrograde instillation through a single J open-ended ureteric stent is also used. Both the antegrade and retrograde approach can be dangerous due to possible ureteric obstruction and consecutive pyelovenous influx during instillation/perfusion. The reflux obtained from a double-J stent has been used but this approach is suboptimal because the drug often does not reach the renal pelvis [204-207].

A systematic review and meta-analysis assessing the oncologic outcomes of patients with papillary UTUC or CIS of the upper tract treated with kidney-sparing surgery and adjuvant endocavitary treatment analysed the effect of adjuvant therapies (i.e., chemotherapeutic agents and/or immunotherapy with BCG) after kidney-sparing surgery for papillary non-invasive (Ta-T1) UTUCs and of adjuvant BCG for the treatment of upper tract CIS, finding no difference between the method of drug administration (antegrade vs. retrograde vs. combined approach) in terms of recurrence, progression, CSS, and OS. Furthermore, the recurrence rates following adjuvant instillations are comparable to those reported in the literature in untreated patients, questioning their efficacy [208]. The analyses were based on retrospective small studies suffering from publication and reporting bias.

Recent evidence suggests that early single adjuvant intracavitary instillation of mitomycin C in patients with low-grade UTUC might reduce the risk of local recurrence [209] (LE: 3). This needs to be confirmed in further studies. The authors report limited complications related to the instillations, but propose a retrograde pyelography before instillations are commenced to exclude contrast extravasation. This concept will need further evaluation in a randomised context [209].

A single-arm phase III trial showed that the use of mitomycin-containing reverse thermal gel (UGN-101) instillations in a chemoablation setting via retrograde catheter to the renal pelvis and calyces was associated with a complete response rate in a total of 42 patients (59%) with biopsy-proven low-grade UTUC measuring less than 15 mm. The most frequently reported all-cause adverse events were ureteric stenosis in 31 (44%) of 71 patients, urinary tract infection in 23 (32%), haematuria in 22 (31%), flank pain in 21 (30%), and nausea in 17 (24%). A total of 19 (27%) of 71 patients had drug-related or procedure-related serious adverse events. No deaths were regarded as related to treatment [210].

7.1.2 Management of high-risk non-metastatic UTUC
7.1.2.1 Surgical approach
7.1.2.1.1 Open radical nephroureterectomy
Open RNU with bladder cuff excision is the standard treatment of high-risk UTUC, regardless of tumour location [22] (LE: 3). Radical nephroureterectomy must be performed according to oncological principles preventing tumour seeding [22]. Section 7.1.6 lists the recommendations for RNU.
7.1.2.1.2 Minimal invasive radical nephroureterectomy

Retroperitoneal metastatic dissemination and metastasis along the trocar pathway following manipulation of large tumours in a pneumoperitoneal environment have been reported in few cases [211, 212]. Several precautions may lower the risk of tumour spillage:

1. avoid entering the urinary tract;
2. avoid direct contact between instruments and the tumour;
3. perform the procedure in a closed system. Avoid morcellation of the tumour and use an endobag for tumour extraction;
4. the kidney and ureter must be removed en bloc with the bladder cuff;
5. invasive or large (T3/T4 and/or N+/M+) tumours are contraindications for minimal-invasive RNU as the outcome is worse compared to an open approach [213, 214].

Laparoscopic RNU is safe in experienced hands when adhering to strict oncological principles. There is a tendency towards equivalent oncological outcomes after laparoscopic or open RNU [212, 215-218] (LE: 3). One prospective randomised study has shown that laparoscopic RNU is inferior to open RNU for non-organ-confined UTUC. However, this was a small trial (n = 80), which was likely underpowered [214] (LE: 2). Oncological outcomes after RNU have not changed significantly over the past three decades despite staging and surgical refinements [219] (LE: 3). In a population-based data set, a hospital volume of ≥ 6 patients per year treated with RNU showed improvement of short-term outcomes (30- and 90-day mortality) and overall long-term survival [220]. A robot-assisted laparoscopic approach can be considered with recent data suggesting oncologic equivalence with the other approaches [221-223].

7.1.2.1.3 Management of bladder cuff

Resection of the distal ureter and its orifice is performed because there is a considerable risk of tumour recurrence in this area and in the bladder [188, 199, 224-226]. Several techniques have been considered to simplify distal ureter resection, including the pluck technique, stripping, transurethral resection of the intramural ureter, and intussusception. None of these techniques has convincingly been shown to be equal to complete bladder cuff excision [16, 224, 225] (LE: 3).

7.1.2.1.4 Lymph node dissection

The use of a LND template is likely to have a greater impact on patient survival than the number of removed LNs [227]. Template-based and completeness of LND improves CSS in patients with muscle-invasive disease and reduces the risk of local recurrence [228]. Even in clinically [229] and pathologically [230] node-negative patients, LND improves survival. The risk of LN metastasis increases with advancing tumour stage [154]. Lymph node dissection appears to be unnecessary in cases of TaT1 UTUC because of the low risk of LN metastasis [231-234], however, tumour staging is inaccurate pre-operatively; therefore a template-based LND should be offered to all patients who are scheduled for RNU for high-risk non-metastatic UTUC. The templates for LND have been described [228, 235, 236].

7.1.3 Peri-operative chemotherapy

7.1.3.1 Neoadjuvant chemotherapy

In patients treated prior to losing their renal reserve several retrospective studies evaluating the role of neoadjuvant chemotherapy have shown promising pathological downstaging and complete response rates [164, 237-240]. No RCTs have been published yet but prospective data from a phase II trial showed that the use of neoadjuvant chemotherapy was associated with a 14% pathological complete response rate for high-grade UTUC [241]. In addition, final pathological stage was ≤ ypT1 in more than 60% of included patients with acceptable toxicity profile. In a systematic review and meta-analysis comprising more than 800 patients, neoadjuvant chemotherapy has shown a pathologic partial response of 43% and a downstaging in 33% of patients, and also an OS and CSS survival benefit compared with RNU alone [242]. Furthermore, neoadjuvant chemotherapy has been shown to result in lower disease recurrence and mortality rates compared to RNU alone without compromising the use of definitive surgical treatment [239, 243-245].

7.1.3.2 Adjuvant chemotherapy

7.1.3.2.1 Chemotherapy

A phase III prospective randomised trial (n = 261) evaluating the benefit of adjuvant gemcitabine-platinum combination chemotherapy initiated within 90 days after RNU vs. surveillance has reported a significant improvement in disease-free survival in patients with pT2–pT4, N (any) or LN-positive (pT any, N1–3) M0 UTUC [246] (LE: 1).

The main limitation of using adjuvant chemotherapy for advanced UTUC remains the limited ability to deliver full dose cisplatin-based regimen after RNU, given that this surgical procedure is likely to impact renal
function [247, 248]. In a retrospective study histological variants of UTUC exhibit different survival rates and adjuvant chemotherapy was only associated with an OS benefit in patients with pure UC [249] (LE: 3).

7.1.3.2.2 Immunotherapy
In a phase 3, multicentre, double-blind RCT involving patients with high-risk muscle-invasive UC who had undergone radical surgery, adjuvant nivolumab improved disease-free survival compared to placebo in the intention-to-treat population (20.8 vs 10.8 months) and among patients with a PD-L1 expression level of 1% or more [250]. The median survival free from recurrence outside the urothelial tract in the intention-to-treat population was 22.9 months with nivolumab and 13.7 months with placebo. Treatment-related adverse events ≥ grade 3 occurred in 17.9% of the nivolumab group and 7.2% of the placebo group. The subgroup of patients with UTUC in this study needs further analysis to better understand the effect of adjuvant nivolumab for high-risk muscle-invasive UC after RNU.

7.1.4 Adjuvant radiotherapy after radical nephroureterectomy
Adjuvant radiation therapy has been suggested to control loco-regional disease after surgical removal. The data remains controversial and insufficient for conclusions [251-254]. Moreover, its added value to chemotherapy remains questionable [253].

7.1.5 Post-operative bladder instillation
The rate of bladder recurrence after RNU for UTUC is 22–47% [174, 224]. Two prospective randomised trials [255, 256] and two meta-analyses [257, 258] have demonstrated that a single post-operative dose of intravesical chemotherapy (mitomycin C, pirarubicin) 2–10 days after surgery reduces the risk of bladder tumour recurrence within the first years post-RNU (LE: 2). Prior to instillation, a cystogram might be considered in case of any concerns about drug extravasation.

Based on current evidence it is unlikely that additional instillations beyond one peri-operative instillation of chemotherapy further substantially reduces the risk of intravesical recurrence [259]. Whilst there is no direct evidence supporting the use of intravesical instillation of chemotherapy after kidney-sparing surgery, single-dose chemotherapy might be effective in that setting as well (LE: 4). Management is outlined in Figures 7.1 and 7.2. One low-level evidence study suggested that bladder irrigation might reduce the risk of bladder recurrence after RNU [260].

7.2 Metastatic disease

7.2.1 Radical nephroureterectomy

The role of RNU in the treatment of patients with metastatic UTUC has recently been explored in several observational studies [261-264]. Although evidence remains very limited, RNU may be associated with cancer-specific [261, 263, 264] and OS benefit in selected patients, especially those fit enough to receive cisplatin-based chemotherapy [262, 263]. It is noteworthy that these benefits may be limited to those patients with only one metastatic site [263]. Nonetheless, given the high risk of bias of the observational studies addressing RNU for metastatic UTUC, indications for RNU in this setting should mainly be reserved for palliative patients, aimed at controlling symptomatic disease [18, 110] (LE: 3).

7.2.2 Metastasectomy

There is no UTUC-specific study supporting the role of metastasectomy in patients with advanced disease. However, several reports including both UTUC and bladder cancer patients suggested that resection of metastatic lesions could be safe and oncologically beneficial in selected patients with a life expectancy of more than 6 months [265-267]. This was confirmed in the most recent and largest study to date [268]. In patients with metastases limited to lung and/or lymph nodes, whose disease responded to systemic chemotherapy, metastasectomy can improve oncological outcomes in individual cases [269] (LE: 3).

Nonetheless, in the absence of data from RCTs, patients should be evaluated on an individual basis and the decision to perform a metastasectomy (surgically) should be made following a shared decision-making process with the patient.

7.2.3 Systemic treatments

7.2.3.1 First-line setting

7.2.3.1.1 Patients fit enough to tolerate cisplatin-based combination chemotherapy

Data from the bladder cancer literature and from small, single-centre UTUC studies suggest that platinum-based combination chemotherapy, especially cisplatin, is efficacious as first-line treatment of metastatic UTUC. Cisplatin-containing combination chemotherapy is standard in advanced or metastatic patients fit enough to tolerate cisplatin [2]. A number of cisplatin-containing chemotherapy regimens are acceptable although gemcitabine and cisplatin is the most widely used. A retrospective analysis of three RCTs showed that primary tumour location in the lower- or upper urinary tract had no impact on progression-free survival (PFS) or OS in patients with locally advanced or metastatic UC treated with platinum-based combination chemotherapy [270]. The efficacy of immunotherapy using programmed death-1 (PD1) or programmed death-ligand 1 (PD-L1) inhibitors has been evaluated in the first-line setting for the treatment of cisplatin-fit patients with metastatic UC, including those with UTUC [271]. The combination of platinum-based chemotherapy with immune checkpoint inhibitors have not resulted in positive significant survival advantages and are not currently recommended [272].

7.2.3.1.2 Patients fit for carboplatin (but unfit for cisplatin-based combination chemotherapy)

Carboplatin-based chemotherapy is recommended in patients unfit for cisplatin [2]. Carboplatin with gemcitabine is the preferred regimen [273].

7.2.3.1.3 Maintenance therapy after first-line platinum-based treatment

Platinum-based chemotherapy followed by maintenance avelumab is preferred to upfront immune checkpoint inhibitors in both PD-L1 biomarker positive and negative patients. Data from a phase III RCT showed that the use of avelumab maintenance therapy after 4 to 6 cycles of gemcitabine plus cisplatin or carboplatin (started within 10 weeks of completion of first-line platinum-based chemotherapy) significantly prolonged OS as compared to best supportive care alone in those patients with advanced or metastatic UC who did not progress during, or responded to, first-line chemotherapy (HR 0.69; 95% CI 0.56–0.86) [274, 275]. An increase in median OS from 14 to 21 months was observed with avelumab. Although no subgroup analysis based on tumour location was available in this study, almost 30% of the included patients had UTUC. Similarly, in a phase II study comprising 108 patients with metastatic UC achieving at least stable disease on first-line platinum-based chemotherapy, maintenance pembrolizumab improved PFS compared to placebo (5.4 vs. 3.0 months) [276].

7.2.3.1.4 Immunotherapy in cisplatin-unfit patients

Pembrolizumab or atezolizumab are alternative choices for patients who are PD-L1 positive and not eligible for cisplatin-based chemotherapy, although RCTs failed to show significant superiority compared with chemotherapy [272, 277]. Final data from randomised trials with durvalumab are similar with no OS benefit [278]. Biomarkers (SP142 for atezolizumab; 22C3 for pembrolizumab) should be used to match the drug, as recommended by the European Medicines Agency (EMA) [279, 280].

In a single-arm phase II trial (n = 370) of cisplatin-ineligible UC, pembrolizumab monotherapy was
associated with an objective response rate of 26% in 69 metastatic UTUC patients [281]. In the overall cohort, a PD-L1 expression of 10% was associated with a greater response rate to pembrolizumab. Treatment-related toxicity was in line with previous studies. In a single-arm phase II trial (n = 119) of cisplatin-ineligible UC, atezolizumab monotherapy was associated with an objective response rate of 39% in 33 (28%) metastatic UTUC patients [282]. Median OS in the overall cohort was 15.9 months and treatment-related toxicity was in line with previous studies. Data from a phase III RCT including 1,213 patients with metastatic cisplatin-eligible and cisplatin-ineligible UC, of which 312 (26%) were diagnosed with UTUC, showed that the combination of atezolizumab with platinum-based chemotherapy prolonged both PFS and OS [277]. No subgroup analysis based on tumour location was performed in this study.

7.2.3.2 Second-line setting
7.2.3.2.1 Immunotherapy
A phase III RCT including 542 patients who received prior platinum-based chemotherapy for advanced UC showed that pembrolizumab could decrease the risk of death compared to second-line chemotherapy (the investigator’s choice of paclitaxel, docetaxel, or vinflunine); median OS: 10.3 months for pembrolizumab and 7.4 months for chemotherapy, HR 0.73, 95% CI: 0.59–0.91 [283]. Responses were more frequent and durable for pembrolizumab compared with chemotherapy (21% vs. 11%). In the UTUC subgroup (n = 75, 13.8%), the OS benefit seemed larger (50%).

The IMVigor211 trial explored atezolizumab in PD-L1 biomarker positive tumours in patients with tumours which have relapsed after platinum-based therapy and failed to show a significant OS advantage [284]. In a phase II study, 48 patients with platinum-refractory UC (18/48 patients with UTUC) were treated with cabozantinib. There was one complete response and 7 partial responses (objective response rate 19%, 95% CI: 9–34). Median PFS was 3.7 months (95% CI: 3–6) [285].

Other immunotherapies such as nivolumab [286], avelumab [287, 288] and durvalumab [289] have shown objective response rates ranging from 17.8% [289] to 19.6% [286] and median OS ranging from 18.2 months to 18.8 months in patients with platinum-resistant metastatic UC. These results were obtained from single-arm phase I or II trials only and the number of UTUC patients included in these studies was only specified for avelumab (n = 7/15.9%) without any subgroup analysis based on primary tumour location [288].

The immunotherapy combination of nivolumab plus ipilimumab has shown significant anti-tumour activity with objective response rate up to 38% in a phase II/I multi-centre trial including 78 patients with metastatic UC progressing after platinum-based chemotherapy [290]. Although UTUC patients were included in this trial, no subgroup analysis was available. Other immunotherapy combinations may be effective in the second-line setting but data are currently limited [291].

7.2.3.2.2 Novel agents
Fibroblast growth factor receptors (FGFR) inhibition
Erdafitinib, a pan-FGFR tyrosine kinase inhibitor of FGFR1–4, was associated with a 40% response rate in a phase II trial in 99 patients with locally advanced or metastatic UC who progressed after first-line chemotherapy and harboured a FGFR DNA genomic alterations (FGFR2 or 3 mutations, or FGFR3 fusions) [292]. This study included 23 UTUC patients with visceral metastases showing a 43% response rate.

Antibody drug conjugates (ADC)
A phase II study enrolled 89 patients (of whom 43% had UTUC) with metastatic UC progressing after therapy with PD-1 or PD-L1 inhibitors. All patients received the antibody–drug conjugate enfortumab vedotin. The objective response rate was 52%, 20% of patients achieved complete response [293].

7.2.3.3 Third-line setting
In an open-label phase II trial a total of 108 patients with metastatic UC with progression on platinum-based and checkpoint inhibitors were treated with the antibody-drug conjugate sacituzumab govitecan. The objective response rate was 27%, with median duration of response 7.2 months, median PFS 5.4 months and OS 10.9 months. The site of primary UC is not mentioned in the publication [294].

A pre-planned subgroup analysis from the phase III RANGE trial assessed the impact on outcomes and safety of ramucirumab added to docetaxel after disease progression on both platinum and immune checkpoint inhibitors therapy [295]. Median PFS was 3.15 months on ramucirumab/docetaxel vs 2.73 months on placebo/docetaxel (HR = 0.786, 95%, CI: 0.404–1.528, p = 0.4877). This trend for ramucirumab benefit occurred despite the ramucirumab arm having a higher percentage of patients with poorer prognosis. However, these findings need confirmation by further studies, as this analysis is limited by patient numbers and an imbalance in the treatment arms.

8. FOLLOW-UP

The risk of recurrence and death evolves during the follow-up period after surgery [296]. A direct relationship exists between event-free follow-up and survival probability after RNU [137]. Stringent follow-up is mandatory to detect metachronous bladder tumours (probability increases over time [297]), local recurrence, and distant metastases.

Surveillance regimens are based on cystoscopy and urinary cytology [15, 297]. Bladder recurrence is not considered a distant recurrence. When kidney-sparing surgery is performed, the ipsilateral UUT requires careful and long-term follow-up due to the high risk of disease recurrence [195, 298, 299] and progression to RNU beyond 5 years [300]. Despite endourological improvements, follow-up after kidney-sparing management is difficult and frequent, and repeated endoscopic procedures are necessary. Following kidney-sparing surgery, and as done in bladder cancer, an early repeated (second look) ureteroscopy within 6 to 8 weeks after primary endoscopic treatment has been proposed, but is not yet routine practice [2, 196]. Section 8.1 presents the summary of evidence and recommendations for follow-up of UTUC.

11. CITATION INFORMATION 95
1. INTRODUCTION

1.1 Aims and scope
The European Association of Urology (EAU) Guidelines Panel for Muscle-invasive and Metastatic Bladder Cancer (MIBC) have prepared these guidelines to help urologists assess the evidence-based management of MIBC and to incorporate guideline recommendations into their clinical practice.

Separate EAU guidelines documents are available addressing upper urinary tract (UUT) tumours [1], non-muscle-invasive bladder cancer (TaT1 and carcinoma in situ) (NMIBC) [2], and primary urethral carcinomas [3].

It must be emphasised that clinical guidelines present the best evidence available to the experts but following guideline recommendations will not necessarily result in the best outcome. Guidelines can never replace clinical expertise when making treatment decisions for individual patients, but rather help to focus decisions - also taking personal values and preferences/individual circumstances of patients into account. Guidelines are not mandates and do not purport to be a legal standard of care.

1.2 Panel composition
The EAU Guidelines Panel consists of an international multidisciplinary group of clinicians, including urologists, oncologists, a pathologist, a radiologist and radiotherapists. In the course of 2021 two patient representatives formally joined the MIBO Guidelines Panel.

Section 5.3 -MIBC and health status, was developed with the assistance of Prof. Dr. S. O’Hanlon, consultant geriatrician, International Society of Geriatric Oncology (SIOG) representative and member of the EAU-EANM-ESTRO-ISUR-ISUP-SIOG Prostate Cancer Guidelines Panel. The MIBC Panel is most grateful for his support.

All experts involved in the production of this document have submitted potential conflict of interest statements which can be viewed on the EAU website Uroweb: https://uroweb.org/guideline/bladder-cancer-muscle-invasive-and-metastatic/?type=panel

1.3 Available publications
A quick reference document (Pocket Guidelines) is available, both in print and as an app for iOS and Android devices. These are abridged versions which may require consultation together with the full text version.

Several scientific publications are available (the most recent paper dating back to 2021 [4], as are a number of translations of all versions of the EAU MIBC Guidelines. All documents are accessible through the EAU website: http://uroweb.org/guideline/bladder-cancer-muscle-invasive-and-metastatic/.

1.4 Publication history and summary of changes
1.4.1 Publication history
The EAU published its first guidelines on bladder cancer (BC) in 2000. This document covered both NMIBC and MIBC. Since these conditions require different treatment strategies, it was decided to give each condition its own guidelines, resulting in the first publication of the MIBC Guidelines in 2004. This 2022 document presents a limited update of the 2021 version.

1.4.2 Summary of changes
New relevant references have been identified through a structured assessment of the literature and incorporated in the various chapters of the 2022 EAU MIBC Guidelines resulting in new sections and added and revised recommendations in:

- Section 5.2 Imaging for staging of MIBC, and in particular Section 5.2.1 Local staging of MIBC, with the provision of a revised recommendation.

### 5.2.6 Summary of evidence and guidelines for staging in muscle-invasive bladder cancer

<tbody>
<tr>
<td>Use CT urography unless it is contraindicated for reasons related to contrast administration or radiation dose, in that case use MRI.</td>
<td>Strong</td>
</tr>
</tbody>
</table>
Considerable new data was added to:

- Section 7.1 Neoadjuvant therapy
- Section 7.1.2 Role of cisplatin-based chemotherapy; this section was revised with considerable new data added.
- Section 7.3.5 Laparoscopic/robotic-assisted laparoscopic cystectomy; a new section on stricture formation has been included.
- Section 7.3.6.2 Different types of urinary diversion, in particular Section 7.3.6.2.1 Uretero-cutaneostomy
- Section 7.6.2 Role of adjuvant immunotherapy has been completely revised including a new recommendation.

7.6.3 **Summary of evidence and guidelines for adjuvant therapy**

- Chapter 8 Follow-up; a new section on variant histologies was added.
2. METHODS

2.1 Data identification

For the 2021 MIBC Guidelines, new and relevant evidence has been identified, collated and appraised through a structured assessment of the literature. A broad and comprehensive literature search, covering all sections of the MIBC Guideline was performed. The search was limited to English language publications. Databases searched included Medline, EMBASE and the Cochrane Libraries, covering a time frame between May 14th, 2020 and June 11th, 2021. A total of 2,290 unique records were identified, retrieved and screened for relevance resulting in 61 new publications having been included in the 2022 print. A detailed search strategy is available online: https://uroweb.org/guideline/bladder-cancer-muscle-invasive-and-metastatic/?type=appendices-publications

For each recommendation within the guidelines there is an accompanying online strength rating form, the basis of which is a modified GRADE methodology [5, 6] which addresses a number of key elements namely:

1. the overall quality of the evidence which exists for the recommendation, references used in this text are grade according to a classification system modified from the Oxford Centre for Evidence-Based Medicine Levels of Evidence [7];
2. the magnitude of the effect (individual or combined effects);
3. the certainty of the results (precision, consistency, heterogeneity and other statistical or study related factors);
4. the balance between desirable and undesirable outcomes;
5. the impact of patient values and preferences on the intervention;
6. the certainty of those patient values and preferences.

These key elements are the basis which panels use to define the strength rating of each recommendation. The strength of each recommendation is represented by the words ‘strong’ or ‘weak’ [6]. The strength of each recommendation is determined by the balance between desirable and undesirable consequences of alternative management strategies, the quality of the evidence (including certainty of estimates), and nature and variability of patient values and preferences.

Additional information can be found in the general Methodology section of this print, and online at the EAU website; http://www.uroweb.org/guideline/. A list of Associations endorsing the EAU Guidelines can also be viewed online at the above address.

The results of a collaborative multi-stakeholder consensus project on the management of advanced and variant BC have been incorporated in the 2020 MIBC Guidelines update [8, 9]. Only statements which reached the a priori defined level of agreement - > 70% agreement and < 15% disagreement – across all stakeholders involved in this consensus project are listed. The methodology is presented in detail in the scientific publications. Since the publication of these consensus papers, emerging evidence prompted a re-evaluation of these findings, resulting in the removal of a number of consensus statements.

2.2 Peer-review

The 2021 print of the MIBC Guidelines were peer reviewed prior to publication.

2.2.1 Lay review

Post publication, the 2018 MIBC Guidelines were shared with seven patients treated for MIBC. Their comments were requested, but not limited to:

• the overall tone of the guidelines content;
• any missing information;
• any information considered incorrect;
• any information which is not presented in a clear fashion;
• any text which is considered redundant and should be omitted;
• any text section that should be more detailed.

Common comments across reviewers:

• In general, the overall tone of the text was considered informational and instructive, but the language used obviously targets medical professionals, which make certain parts of the text difficult to understand for lay persons. The use of many abbreviations is considered an additional hindrance, as are the methodological elements. In case the EAU are considering producing a lay version of this text, the language needs to be adapted and clear instructions are to be provided.
• It is difficult for lay reviewers to comment on what may be omitted since, in their opinion, they lack the expertise.
• Some sections, such as ‘Recurrent disease’ and ‘Markers’ denote areas where less evidence is available. Consequently, the available data is less systematically presented which makes these sections more difficult to understand.
• There is an interest whether screening for BC is a consideration.
• In particular ‘follow-up’, ‘quality of life’ and ‘survivorship aspects’ should be elaborated on; providing additional information on what may be expected after treatment is considered very helpful for patients and their families. Also lifestyle elements would be of relevance (healthy living, ‘what to do to prevent cancer’). For this section, in particular, involvement of patients in the text development was considered missing. Transparency about the process of patient involvement in guidelines development was considered most relevant.

The MIBC Guidelines Panel is most grateful for the unique insights and guidance provided by the lay reviewers.

2.3 Future goals
Topics considered for inclusion in the 2023 update of the MIBC Guidelines:
• a systematic review on the role of Positron Emission Tomography (PET) in the diagnosis and staging of patients presenting with suspected MIBC;
• development of a diagnostic pathway for the assessment of visible and non-visible haematuria;
• participation in developing strategies to ensure meaningful participation of patients in the development and implementation of the MIBC Guidelines.

3. EPIDEMIOLOGY, AETIOLOGY AND PATHOLOGY

3.1 Epidemiology
Bladder cancer is the 7th most commonly diagnosed cancer in males, whilst it drops to 10th position when both genders are considered [10]. The worldwide age-standardised incidence rate (per 100,000 person/years) is 9.5 for men and 2.4 for women [10]. In the European Union, the age-standardised incidence rate is 20 for men and 4.6 for women [10]. In Europe, the highest age-standardised incidence rate has been reported in Belgium (31 in men and 6.2 in women) and the lowest in Finland (18.1 in men and 4.3 in women) [10].

Worldwide, the BC age-standardised mortality rate (per 100,000 person/years) was 3.3 for men vs. 0.86 for women in 2012 [10]. Bladder cancer incidence and mortality rates vary across countries due to differences in risk factors, detection and diagnostic practices, and availability of treatments. The variations are, however, also partly caused by the different methodologies used in the studies and the quality of data collection [11, 12]. The incidence and mortality of BC has decreased in some registries, possibly reflecting the decreased impact of causative agents [13, 14].

Approximately 75% of patients with BC present with disease confined to the mucosa (stage Ta, carcinoma in situ [CIS]) or submucosa (stage T1). In younger patients (< 40 years) this percentage is even higher [15]. Patients with TaT1 and CIS have a high prevalence due to long-term survival in many cases and lower risk of cancer-specific mortality (CSM) compared to T2-4 tumours [10, 11].

3.2 Aetiology
3.2.1 Tobacco smoking
Tobacco smoking is the most well-established risk factor for BC, causing 50–65% of male cases and 20–30% of female cases [16, 17]. A causal relationship has been established between exposure to tobacco and cancer in studies in which chance, bias and confounding can be discounted with reasonable confidence [18].

The incidence of BC is directly related to the duration of smoking and the number of cigarettes smoked per day [19]. A meta-analysis looked at 216 observational studies on cigarette smoking and cancer published between 1961 and 2003, and the pooled risk estimates for BC demonstrated a significant association for both current and former smokers [20]. Recently, an increase in risk estimates for current smokers relative to never smokers has been described suggesting this could be due to changes in cigarette composition [16]. Starting to smoke at a younger age increased the risk of death from BC [21]. An immediate decrease in the risk of BC was observed in those who stopped smoking. The reduction was about 40% within one to four years of quitting smoking and 60% after 25 years of cessation [19]. Encouraging people to stop smoking would result in the incidence of BC decreasing equally in men and women [16].
3.2.2 **Occupational exposure to chemicals**

Occupational exposure is the second most important risk factor for BC. Work-related cases accounted for 20–25% of all BC cases in several series and it is likely to occur in occupations in which dyes (with the exception of hair dyes [22]), rubbers, textiles, paints, leathers, and chemicals are used [23, 24]. The risk of BC due to occupational exposure to carcinogenic aromatic amines is significantly greater after ten years or more of exposure; the mean latency period usually exceeds 30 years [25, 26]. Population-based studies established the occupational attribution for BC in men to be 7.1%, while no such attribution was discernible for women [11, 27].

3.2.3 **Radiotherapy**

Increased rates of secondary bladder malignancies have been reported after external-beam radiotherapy (EBRT) for gynaecological malignancies, with relative risks (RR) of 2–4 [24]. In a population-based cohort study, the standardised incidence ratios for BC developing after radical prostatectomy (RP), EBRT, brachytherapy, and EBRT-brachytherapy were 0.99, 1.42, 1.10, and 1.39, respectively, in comparison with the general U.S. population [28].

It has recently been proposed that patients who have received radiotherapy (RT) for prostate cancer with modern modalities such as intensity-modulated radiotherapy (IMRT) may have lower rates of in-field bladder- and rectal secondary malignancies [29]. Nevertheless, since longer follow-up data are not yet available, and as BC requires a long period to develop, patients treated with radiation and with a long life expectancy are at a higher risk of developing BC [29].

3.2.4 **Dietary factors**

Several dietary factors have been related to BC; however, the links remain controversial. The European Prospective Investigation into Cancer and Nutrition (EPIC) study is an on-going multicentre cohort study designed to examine the association between diet, lifestyle, environmental factors and cancer. They found no links between BC and fluid intake, red meat, vegetable and fruit consumption and only recently an inverse association between dietary intake of flavonoids and lignans and the risk of aggressive BC tumours has been described [30].

3.2.5 **Metabolic disorders**

In a large prospective study pooling six cohorts from Norway, Sweden, and Austria (The Metabolic syndrome and Cancer project, Me-Can 2.0), metabolic aberrations, especially elevated blood pressure and triglycerides, were associated with increased risks of BC among men, whereas high body mass index (BMI) was associated with decreased BC risk. The associations between BMI, blood pressure and BC risk significantly differed between men and women [31].

The association of diabetes mellitus (DM) with the risk of BC has been evaluated in numerous meta-analyses with inconsistent results. When analysing specific subpopulations, DM was associated with BC or CSM risk especially in men [32]. Thiazolidinediones (pioglitazone and rosiglitazone) are oral hypoglycaemic drugs used for the management of type 2 DM. Their use and the association with BC is still a matter of debate. In a recent meta-analysis of observational studies the summary results indicated that pioglitazone use was significantly associated with an increased risk of BC which appears to be linked to higher dose and longer duration of treatment [33]. The U.S. Food and Drug Administration (FDA) recommend that healthcare professionals should not prescribe pioglitazone in patients with active BC [34]. Several countries in Europe have removed this agent from the market or included warnings for prescription. Moreover, the benefits of glycaemic control vs. unknown risks for cancer recurrence with pioglitazone should be considered in patients with a prior history of BC.

3.2.6 **Bladder schistosomiasis and chronic urinary tract infection**

Bladder schistosomiasis (bilharzia) is the second most common parasitic infection after malaria, with about 600 million people exposed to infection in Africa, Asia, South America, and the Caribbean [35]. There is a well-established relationship between schistosomiasis and urothelial carcinoma (UC) of the bladder, which can progress to squamous cell carcinoma (SCC), however, better control of the disease is decreasing the incidence of SCC of the bladder in endemic zones such as Egypt [36, 37].

Similarly, invasive SCC has been linked to the presence of chronic urinary tract infection (UTI) distinct from schistosomiasis. A direct association between BC and UTIs has been observed in several case-control studies, which have reported a two-fold increased risk of BC in patients with recurrent UTIs in some series [38]. However, a recent meta-analysis found no statistical association when pooling data from the most recent and highest quality studies which highlights the need for higher quality data to be able to draw conclusions [39].

Similarly, urinary calculi and chronic irritation or inflammation of the urothelium have been described as possible risk factors for BC. A meta-analysis of case-control and cohort studies suggests a positive association between history of urinary calculi and BC [40].
3.2.7 Gender

Although men are more likely to develop BC than women, women present with more advanced disease and have worse survival rates. A meta-analysis including nearly 28,000 patients shows that female gender was associated with a worse survival outcome (hazard ratio [HR]: 1.20, 95% CI: 1.09–1.32) compared to male gender after radical cystectomy (RC) [41]. This finding had already been presented in a descriptive nationwide analysis based on 27,773 Austrian patients. After their analysis the authors found that cancer-specific survival (CSS) was identical for pT1-tumours in both sexes, while women had a worse CSS in both age cohorts (< 70 years and ≥ 70 years) with higher tumour stages [42]. However, treatment patterns are unlikely to explain the differences in overall survival (OS) [43]. In a population-based study from the Ontario Cancer Registry analysing all patients with BC treated with cystectomy or radical RT between 1994 and 2008, no differences in OS, mortality and outcomes were found between males and females following radical therapy [44]. The gender-specific difference in survival for patients with BC was also analysed in the Norwegian population. Survival was inferior for female patients but only within the first 2 years after diagnosis. This discrepancy was partly attributed to a more severe T-stage in female patients at initial diagnoses [45].

A population-based study from the MarketScan databases suggests that a possible reason for worse survival in the female population may be that women experienced longer delays in diagnosis than men, as the differential diagnosis in women includes diseases that are more prevalent than BC [46]. Furthermore, differences in the gender prevalence of BC may be due to other factors besides tobacco and chemical exposure. In a large prospective cohort study, post-menopausal status was associated with an increase in BC risk, even after adjustment for smoking status. This finding suggests that the differences in oestrogen and androgen levels between men and women may be responsible for some of the difference in the gender prevalence of BC [47-49]. Moreover, a recent population study assessing impact of hormones on BC suggests that younger age at menopause (< 45 years) is associated with an increased risk of BC [50].

3.2.8 Genetic factors

There is growing evidence that genetic susceptibility factors and family association may influence the incidence of BC. A recent population-based study of cancer risk in relatives and spouses of UC patients showed an increased risk for first- and second-degree relatives, and suggests genetic or environmental roots independent of smoking-related behaviour [51]. Shared environmental exposure was recognised as a potentially confounding factor [52]. Recent studies detected genetic susceptibility with independent loci, which are associated with BC risk [53].

Genome-wide association studies (GWAS) of BC identified several susceptibility loci associated with BC risk [54, 55].

3.3 Pathology

3.3.1 Handling of transurethral resection and cystectomy specimens
During transurethral resection (TUR), a specimen from the tumour and normal looking bladder wall should be taken, if possible. Specimens should be taken from the superficial and deep areas of the tumour and sent to the pathology laboratory separately, in case the outcome will impact on treatment decisions. If random biopsies of the flat mucosa are taken, each biopsy specimen of the flat mucosa should also be submitted separately [56]. The sampling sites must be recorded by the urologist; the pathologist report should include location of tumour tissue in the cystectomy specimen. Anatomical tumour location is relevant for staging and prognosis [57, 58].

In RC, bladder fixation must be carried out as soon as possible. The pathologist must open the specimen from the urethra to the bladder dome and fix the specimen. In a female cystectomy specimen, the length of the urethral segment removed en bloc with the specimen should be checked, preferably by the urological surgeon [59].

Specimen handling should follow the general rules as published by a collaborative group of pathologists and urologists [60, 61]. It must be stressed that it may be very difficult to confirm the presence of a neoplastic lesion using gross examination of the cystectomy specimen after TUR or chemotherapy, so the entire retracted or ulcerated area should be included.

It is compulsory to study the urethra, the ureters, the prostate in men and the radial margins [62]. In urethra-sparing cystectomy; the level of urethral dissection, completeness of the prostate, specifically at the apex (in men), and the inclusion of the entire bladder neck and amount of adjacent urethra, uterus and vaginal vault (in women) have to be documented by the pathologist.

All lymph node (LN) specimens should be provided in their totality, in clearly labelled containers. In case of doubt or adipose differentiation of the LNs, the entire specimen is to be included. Lymph nodes should be counted and measured on slides; capsular extension and percentage of LN invasion should be reported as well as vascular embols [63, 64]. In case of metastatic spread in the perivesical fat without real LN structures (capsule, subcapsular sinus), this localisation should nevertheless be considered as N+. Potentially positive soft tissue margins should be inked by the pathologist for evaluation [65]. In rare cases, fresh frozen sections may be helpful to determine treatment strategy [66].

3.3.2 Pathology of muscle-invasive bladder cancer
All MIBC cases are high-grade UCs. For this reason, no prognostic information can be provided by grading MIBC [67]. However, identification of morphological subtypes is important for prognostic reasons and treatment decisions [68-70].

The data presented in these guidelines are based on the 2004/2016 World Health Organization (WHO) classifications [71, 72].

Currently the following differentiations are used [68, 73]:
1. urothelial carcinoma (more than 90% of all cases);
2. urothelial carcinomas with partial squamous and/or glandular or trophoblastic divergent differentiation;
3. micropapillary UC;
4. nested variant (including large nested variant) and microcystic UC;
5. plasmacytoid, giant cell, signet ring, diffuse, undifferentiated;
6. lymphoepithelioma-like;
7. small-cell carcinomas;
8. sarcomatoid UC;
9. neuroendocrine variant of UC;
10. some UCs with other rare differentiations.

Outcomes may vary for divergent histologies, which need to be mentioned following international reporting standards [68, 74].

4. **STAGING AND CLASSIFICATION SYSTEMS**

4.1 **Pathological staging**

For staging, the Tumour, Node, Metastasis (TNM) Classification (2017, 8th edition) is recommended [75]. Blood and lymphatic vessel invasion have an independent prognostic significance [76, 77].

4.2 **Tumour, node, metastasis classification**

The TNM classification of malignant tumours is the method most widely used to classify the extent of cancer spread [75] (Table 4.1).

Staging after neoadjuvant chemotherapy (NAC) and RC can be done, but must be mentioned as ypTNM (International Collaboration on Cancer Reporting) [74]. ypT0N0 after NAC and cystectomy is associated with good prognosis [78, 79].

5. DIAGNOSTIC EVALUATION

5.1 Primary diagnosis

5.1.1 Symptoms
Painless visible haematuria is the most common presenting complaint. Other presenting symptoms and clinical signs include non-visible haematuria, urgency, dysuria, increased frequency, and in more advanced tumours, pelvic pain and symptoms related to urinary tract obstruction.

5.1.2 Physical examination
Physical examination should include rectal and vaginal bimanual palpation. A palpable pelvic mass can be found in patients with locally advanced tumours. In addition, bimanual examination under anaesthesia should be carried out before and after TUR of the bladder (TURB) to assess whether there is a palpable mass or if the tumour is fixed to the pelvic wall [80, 81]. However, considering the discrepancy between bimanual examination and pT stage after cystectomy (11% clinical overstaging and 31% clinical understaging), some caution is suggested with the interpretation of bimanual examination [82].

5.1.3 Bladder imaging
Patients with a bladder mass identified by any diagnostic imaging technique should undergo cystoscopy, biopsy and/or resection for histopathological diagnosis and staging.

The high specificity of diagnostic imaging for detecting BC means that patients with imaging positive for BC may avoid diagnostic flexible cystoscopy and go directly to rigid cystoscopy and transurethral resection [83, 84].
5.1.4 Urinary cytology
Examination of voided urine or bladder washings for exfoliated cancer cells has high sensitivity in high-grade tumours and is a useful indicator in cases of high-grade malignancy or CIS. However, positive urinary cytology may originate from a urothelial tumour located anywhere in the urinary tract.

Evaluation of cytology specimens can be hampered by low cellular yield, UTIs, stones or intravesical instillations, but for experienced readers, specificity exceeds 90% [85, 86]. However, negative cytology does not exclude a tumour. There is no known urinary marker specific for the diagnosis of invasive BC [87].

A standardised reporting system, the ‘Paris System’ redefining urinary cytology diagnostic categories was published in 2016 [88]:

- adequacy of urine specimens (Adequacy);
- negative for high-grade UC (Negative);
- atypical urothelial cells (AUC);
- suspicious for high-grade UC (Suspicious);
- high-grade UC (HGUC);
- low-grade urothelial neoplasia (LGUN).

5.1.5 Cystoscopy
Ultimately, the diagnosis of BC is made by cystoscopy and histological evaluation of resected tissue. An (outpatient) flexible cystoscopy is recommended to obtain a complete image of the bladder. However, in daily practice, if a bladder tumour has been visualised unequivocally by imaging studies such as computed tomography (CT), magnetic resonance imaging (MRI), or ultrasound (US), diagnostic cystoscopy may be omitted and the patient can proceed directly to TURB for histological diagnosis and resection. During the procedure, a thorough investigation of the bladder with rigid cystoscopy under anaesthesia is mandatory in order not to miss any tumours at the level of the bladder neck. Currently, there is no evidence for the role of photodynamic diagnosis (PDD) in the standard diagnosis of invasive BC.

A careful description of the cystoscopic findings is necessary. This should include documentation of the site, size, number, and appearance (papillary or solid) of the tumours, as well as a description of any mucosal abnormalities [89]. The use of a bladder diagram is recommended.

The use of PDD could be considered if a T1 high-grade tumour is present and to identify associated CIS. Presence of CIS may lead to a modified treatment plan (see EAU Guidelines on Non-muscle-invasive Bladder Cancer [2]). Photodynamic diagnosis is highly sensitive for the detection of CIS and in experienced hands the rate of false-positive results may be similar to that with regular white-light cystoscopy [77, 90].

5.1.6 Transurethral resection of invasive bladder tumours
The goal of TURB is to enable histopathological diagnosis and staging, which requires the inclusion of bladder muscle in the resection specimen.

In case MIBC is suspected, tumours need to be resected separately in parts, which include the exophytic part of the tumour, the underlying bladder wall with the detrusor muscle, and the edges of the resection area. At least the deeper part of the resection specimen must be referred to the pathologist in a separate labelled container to enable making a correct diagnosis. In cases in which RT is considered and CIS is to be excluded, PDD can be used [91].

The involvement of the prostatic urethra and ducts in men with bladder tumours has been reported. The exact risk is not known, but it seems to be higher if the tumour is located on the trigone or bladder neck, with concomitant bladder CIS, and in the case of multiple tumours [58, 92, 93]. Involvement of the prostatic urethra can be determined either at the time of primary TURB or by frozen section during the cystoprostatectomy procedure. A frozen section has a higher negative-predictive value and is more accurate [94-96].

A negative urethral frozen section can reliably identify patients in whom urethrectomy should be avoided. However, a positive pre-operative biopsy seems to have limited utility as these findings are not reliably associated with final margin status [94, 97].

Diagnosis of a urethral tumour before cystectomy will result in a urethrectomy which could be a contraindication for an orthotopic diversion. However, an orthotopic diversion should not be denied based on positive pre-operative biopsy findings alone and frozen section should be part of the RC procedure, in particular in male patients [98, 99].

5.2 **Imaging for staging of MIBC**

In clinical practice, tumour stage and histopathological grade are used to guide treatment and determine prognosis [73, 100, 101]. In symptomatic and high-risk patients imaging is used to assess bladder abnormalities. In addition, imaging is increasingly becoming an essential investigation for local- and distant staging of BC.

The goal of imaging patients with BC is to:

- detect lesions (US when applicable);
- differentiate T1 from T2 tumours as their treatment will differ (MRI using the Vesical Imaging Reporting and Data System [VI-RADS] score);
- Evaluate the extent of locally advanced tumour stage or tumour spread to LNs (CT scan and MRI for abdominal- and pelvic LNs or PET/CT scan);
- assess tumour spread to the upper UT or other distant organs (e.g., liver, lungs, bones, peritoneum, pleura, and adrenal glands) (CT urography for evaluating the UUT and PET/CT to detect distant organs metastasis).

Staging must be accurate to allow for the most optimal treatment choice.
5.2.1 Local staging of MIBC

5.2.1.1 Magnetic resonance imaging for local staging of MIBC

Magnetic resonance imaging has superior soft tissue contrast resolution compared with CT and can evaluate post-biopsy reaction as enhancement of the tumour occurs earlier than that of the normal bladder wall due to neovascularisation [102, 103].

The accuracy of MRI for primary tumour staging varies from 73% to 96% (mean 85%). Huang et al., in a systematic review, showed a pooled sensitivity and specificity of 0.90 and 0.88, respectively, with results going up to 0.92 and 0.96 when MRI was performed with a 3T scan, with diffusion-weighted magnetic resonance imaging (DWI) as part of the acquisition protocol [104]. A systematic review evaluating 20 studies (n = 1,724), showed a pooled sensitivity and specificity for differentiating between stages ≤ T1 and ≥ T2 of 0.92 (95% CI: 0.88–0.95) and 0.88 (95% CI: 0.78–0.94), respectively [105]. Considering the link established between the use of gadolinium-based contrast agents and nephrogenic systemic fibrosis (NSF), in patients with impaired renal function contrast medium should be managed according to the European Society of Urogenital Radiology (ESUR) Guidelines [106].

More recently, multiparametric (mp) MRI using the VI-RADS scoring system has been introduced which proved to be able to differentiate between muscle- and non-muscle-invasive primary BC (T1 vs. T2 tumours) with high diagnostic accuracy [107]. The VI-RADS offers a standardised approach to both acquisition and reporting of mpMRI for BC, however, the best use of mpMRI in this setting and which cut-off levels are to be used for VI-RADS scoring still need to be determined [103]. To date, the VI-RADS score has been validated by several research groups, showing good diagnostic performance in detecting MIBC [108, 109].

A meta-analysis found that the pooled sensitivity and specificity of mpMRI with VI-RADS acquisition and scoring for predicting MIBC were 0.83 and 0.90, respectively. The diagnostic performance of VI-RADS is similar to the diagnostic performance of bladder MRI in determining MIBC based on a previous meta-analysis of 24 studies in which the pooled sensitivity and specificity were 0.92 (95% CI: 0.88–0.95) and 0.87 (95% CI: 0.78–0.93), respectively [110]. The analysis found substantial inter-reader agreement, with kappa (κ) values ranging from 0.81 to 0.92 [110]. A systematic review and meta-analysis (n = 1,016) showed a pooled weighted mean κ estimate of 0.83 (95% CI: 0.78–0.88) [111].

5.2.1.2 CT imaging for local staging of MIBC

The advantages of CT include high spatial resolution, shorter acquisition time, wider coverage in a single breath hold, and lower susceptibility to variable patient factors. Computed tomography is unable to differentiate between stages Ta to T3a tumours, but it is useful for detecting invasion into the perivesical fat (T3b) and adjacent organs. The accuracy of CT in determining extravesical tumour extension varies from 55% to 92% [112] and increases with more advanced disease [113].

Both CT and MRI may be used for assessment of local invasion by T3b disease, or higher, but they are unable to accurately diagnose microscopic invasion of perivesical fat (T2 vs. T3a) [114]. Contrast-enhanced CT using iodinated contrast media can be considered as an alternative to MRI when MRI is contraindicated [115].

5.2.2 Imaging of lymph nodes in MIBC

Assessment of LN metastases based solely on size is limited by the inability of both CT and MRI to identify metastases in normal-sized or minimally-enlarged nodes. The sensitivity for detection of LN metastases is low (48–87%). Specificity is also low because nodal enlargement may be due to benign disease. Overall, CT and MRI show similar results in the detection of LN metastases in a variety of primary pelvic tumours [116-120]. Pelvic nodes > 8 mm and abdominal nodes > 10 mm in maximum short-axis diameter, detected by CT or MRI, should be regarded as pathologically enlarged [121, 122].

Positron emission tomography (PET) combined with CT is increasingly being used in clinical practice and its exact role continues to be evaluated [123].

5.2.3 Upper urinary tract urothelial carcinoma

5.2.3.1 Computed tomography urography

Computed tomography urography has the highest diagnostic accuracy of the available imaging techniques [124]. The sensitivity of CT urography for UTUC is 0.67–1.0 and specificity is 0.93–0.99 [125].

Rapid acquisition of thin sections allows high-resolution isotropic images that can be viewed in multiple planes to assist with diagnosis without loss of resolution. Epithelial ‘flat lesions’ without mass effect or urothelial thickening are generally not visible with CT.

The secondary sign of hydronephrosis is associated with advanced disease and poor oncological outcome [126, 127]. The presence of enlarged LNs is highly predictive of metastases in UTUC [128].
5.2.3.2 Magnetic resonance urography
Magnetic resonance urography is indicated in patients who cannot undergo CT urography, usually when radiation or iodinated contrast media are contraindicated [129]. The sensitivity of MR urography is 0.75 after contrast injection for tumours < 2 cm [129]. The use of MR urography with gadolinium-based contrast media should be limited in patients with severe renal impairment (< 30 mL/min creatinine clearance), due to the risk of NSF. Computed tomography urography is generally preferred to MR urography for diagnosing and staging UTUC.

5.2.4 Distant metastases at sites other than lymph nodes
Prior to any curative treatment, it is essential to evaluate the presence of distant metastases. Computed tomography and MRI are the diagnostic techniques of choice to detect lung [130] and liver metastases [131], respectively. Bone and brain metastases are rare at the time of presentation of invasive BC. A bone scan and additional brain imaging are therefore not routinely indicated unless the patient has specific symptoms or signs to suggest bone or brain metastases [132, 133]. Magnetic resonance imaging is more sensitive and specific for diagnosing bone metastases than bone scintigraphy [134, 135].

5.2.5 Future developments
Evidence is accruing in the literature suggesting that 18F-fluorodeoxyglucose (FDG)-positron emission tomography (PET)/CT might have potential clinical use for staging metastatic BC [136, 137], but results of further trials are awaited before a recommendation can be made. The potential role of mpMRI as first-line test for local staging of BC rather than TURB has been demonstrated in a recent clinical trial [138].

Future trends might include image analysis radiomic-based techniques in predicting MIBC. A meta-analysis (n = 860) provided summary estimates for sensitivity and specificity in predicting MIBC of 82% (95% CI: 77–86%) and 81% (95% CI: 76–85%), respectively [139].

A clinical trial assessed the role of PET/CT in evaluating LN involvement in patients receiving neoadjuvant pembrolizumab. The performance of PET/CT did not justify its routine use in cN0 MIBC patients, but proved useful in optimising selection of MIBC patients suited for neoadjuvant immunotherapy strategies in a clinical trial setting [140].

The first study evaluating the performance of MRI in assessing therapeutic response to induction chemotherapy showed superiority of DWI over T2-weighted and dynamic contrast-enhanced (DCE)-MRI [141]. The high specificity of DWI indicates that it is useful for accurate prediction of a complete histopathological response, allowing better patient selection for bladder-sparing protocols. Pre-operative MRI in different settings may provide useful information regarding treatment response. Potential future application of the VI-RADS score may include prediction of therapy response as well as peri-operative outcomes [142].

5.3 MIBC and health status
Complications from RC may be directly related to pre-existing comorbidity as well as the surgical procedure, bowel anastomosis, or urinary diversion. A significant body of literature has evaluated the usefulness of age as a prognostic factor for RC, although chronological age is less important than frailty [143-145]. Frailty is a syndrome of reduced ability to respond to stressors. Patients with frailty have a higher risk of mortality and
negative side effects of cancer treatment [146]. Controversy remains regarding age, RC and the type of urinary diversion. Radical cystectomy is associated with the greatest risk reduction in disease-related and non-disease-related death in patients aged < 80 years [147].

The largest retrospective study on RC in septuagenarians and octogenarians based on data from the National Surgical Quality Improvement Program database (n = 1,710) showed no significant difference for wound, cardiac, or pulmonary complications. However, the risk of mortality in octogenarians compared to septuagenarians is higher (4.3% vs. 2.3%) [148]. Although some octogenarians successfully underwent a neobladder procedure, most patients were treated with an ileal conduit diversion. It is important to evaluate functioning and quality of life (QoL) of older patients using a standardised geriatric assessment, as well as carrying out a standard medical evaluation [149].

Sarcopenia has been shown to be an independent predictor for OS and CSS in a large multicentre study with patients undergoing RC for BC [150]. In order to predict CSM after RC in patients receiving neoadjuvant chemotherapy (NAC), sarcopenia should be assessed after completing the chemotherapy [151]. Other risk factors for morbidity include prior abdominal surgery, extravesical disease, and prior RT [152]. Female gender, an increased BMI and lower pre-operative albumin levels are associated with a higher rate of parastomal hernias [153]. Low pre-operative serum albumin is also associated with impaired wound healing, gastrointestinal (GI) complications and a decrease of recurrence-free and OS after RC [154, 155]. Therefore, it could be used as a prognostic biomarker for patients undergoing RC.

5.3.1 Evaluation of comorbidity, frailty and cognition

Rochon et al., have shown that evaluation of comorbidity provides a better indicator of life expectancy in MIBC than patient age [156]. Evaluation of comorbidity helps to identify factors likely to interfere with, or have an impact on, treatment and the evolution and prognosis of MIBC [157].

The value of assessing overall health before recommending and proceeding with surgery was emphasised by Zietman et al., who have demonstrated an association between comorbidity and adverse pathological and survival outcomes following RC [158]. Similar results were found for the impact of comorbidity on cancer-specific and other-cause mortality in a population-based competing risk analysis of > 11,260 patients from the Surveillance, Epidemiology, and End Results (SEER) registries. Age carried the highest risk for other-cause mortality but not for increased cancer-specific death, while the stage of locally advanced tumour was the strongest predictor for decreased CSS [159].

Stratifying older patients according to frailty using a multidisciplinary approach will help select patients most likely to benefit from radical surgery and to optimise treatment outcomes [160]. There are many different screening tools available for frailty and local approaches can be used. Examples include the G8 and the Clinical Frailty Scale (See Table 5.1 and Figure 5.1 below).

Cognitive impairment can be screened for using a tool such as the mini-COG (https://mini-cog.com/), which consists of three-word recall and a clock-drawing test, and can be completed within 5 minutes. A score of ≤ 3/5 indicates the need to refer the patient for full cognitive assessment. Patients with any form of cognitive impairment (e.g., Alzheimer’s or vascular dementia) may need a capacity assessment of their ability to make an informed decision, which is an important factor in health status assessment. Cognitive impairment also predicts risk of delirium, which is important for patients undergoing surgery [161].

Eastern Cooperative Oncology Group (ECOG) performance status (PS) scores and Karnofsky index have shown that there is no correlation between morbidity and competitive activity level [180]. The age-adjusted Comorbidity Index (CCI) ranges from 0 to 30 according to the importance of comorbidity described [164], seven of which have been validated [165-171]. The Charlson Comorbidity Index (CCI) has been widely studied in patients with BC and found to be an independent prognostic factor for perioperative mortality [172, 173], overall mortality [174], and CSM [147, 175-177]. Only the age-adjusted version of the CCI has been correlated with both cancer-specific and other-cause mortality [178].

</tr>
</tbody>
</table>

**6** LIVING WITH MODERATE FRAILITY

People who need help with all outside activities and with keeping house. Inside, they often have problems with stairs and need help with bathing and might need minimal assistance (cuing, standby) with dressing.

**7** LIVING WITH SEVERE FRAILITY

Completely dependent for personal care, from whatever cause (physical or cognitive). Even so, they seem stable and not at high risk of dying (within ~6 months).

**8** LIVING WITH VERY SEVERE FRAILITY

Completely dependent for personal care and approaching end of life. Typically, they could not recover even from a minor illness.

**9** TERMINALLY ILL

Approaching the end of life. This category applies to people with a life expectancy <6 months, who are not otherwise living with severe frailty. (Many terminally ill people can still exercise until very close to death.)

**SCORING FRAILTY IN PEOPLE WITH DEMENTIA**

The degree of frailty generally corresponds to the degree of dementia. Common symptoms in mild dementia include forgetting the details of a recent event, though still remembering the event itself, repeating the same question or story and social withdrawal.

**5.3.2 Comorbidity scales, anaesthetic risk classification and geriatric assessment**

A range of comorbidity scales has been developed [164], seven of which have been validated [165-171]. The Charlson Comorbidity Index (CCI) ranges from 0 to 30 according to the importance of comorbidity described at four levels and is calculated by healthcare practitioners based on patients’ medical records. The score has been widely studied in patients with BC and found to be an independent prognostic factor for peri-operative mortality [172, 173], overall mortality [174], and CSM [147, 175-177]. Only the age-adjusted version of the CCI was correlated with both cancer-specific and other-cause mortality [178]. The age-adjusted CCI (Table 5.2) is the most widely used comorbidity index in cancer for estimating long-term survival and is easily calculated [179].

Health assessment of oncology patients must be supplemented by measuring their activity level. Extermann et al., have shown that there is no correlation between morbidity and competitive activity level [180]. The Eastern Cooperative Oncology Group (ECOG) performance status (PS) scores and Karnofsky index have been

Total score 0–17
validated to measure patient activity [181]. Performance score is correlated with patient OS after RC [176] and palliative chemotherapy [182-184].

Patients who have screened positive for frailty or cognitive impairment benefit from an assessment by a geriatrician. This allows identification of geriatric syndromes and any scope for optimisation. The most complete protocol is the Comprehensive Geriatric Assessment (CGA) [185] which is useful in the care of cancer patients [186]. In BC, the CGA has been used to adapt gemcitabine chemotherapy in previously untreated older patients with advanced BC [187].

**Interpretation:**

1. Calculate Charlson Comorbidity Score or Index \( = i \)
   - Add comorbidity score to age score
   - Total denoted as ‘i’ in the Charlson Probability calculation (see below).
   - \( i = \text{sum of comorbidity score to age score} \)

2. Calculate Charlson Probability (10-year mortality = \( Y \))
   - Calculate \( Y = 10^{(i \times 0.9)} \)
   - Calculate \( Z = 0.983^Y \) (where \( Z \) is the 10-year survival)

6. MARKERS

6.1 Introduction
Both patient and tumour characteristics guide treatment decisions and prognosis of patients with MIBC.

6.2 Prognostic markers

6.2.1 Histopathological and clinical markers
The most important histopathological prognostic variables after RC and LN dissection are tumour stage and LN status [188]. In addition, other histopathological parameters of the RC specimen have been associated with prognosis.

The value of lymphovascular invasion was reported in a systematic review and meta-analysis including 78,000 patients from 65 studies treated with RC for BC [189]. Lymphovascular invasion was present in 35% of the patients and correlated with a 1.5-fold higher risk of recurrence and CSM, independent of pathological stage and peri-operative chemotherapy. This correlation was even stronger in those patients with node-negative disease [190].

In a systematic review and meta-analysis including 23 studies and over 20,000 patients, the presence of concomitant CIS in the RC specimen was associated with a higher odds ratio (OR) of ureteral involvement (pooled OR: 4.51, 2.59–7.84). Concomitant CIS was not independently associated with OS, recurrence-free survival (RFS) and DSS in all patients, but in patients with organ-confined disease concomitant CIS was associated with worse RFS (pooled HR: 1.57; 1.12–2.21) and CSM (pooled HR: 1.51, 1.001–2.280) [190].

Tumour location has been associated with prognosis. Tumours located at the bladder neck or trigone of the bladder appear to have an increased likelihood of nodal metastasis (OR: 1.83, 95% CI: 1.11–2.99) and have been associated with decreased survival [188, 191-193].

Prostatic urethral involvement at the time of RC was also found to be associated with worse survival outcomes. In a series of 995 patients, prostatic involvement was recorded in 31% of patients. The 5-year CSS in patients with CIS of the prostatic urethra was 40%, whilst the prognosis of patients with UC invading the prostatic stroma was worse with a 5-year CSS of only 12% [194].

Neutrophil-to-lymphocyte ratio (NLR) has emerged as a prognostic factor in UUT tumours [1] and other non-urological malignancies. In a pooled analysis of 21 studies analysing the prognostic role of NLR in BC, the authors correlated elevated pre-treatment NLR with OS, RFS and disease-free survival (DFS) in both localised and metastatic disease [195]. In contrast, a secondary analysis of the Southwest Oncology Group (SWOG) 8710 trial, a randomised phase III trial assessing cystectomy ± NAC in patients with MIBC, suggests that NLR is neither a prognostic nor a predictive biomarker for OS in MIBCs [196].

In patients with LN-positive disease, the American Joint Committee on Cancer (AJCC)-TNM staging system provides 3 subcategories. In addition, several other prognostic LN-related parameters have been reported. These include, but are not limited to, the number of positive LNs, the number of LNs removed, LN density (the ratio of positive LNs to the number of LNs removed) and extranodal extension. In a systematic review and meta-analysis, it was reported that LN density was independently associated with OS (HR: 1.45, 95%, CI: 1.11–1.90) [197]. It has been suggested that LN density outperforms the AJCC-TNM staging system for LN-positive disease in terms of prognostic value [198, 199]. However, in spite of these studies supporting the use of LN density, LN density relies on the number of LNs removed which, in turn, is subject to surgical and pathological factors. This makes the concept of LN density difficult to apply uniformly [200].

Two studies investigated whether any of the reported LN-related parameters may be superior to the routinely used AJCC-TNM staging system [200, 201]. Whilst the conclusion was that the AJCC-TNM staging system for LN status did not perform well, none of the other tested variables outperformed the AJCC system.

6.2.2 Molecular markers

6.2.2.1 Molecular subtypes based on the Cancer Genome Atlas cohort
The updated Cancer Genome Atlas (TCGA) reported on 412 MIBCs and identified two main groups; luminal and basal-squamous - consisting of five mRNA expression-based molecular subtypes including luminal-papillary, luminal-infiltrated, luminal; basal-squamous; and neuronal, a subtype associated with poor survival in which the majority of tumours do not have small cell or neuroendocrine histology. Each subtype is associated with distinct mutational profiles, histopathological features and prognostic and treatment implications [202].

The basal-squamous subtype is characterised by expression of basal keratin markers, immune infiltrates and is felt to be chemosensitive. The different luminal subtypes are characterised by fibroblast growth factor receptor 3 (FGFR3) alterations (luminal-papillary [LumP], epithelial-mesenchymal transition (EMT) markers (luminal-infiltrated) and may be associated with chemotherapy resistance [69, 70, 202, 203].
In 2019, a consensus on molecular subtype classification was reported [204]. The authors analysed 1,750 MIBC transcriptomic profiles from 18 datasets and identified six MIBC molecular classes that reconcile all previously published classification schemes. The molecular subgroup classes include LumP, luminal non-specified (LumNS), luminal unstable (LumU), stroma-rich, basal/squamous (Ba/Sq), and neuroendocrine-like (NE-like). Each class has distinct differentiation patterns, oncogenic mechanisms, tumour micro-environments and histological and clinical associations. However, the authors stressed that consensus was reached for biological rather than clinical classes. Therefore, at this time, the classification should be considered as a research tool for retrospective and prospective studies until future studies establish how these molecular subgroups can be used best in a clinical setting.

Molecular classification of MIBC is still evolving and treatment tailored to molecular subtype is not a standard yet. A novel 12-gene signature derived from patients in the TCGA utilising published gene signatures has been developed and externally validated to predict OS in MIBC [205]. Interestingly, a recently published analysis of molecular subtyping in MIBC demonstrated that although molecular subtypes reflect the heterogeneity of bladder tumours and are associated with tumour grade, clinical parameters outperformed subtypes for predicting outcome [206]. In the coming years, new insights into BC carcinogenesis may change our management of the disease and our ability to better predict outcomes [207]. Outside clinical trials, molecular subtyping, either by expression profiling or immunohistochemistry, is not yet part of routine clinical work-up awaiting more conclusive data.

6.3 Predictive markers

6.3.1 Clinical and histopathological markers

Based on retrospective data only, patients with secondary MIBC have a worse response to NAC compared to patients with primary MIBC [208]. Pietzak et al., retrospectively analysed clinico-pathologic outcomes comparing 245 patients with clinical T2–4a N0M0 primary MIBC and 43 patients with secondary MIBC treated with NAC and RC. They found that patients with secondary MIBC had lower pathologic response rates following NAC than those with primary MIBC (univariable 26% vs. 45%, multivariable OR: 0.4 [95% CI: 0.18–0.84, p = 0.02]). They also found that MIBC patients progressing after NAC had worse CSS as compared to patients treated with cystectomy alone (p = 0.002).

Variant histologies and non-UC have also been linked to worse outcomes after NAC, but there is, as yet, insufficient data to conclude that they can be considered as predictive markers [209].

6.3.2 Molecular markers

Several predictive biomarkers have been investigated such as serum vascular endothelial growth factor [210], circulating tumour cells as well as defects in DNA damage repair (DDR) genes including ERCC2, ATM, RB1 and FANCC that may predict response to cisplatin-based NAC [211, 212]. More recently, alterations in FGFR3 including both mutations and gene fusions have been shown to be associated with response to FGFR inhibitors [213, 214].

More recent efforts have focused on markers for predicting response to immune checkpoint inhibition. Programmed death-ligand 1 (PD-L1) expression by immunohistochemistry has been evaluated in several studies with mixed results which may in part be related to the use of different antibodies and various scoring systems evaluating different compartments, i.e., tumour cells, immune cells, or both. The major limitation of PD-L1 staining relates to the significant proportion of PD-L1-negative patients that respond to immune checkpoint blockade. For example, in the IMvigor 210 phase II study of atezolizumab in patients with advanced/metastatic UC who progressed after platinum-based chemotherapy, responses were seen in 18% of patients with low/no PD-L1 expression [215]. At present, the only indication for PD-L1 testing relates to the use of immune checkpoint inhibitors as monotherapy in patients with locally advanced or metastatic UC unfit for cisplatin-containing chemotherapy who have not received prior therapy. In this setting, atezolizumab (approved by the FDA and EMA) or pembrolizumab (EMA approval only) should only be used in patients unfit for cisplatin-containing chemotherapy whose tumours overexpress PD-L1 [i.e., in case of atezolizumab; tumour-infiltrating immune cells (IC) covering ≥ 5% of the tumour area using the SP142 assay; in case of pembrolizumab, a combined positive score (CPS) of ≥ 10 using the Dako 22C33 platform] [216]. The FDA revised the label for pembrolizumab in patients with advanced UC with approval in first line only for patients not eligible for any platinum-based chemotherapy, however, irrespective of PD-L1 status.

Urothelial cancer is associated with a high tumour mutational burden (TMB) [217]. Both predicted neoantigen burden and TMB have been associated with response to immune checkpoint blockade in several malignancies. High TMB has been associated with response to immune checkpoint inhibitors in metastatic BC [215, 218]. Conflicting results have been seen in studies evaluating immune checkpoint inhibitors in the neoadjuvant setting with the Pembrolizumab as Neoadjuvant Therapy Before Radical Cystectomy in Patients With
Muscle-Invasive Urothelial Bladder Carcinoma (PURE)-01 study utilising pembrolizumab demonstrating an association of high TMB with response while there was no association with atezolizumab in the Phase II study investigating the safety and efficacy of neoadjuvant atezolizumab in MIBC (ABACUS) [219, 220].

Other markers that have been evaluated in predicting response to immune checkpoint inhibitors include molecular subtypes as discussed earlier, CD8 expression by immunohistochemistry and other immune gene cell signatures. Recent work has focused on the importance of stroma including the role of transforming growth factors (TGFs) in predicting response to immune checkpoint blockade [221, 222]. Most recently, Powles et al., have reported on the potential for ctDNA to guide the use of adjuvant immunotherapy (IO) in UC [223]. In 581 patients from a phase III RCT of adjuvant atezolizumab vs. observation in UC, ctDNA testing at the start of therapy identified 214 (37%) patients who were positive for ctDNA and who had poor prognosis (observation arm HR = 6.3, 95% CI: 4.45–8.92; p < 0.0001). Patients who were positive for ctDNA had improved DFS and OS in the atezolizumab arm vs. the observation arm (DFS HR = 0.58 [95% CI: 0.43–0.79]; p = 0.0024, OS HR = 0.59 [95% CI: 0.41–0.86]). There was no difference in DFS or OS between treatment arms for patients who were negative for ctDNA. The rate of ctDNA clearance at week 6 was higher in the atezolizumab arm (18%) than in the observation arm (4%) (p = 0.0204). An ongoing clinical trial (IMvigor011) is evaluating atezolizumab as adjuvant therapy in patients with high-risk MIBC who are ctDNA positive following cystectomy [224]. Although promising, there are currently no validated predictive molecular markers that are routinely used in clinical practice. Further validation studies are awaited.

6.4 Conclusion
The updated TCGA and other efforts have refined our understanding of the molecular underpinnings of BC biology. Molecular subtypes, immune gene signatures as well as stromal signatures may ultimately have an important role in predicting response to IO. Although PD-L1 expression by immunohistochemistry and TMB have demonstrated predictive value in certain settings, additional studies are needed. Prospectively validated prognostic and predictive molecular biomarkers will present valuable adjuncts to clinical and pathological data, but large phase III RCTs with long-term follow-up will be needed to clarify the many questions remaining.

7. DISEASE MANAGEMENT

7.1 Neoadjuvant therapy

7.1.1 Introduction
The standard treatment for patients with urothelial MIBC and MIBC with variant histologies is RC. However, RC only provides 5-year survival in about 50% of patients [225-229]. To improve these results in patients with cN0M0 disease, cisplatin-based NAC has been used since the 1980s [225-231].

7.1.2 Role of cisplatin-based chemotherapy
There are theoretical advantages and disadvantages of administering chemotherapy before planned definitive surgery to patients with resectable muscle-invasive cN0M0 UC of the bladder:

- Chemotherapy is delivered at the earliest time-point, when the burden of micrometastatic disease is expected to be low.
- Potential reflection of in-vivo chemosensitivity.
- Tolerability of chemotherapy and patient compliance are expected to be better pre-cystectomy.
- Patients may respond to NAC and have a favourable pathological response as determined mainly by achieving ypT0, ≤ ypT1, ypN0 and negative surgical margins.
- Delayed cystectomy might compromise the outcome in patients not sensitive to chemotherapy [232-234]. A comparative survival analysis of patients treated with NAC and RC vs. RC alone based on data from the National Cancer Database showed that organ-confined disease (≤ pT2) after NAC was associated with decreased risk of death (HR: 0.85, 95% CI: 0.79–0.91) compared to RC alone, whereas > pT2 was associated with increased risk of death (HR: 1.46, 95% CI: 1.34–1.60) [235]. However, there are
no prospective trials indicating that delayed surgery due to NAC has a negative impact on survival. In the phase III VESPER trial, comparing gemcitabine/cisplatin (GC) vs. high-dose-intensity methotrexate, vinblastine, doxorubicine and cisplatin (HD-MVAC) in the peri-operative setting, approximately 90% of patients proceeded to surgery (with median delay of 48 days for GC and 51 days for ddMVAC) [236].

- Neoadjuvant chemotherapy does not seem to affect the outcome of surgical morbidity. In one randomised trial the same distribution of grade 3–4 post-operative complications was seen in both treatment arms [237]. In the combined Nordic trials (n = 620), NAC did not have a major adverse effect on the percentage of performable cystectomies. The cystectomy frequency was 86% in the experimental arm and 87% in the control arm with 71% of patients receiving all three chemotherapy cycles [238].
- Clinical staging using bimanual palpation, CT or MRI may result in over- and understaging and have a staging accuracy of only 70% [78]. Overtreatment is a possible negative consequence.
- Gender may have an impact on chemotherapeutic response and oncologic outcomes [239, 240].
- Neoadjuvant chemotherapy should only be used in patients eligible for cisplatin-combination chemotherapy; other combinations (or monotherapies) are inferior in metastatic BC and have not been fully tested in a neoadjuvant setting [237, 241-249].

7.1.2.1 Summary of available data
Several phase III RCTs addressed the potential survival benefit of NAC administration [237, 241-246, 250-254]. The main differences in trial designs were the type of chemotherapy (i.e., single-agent cisplatin or combination chemotherapy) and the number of cycles provided. Patients had to be fit for cisplatin. Since these studies differed considerably for patient numbers, patient characteristics (e.g., clinical T-stages included) and the type of definitive treatment offered (cystectomy and/or RT), pooling of results was not possible.

Three meta-analyses were undertaken to establish if NAC prolongs survival [247-249]. In a meta-analysis including updated patient data from 11 randomised trials (n = 3,005), a significant survival benefit was shown in favour of NAC [249]. The most recent meta-analysis included four additional randomised trials, and used the updated results from the Nordic I, Nordic II, and BA06 30894 trials including data from 427 new patients and updated information from 1,596 patients. The results of this analysis confirmed the previously published data and showed an 8% absolute improvement in survival at five years with a number needed-to-treat of 12.5 [255]. Only cisplatin-combination chemotherapy with at least one additional chemotherapeutic agent resulted in a meaningful therapeutic benefit [247, 249]; the regimens tested were methotrexate, vinblastine, adriamycin (epirubicin) plus cisplatin (MVA(E)C), cisplatin, methotrexate plus vinblastine (CMV), cisplatin plus methotrexate (CM), cisplatin plus adriamycin and cisplatin plus 5-fluorouracil (5-FU) [256].

The updated analysis of a large phase III RCT [241] with a median follow-up of eight years confirmed previous results and provided additional findings:
- 16% reduction in mortality risk;
- improvement in 10-year survival from 30% to 36% with neoadjuvant CMV;
- benefit with regard to distant metastases;
- the addition of neoadjuvant CMV provided no benefit for locoregional control and locoregional DFS, independent of the definitive treatment.

More modern chemotherapeutic regimens such as GC have shown similar pT0/pT1 rates as methotrexate, vinblastine, adriamycin plus cisplatin in retrospective series and pooled data analyses [256-259]. Modified ddMVAC was tested in two small single-arm phase II studies demonstrating high rates of pathologic complete remission [260, 261]. Moreover, a large cross-sectional analysis showed higher rates of down-staging and pathological complete response for ddMVAC [262].

The recently reported results from the GETUG/AFU V05 VESPER RCT of perioperative chemotherapy with 6 cycles of ddMVAC vs. 4 cycles of GC in 493 patients (437 neoadjuvant and 56 adjuvant) demonstrated similar pathologic response rates (< pT2N0) in patients treated with ddMVAC 42% and GC 36% (p = 0.2). The < ypT2N0 rate was 63% and 50% in the ddMVAC and GC patients, respectively. Progression-free survival was significantly improved in the NAC receiving ddMVAC as compared to GC (HR = 0.70, 95% CI: 0.51–0.96; p = 0.025), however, the PFS endpoint was not significant in the entire perioperative chemotherapy population (HR: 0.77, 95% CI: 0.57–1.02; p = 0.077). Dose-dense MVAC was associated with more severe asthenia and GI side effects than GC [236]. Another dose-dense regimen using GC was reported in two small phase II trials [263, 264]. While pathological response rates (< pT2) in the range of 45%–57% were achieved, one trial had to be closed prematurely due to high rates of severe vascular events [263]. This approach is therefore not recommended outside of clinical trials.

As an alternative to the standard dose of cisplatin-based NAC with 70 mg/m² on day 1, split-dose modifications regimens are often used with 35 mg/m² on days 1+8 or days 1+2. In a retrospective analysis
the standard schedule was compared to a split-dose schedule in terms of complete and partial pathological response. A lower number of complete and partial response rates was seen in the split-dose group, but these results were not statistically significant [265].

There seem to be differences in the outcomes of patients treated with NAC for primary or secondary MIBC. However, in the absence of prospective data, patients with secondary MIBC should be treated similarly to those presenting with primary MIBC [208].

It is unclear, if patients with non-UC histology will also benefit from NAC. A retrospective analysis demonstrated that patients with neuroendocrine tumours had improved OS and lower rates of non-organ-confined disease when receiving NAC. In case of micropapillary differentiation, sarcomatoid differentiation and adenocarcinoma, lower rates of non-organ confined disease were found, but no statistically significant impact on OS. Patients with squamous cell carcinoma did not benefit from NAC [266]. A 2019 systematic review showed benefit of NAC for patients with micropapillary-, plasmacytoid-, sarcomatoid-, and mixed variants but especially for patients with neuroendocrine tumours [68].

7.1.3 The role of imaging and predictive biomarkers

Data from small imaging studies aiming to identify responders in patients treated with NAC suggest that response after two cycles of treatment is predictive of outcome. Although mpMRI has the advantage of better resolution of the bladder wall tissue planes as compared to CT, it is not ready yet for standard patient care. However, bladder mpMRI may be useful to inform on tumour stage after TURB and response to NAC [107]. So far PET/CT, MRI or DCE-MRI cannot accurately assess treatment response [267-270]. To identify progression during NAC imaging is being used in many centres notwithstanding the lack of supporting evidence.

For responders to NAC, especially in those with a complete response (pT0 N0), treatment has a major positive impact on OS [271, 272]. Therefore, reliable predictive markers to identify patients most likely to benefit from chemotherapy are needed. Molecular tumour profiling might guide the use of NAC in the future but, as yet, this is not applicable in routine practice [273-275] (see Chapter 6 - Markers).

7.1.4 Role of neoadjuvant immunotherapy

Inhibition of PD-1/PD-L1 checkpoint has demonstrated significant benefit in patients with unresectable and metastatic BC in the second-line setting and in platinum-ineligible PD-L1+ patients as first-line treatment using different agents. Checkpoint inhibitors are increasingly tested also in the neoadjuvant setting; either as monotherapy or in combination with chemotherapy or CTLA-4 checkpoint inhibition. Data from two phase II trials have been presented with encouraging results [219, 220]. The results of the phase II trial using the PD-1 inhibitor pembrolizumab reported a complete pathological remission (pT0) in 42% and pathological response (< pT2) in 54% of patients, whereas in the single-arm phase II trial with atezolizumab a pathologic complete response rate of 31% was reported. In a recent study evaluating neoadjuvant GC plus pembrolizumab in MIBC, the primary endpoint was met with 56% of 46 evaluable patients downstaged to < ypT2N0 and 36% achieving ypT0N0 [276]. However, immunotherapy alone, or in combination, is not yet approved in the neoadjuvant setting.

7.2 Pre- and post-operative radiotherapy in muscle-invasive bladder cancer

7.2.1 Post-operative radiotherapy

Given the high rates of local-regional failure after RC in patients with locally advanced (pT3–4) BC, estimated at ~30%, as well as the high risk of distant failure and poor survival for these patients, there is an interest in adjuvant therapies that address both the risk of local and distant disease. Data on adjuvant RT after RC are limited and further prospective studies are needed, but a more recent phase II trial compared adjuvant sequential chemotherapy and radiation vs. adjuvant chemotherapy alone in 120 patients with locally advanced disease and negative margins after RC (with one or more risk factors: ≥ pT3b, grade 3, or node-positive), in a study population with 53% UC and 47% SCC. Addition of adjuvant RT to chemotherapy alone was associated with a statistically significant improvement in local relapse-free survival (at 2 years 96% vs. 69% favouring the addition of RT). Disease-free survival and OS also favoured the addition of RT, but those differences were not statistically significant and the study was not powered for those endpoints. Late-grade ≥ 3 GI toxicity in the chemoradiation arm was low (7% of patients) [277].

A 2019 systematic review evaluating the efficacy of adjuvant radiation for BC or UTUC found no clear benefit of adjuvant radiation following radical surgery (e.g., cystectomy), although the combination of adjuvant radiation with chemotherapy may be beneficial in locally advanced disease [278].

While there are no conclusive data demonstrating improvements in OS it is reasonable to consider adjuvant radiation in patients with pT3/pT4 pN0–2 urothelial BC following RC, although this approach has been evaluated in only a limited number of studies. Radiation fields should encompass areas at risk for harbouring residual microscopic disease based on pathologic findings at surgery and may include cystectomy bed and pelvic LNs. Doses in the range of 45 to 50.4 Gy may be considered. For patients who have not had prior NAC, it may be reasonable to sandwich adjuvant radiation between cycles of adjuvant chemotherapy. The safety and efficacy of concurrent radiosensitising chemotherapy in the adjuvant setting needs further study.

7.2.2 Pre-operative radiotherapy

To date, six RCTs have been published investigating pre-operative RT, although all are from several decades ago. In the largest trial, pre-operative RT at a dose of 45 Gy was used in patients with muscle-invasive tumours resulting in a significant increase in pathological complete response (9% to 34%) in favour of pre-operative RT, which was also a prognostic factor for survival [279]. The OS data were difficult to interpret since chemotherapy was used in a subset of patients only and more than 50% of patients (241/475) did not receive the planned treatment and were excluded from the final analyses. Two smaller studies using a dose of 20 Gy showed only a small survival advantage in > T3 tumours [280, 281]. Two other small trials confirmed downstaging after pre-operative RT [282, 283].

A meta-analysis of five RCTs showed a difference in 5-year survival (OR: 0.71, 95% CI: 0.48–1.06) in favour of pre-operative RT [284]. However, the meta-analysis was potentially biased by data from the largest trial in which patients were not given the planned treatment. When the largest trial was excluded from the analysis, the OR became 0.94 (95% CI: 0.57–1.55), which was not significant.

A more recent RCT, comparing pre-operative vs. post-operative RT and RC (n = 100), showed comparable OS, DFS and complication rates [285]. Approximately half of these patients had UC, while the other half had SCC.

In general, such older data is limited in being able to provide a robust evidence base for modern guideline recommendations.

Recommendations | Strength rating
--- | ---
Do not offer pre-operative radiotherapy (RT) for operable muscle-invasive bladder cancer since it will only result in down-staging, but will not improve survival. | Strong
Do not offer pre-operative RT when subsequent radical cystectomy (RC) with urinary diversion is planned. | Strong
Consider offering adjuvant radiation in addition to chemotherapy following RC, based on pathologic risk (pT3b–4 or positive nodes or positive margins). | Weak

7.3 Radical surgery and urinary diversion

7.3.1 Removal of the tumour-bearing bladder

7.3.1.1 Introduction
Radical cystectomy is the standard treatment for localised MIBC in most Western countries [225, 286]. Increased recognition of the central patient role as a healthcare consumer and a greater focus on patients’ QoL contributed to an increasing trend of utilising bladder-preserving treatment modalities, such as radio- and/or chemotherapy (see Section 7.5). Performance status and life expectancy influence the choice of primary management as well as the type of urinary diversion with RC being reserved for patients with a longer life expectancy without concomitant disease and a better PS. Frailty, nutritional status and decreased kidney function are conditions significantly related to an increased risk of post-operative adverse events (AEs) [287-289].

7.3.1.2 Radical cystectomy: timing
A 2020 meta-analysis including 19 studies concluded that a delay of > 3 months has a negative effect on OS (HR: 1.34, 95% CI: 1.18–1.53). Authors highlighted the lack of standardisation how delays were defined in the included studies which prohibited defining a clear cut-off time, although most studies used a cut-off of < 3 months [290]. Overall conclusion was that BC patients scheduled for RC should be treated without delays to maximise survival.

7.3.2 Radical cystectomy: indications
Traditionally, RC was recommended in patients with T2–T4a, N0–Nx, M0 disease [286]. Other indications include BCG-refractory, BCG-relapsing and BCG-unresponsive NMIBC (see EAU Guidelines on Non-muscle-invasive Bladder Cancer [2]), as well as extensive papillary disease that cannot be controlled with TURB and intravesical chemotherapy alone.

Salvage cystectomy is indicated in non-responders to conservative therapy, recurrence after bladder-sparing treatment, and non-UC. It is also used as a purely palliative intervention, including for fistula formation, pain and recurrent visible haematuria (see Section 7.4.1 - Palliative cystectomy).

7.3.3 Radical cystectomy: technique and extent
Different approaches have been described to improve voiding and sexual function in patients undergoing RC for BC. No consensus exists regarding which approach preserves function best. Concern remains regarding the impact of ‘sparing-techniques’ on oncological outcomes.

To determine the effect of sexual function-preserving cystectomy (SPC) on functional and oncological outcomes the Panel undertook two systematic reviews addressing sparing techniques in men and women [291, 292].

7.3.3.1 Radical cystectomy in men
In men, standard RC includes removal of the bladder, prostate, seminal vesicles, distal ureters, and regional LNs.

7.3.3.1.1 Concomitant prostate cancer
Prostate cancer is found in 21–50% of male patients undergoing RC for BC [293-296]. Incidentally discovered clinically significant prostatic adenocarcinoma did not alter survival [295, 296]. Pathological reporting of the specimens should follow the recommendations as presented in the EAU-EANM-ESTRO-ESUR-ISUP-SIOG Guidelines on Prostate Cancer [297].

7.3.3.1.2 Sexual-preserving techniques
Four main types have been described:
1. **Prostate sparing cystectomy**: part of or the whole prostate is preserved including seminal vesicles, vas deferens and neurovascular bundles.
2. **Capsule sparing cystectomy**: the capsule or peripheral part of the prostate is preserved with adenoma (including prostatic urethra) removed by TURP or en bloc with the bladder. Seminal vesicles, vas deferens and neurovascular bundles are also preserved.
3. **Seminal sparing cystectomy:** seminal vesicles, vas deferens and neurovascular bundles are preserved.

4. **Nerve-sparing cystectomy:** the neurovascular bundles are the only tissue left in place.

Twelve studies recruiting a total of 1,098 patients were identified, including nine comparative studies [298-308] and three single-arm case series [309-311]. In the majority of cases, an open surgical approach was used and the urinary diversion of choice was an orthotopic neobladder. Median follow-up was longer than three years in nine studies, with three studies presenting results with a median follow-up longer than five years.

The majority of the studies included patients who were potent pre-operatively with organ-confined disease without tumour in the bladder neck and/or prostatic urethra. Prostate cancer was ruled out in all of the SPC techniques, except in nerve-sparing cystectomy.

Oncological outcomes did not differ between groups in any of the comparative studies that measured local recurrence, metastatic recurrence, DSS and OS, at a median follow-up of three to five years. Local recurrence after SPC was commonly defined as any UC recurrence below the iliac bifurcation within the pelvic soft tissue and ranged from 1.2–61.1% vs. 16–55% in the control group. Metastatic recurrence ranged from 0–33.3%.

For techniques preserving prostatic tissue (prostate- or capsule-sparing), rates of incidental prostate cancer in the intervention group ranged from 0–15%. In no case was incidental prostate cancer with ISUP grade > 4 reported.

Post-operative potency was significantly better in patients who underwent any type of sexual-preserving technique compared to conventional RC (p < 0.05), ranging from 80–90%, 50–100% and 29–78% for prostate-, capsule- or nerve-sparing techniques, respectively. Data did not show superiority of any sexual-preserving technique.

Urinary continence, defined as the use of ‘no pads’ in the majority of studies, ranged from 88–100% (day-time continence) and from 31–96% (night-time continence) in the prostate-sparing cystectomy patients. No major impact was shown with regard to continence rates for any of the three approaches.

The evidence base suggests that these procedures may yield better sexual outcomes than standard RC without compromising oncological outcomes. However, the overall quality of the evidence was moderate, and hence if a sexual-preserving technique is offered, patients must be carefully selected, counselled and closely monitored.

### 7.3.3.2 Radical cystectomy in women

In women, standard RC includes removal of the bladder, the entire urethra and adjacent vagina, uterus, distal ureters, and regional LNs [312]. Pelvic floor disorders, sexual and voiding dysfunction in female patients are prevalent after RC [313]. As part of the pre-operative evaluation a gynaecological history should be obtained and patients should be counselled on the potential negative impact of RC on sexual function and/or vaginal prolapse. Most importantly, a history of cervical cancer screening, abnormal vaginal bleeding and a family history of breast and/or ovarian cancer should be recorded, as well as ruling out possible pelvic organ prolapse. Equally important is screening for sexual and urinary function and prolapse post-operatively. Better imaging modalities, increased knowledge of the function of the pelvic structures and improved surgical
techniques have enabled less destructive methods for treating high-risk BC.

Pelvic organ-preserving techniques involve preserving the neurovascular bundle, vagina, uterus, ovaries or variations of any of the stated techniques. From an oncological point of view, concomitant malignancy in gynaecological organs is rare and local recurrences reported after RC are infrequent [314, 315]. In premenopausal women, by preserving ovaries, hormonal homeostasis will be preserved, decreasing risk of cognitive impairment, cardiovascular diseases and loss of bone density. In case of an increased risk of hereditary breast or ovarian cancer (i.e., BRCA1/2 mutation carriers or patients with Lynch syndrome), salpingooophorectomy should be advised after childbearing and to all women over 40 years of age [316]. On the other hand, preservation of the uterus and vagina will provide the necessary support for the neobladder, thereby reducing the risk of urinary retention. It also helps to avoid post-operative prolapse as removal of the uterus predisposes to an anterior or posterior vaginal prolapse. In case of an already existing prolapse of the uterus, either isolated or combined with a vaginal prolapse, removing the uterus will be beneficial. It is noteworthy that by resecting the vaginal wall, the vagina shortens which could potentially impair sexual satisfaction and function.

Based on retrospective low quality data only, a systematic review evaluating the advantages and disadvantages of sexual-function preserving RC and orthotopic neobladder in female patients concluded that in well-selected patients, sparing female reproductive organs during RC appears to be oncologically safe and provides improved functional outcomes [292].

Pelvic organ-preserving RC could be considered also in elderly and fragile patients having abdominal diversions. By reducing excision range, it might be beneficial from the point of reduced operating time, estimated blood loss and quicker bowel recovery [317].

7.3.4 Lymphadenectomy: role and extent

Controversies in evaluating the clinical significance of lymphadenectomy (LND) are related to two main aspects of nodal dissection: therapeutic procedure and/or staging instrument.

Two important autopsy studies have been performed for RC so far. The first study showed that in 215 patients with MIBC and nodal dissemination, the frequency of metastasis was 92% in regional (perivesical or pelvic), 72% in retroperitoneal, and 35% in abdominal LNs. There was also a significant correlation between nodal metastases and concomitant distant metastases (p < 0.0001). Approximately 47% of the patients had both nodal metastases and distant dissemination and only 12% of the patients had nodal dissemination as the sole metastatic manifestation [318].

The second autopsy study focused on the nodal yield when super-extended pelvic LND was performed. Substantial inter-individual differences were found with counts ranging from 10 to 53 nodes [319]. These findings demonstrate the limited utility of node count as a surrogate for extent of dissection.

Regional LNs have been shown to consist of all pelvic LNs below the bifurcation of the aorta [320-324]. Mapping studies also found that skipping lesions at locations above the bifurcation of the aorta without more distally located LN metastases is rare [324, 325].

The optimal extent of LND has not been established to date. Standard LND in BC patients involves removal of nodal tissue cranially up to the common iliac bifurcation, with the ureter being the medial border, and including the internal iliac, presacral, obturator fossa and external iliac nodes [326]. Extended LND includes all LNs in the region of the aortic bifurcation, and presacral and common iliac vessels medial to the crossing ureters. The lateral borders are the genitofemoral nerves, caudally the circumflex iliac vein, the lacunar ligament and the LN.
of Cloquet, as well as the area described for standard LND [326-330]. A super-extended LND extends cranially to the level of the inferior mesenteric artery [331, 332].

In order to assess how and if cancer outcome is influenced by the extent of LND in patients with clinical N0M0 MIBC, a systematic review of the literature was undertaken [333]. Out of 1,692 abstracts retrieved and assessed, nineteen studies fulfilled the review criteria [326-330, 332, 334-346]. All five studies comparing LND vs. no LND reported a better oncological outcome for the LND group. Seven out of twelve studies comparing (super)extended with limited or standard LND reported a beneficial outcome for (super)extended LND in at least a subset of patients which is in concordance with the findings of several other meta-analyses [347, 348]. No difference in outcome was reported between extended and super-extended LND in the two high-volume-centre studies identified [332, 344]. The LEA trial, a prospective phase III RCT, including 401 patients with a median follow-up of 43 months reported [349]. Extended LND failed to show a significant advantage (the trial was designed to show an absolute improvement of 15% in 5-year RFS by extended LND) over limited LND in RFS, CSS, and OS. Results from another large RCT on the therapeutic impact of the extent of LND are expected shortly.

It has been suggested that PFS as well as OS might be correlated with the number of LNs removed during surgery. Although there are no data from RCTs on the minimum number of LNs that should be removed, survival rates increase with the number of dissected LNs [350]. In retrospective studies removal of at least ten LNs has been postulated as sufficient for evaluation of LN status, as well as being beneficial for OS [351]. Submitting separate nodal packets instead of en bloc has shown significant increased total LN yield, but did not result in an increased number of positive LNs, making LN density an inaccurate prognosticator [352]. In conclusion, extended LND might have a therapeutic benefit compared to less extensive LND, but due to study bias no firm conclusions can be drawn [333, 353].

7.3.5 Laparoscopic/robotic-assisted laparoscopic cystectomy

A number of recent systematic reviews comparing open RC (ORC) and robot-assisted RC (RARC) reach similar conclusions; RARC has an approximately one-day shorter length of hospital stay (LOS) and less blood loss, but a longer operative time. Complication rates seem similar for both approaches but all published reviews suffer from low quality data.

In minimally-invasive cystectomy, with increasing age, LOS is markedly shorter; up to 2.56 days in patients over 80 years old [354].

Although the low level of evidence of the studies included in these reviews remains a major limitation, a recent Cochrane review incorporating data from all five published RCTs corroborates most findings [355]. Time to recurrence, positive surgical margin rates, grade 3–5 complications and QoL were comparable for RARC and ORC, whilst transfusion rate was likely lower after RARC. For other endpoints outcomes were uncertain due to study limitations.

The Pasadena Consensus Panel (a group of experts on RC, LND and urinary reconstruction) reached similar conclusions [356]. Additionally, they reported that RARC was associated with increased costs, although compared to laparoscopic RC (LRC) there are ergonomic advantages for the surgeon. For both techniques, surgeons’ experience and institutional volume strongly predicted outcome. According to the literature, proficiency is reached after 20–250 cases. However, after statistical modelling, the Pasadena Consensus Panel suggested 30 cases but they also concluded that challenging patients (high BMI, post chemotherapy or RT, pelvic surgery, T4 or bulky tumours or positive nodes) should be performed by experienced robotic surgeons only. Safety of RC after RT was confirmed by a small retrospective study (n = 46) [357]. In experienced hands the percentage of 90-day (major) complications after robotic cystectomy was independent of previous RT [358].

Data on post-RC uretero-enteric stricture rates for both ORC and RARC remain inconclusive. Results are mainly reported by high-volume centres or derive from population-based studies with a large variety of endpoints and poor controlling of potential confounders, making comparison difficult [358-363]. From a surgical technique perspective, the main risk-factor for complications comparing ORC and RARC may be tissue handling; the same applies to different diversion techniques in RARC patients, as those managed by extracorporeal diversion (RARC-ECUD) tend to have more strictures compared to intracorporeal diversion (RARC-ICUD) [362]. This is explained by the need for more extensive dissection of ureter in RARC-ECUD, more tension, resulting in impaired blood supply [364, 365].

Positive surgical margins, as a surrogate for oncological outcome, are comparable between RARC and ORC, although with low certainty [355]. Recurrence-free survival, CSS and OS have been documented as similar
in all RCTs including the largest RAZOR (Robot-assisted radical cystectomy versus open radical cystectomy in patients with bladder cancer) trial (n = 302) [366]. Age over 70, poor PS and major complications were significant predictors of 36-month PFS whilst stage and positive margins were significant predictors of recurrence, PFS and OS. The surgical approach was not a significant predictor of any outcome. A larger (n = 595) single-centre study with a median follow-up of over five years also found comparable recurrence and survival data, including atypical recurrences (defined as one or a combination of the following: port-site metastasis or peritoneal carcinomatosis) [367]. However, recently, port-site metastases and atypical recurrences were reviewed by Mantica et al. [368]. Based on 31 studies and 6,720 evaluable patients, 105 patients (1.63%) were identified with an atypical recurrence, of which 63 (60%) were peritoneal carcinomatosis and 11 (10.5%) port-site metastases. The authors acknowledge, however, that these results may be linked to publication bias and retrospective study design of the included studies. Wei et al., detected residual cancer cells in pelvic washing specimens during or after, but not before, RARC in approximately half of the patients (9/17), which was associated with aggressive variant histology and cancer recurrence. These findings need confirmation in larger studies [369].

The largest RCT to date, the RAZOR trial, supports all of the above findings showing RARC to be non-inferior to ORC in terms of 2-year PFS (72.3% vs. 71.6%), AEs (67% vs. 69%) and QoL [370]. A systematic review of five RCTs including the RAZOR trial supports all of the above findings showing RARC to be non-inferior to ORC with regard to time to recurrence, rates of major complications, QoL, and positive surgical margin rates (all low-certainty evidence) [371].

Most reviewed series, including the RAZOR trial, offer extracorporeal reconstruction. Hussein et al., retrospectively compared extracorporeal reconstruction (n = 1,031) to intracorporeal reconstruction (n = 1,094); the latter was associated with a shorter operative time and fewer blood transfusions but more high-grade complications, which, again, decreased over time [372]. A retrospective report from a high-volume centre found less (major) complications after intracorporeal reconstruction (n = 301) as compared to extracorporeal reconstruction (n = 375) and open RC (n = 272) [373]. It is important to note that, although an intracorporeal neobladder is a very complex robotic procedure [374], the choice for neobladder or cutaneous diversion should not depend on the surgical approach.

An interim analysis of a small RCT of ORC (n = 27) vs. RARC with intracorporeal urinary diversion (n = 24), found comparable results at one year after surgery for most health-related quality of life (HRQoL) domains. Patients receiving ORC were more likely to experience a decline in role functioning and higher symptoms scale, while RARC-intracorporeal urinary diversion patients were more likely to report significant increases in urinary symptoms and problems [375]. A prospective, non-randomised, multicentre comparative effectiveness study showed no statistically significant differences after 12-months between ORC (n = 154) and RARC (n = 159) in terms of complications (67 vs. 64%) and HRQoL [376].

### 7.3.5.1 Laparoscopic radical cystectomy versus robot-assisted radical cystectomy

For LRC a review including sixteen studies came to similar conclusions as described for RARC [374]. As compared to ORC, LRC had a significantly longer operative time, fewer overall complications, less blood transfusions and analgesic use, less blood loss and a shorter LOS. However, the review was limited by the inherent limitations of the included studies. Although this review also showed better oncological outcomes, these appeared comparable to ORC series in a large LRC multicentre study [377].

The CORAL study was a small single-centre RCT comparing open (n = 20) vs. robotic (n = 20) vs. laparoscopic (n = 19) RC [378, 379]. The 30-day complication rate was significantly higher in the open arm (70%) compared to the laparoscopic arm (26%). There was no difference between the 90-day Clavien complication rates in the three study arms. Limitations of this study include the small sample size, three different although experienced surgeons, and cross over between arms.

### 7.3.6 Urinary diversion after radical cystectomy

From an anatomical standpoint, three alternatives are currently used after cystectomy:

- abdominal diversion, such as an uretero-cutaneostomy, ileal or colonic conduit, and various forms of a continent pouch (infrequently used);
- urethral diversion, which includes various forms of GI pouches attached to the urethra as a continent orthotopic urinary diversion (neobladder, orthotopic bladder substitution);
- rectosigmoid diversions, such as uretero-(ileo-)rectostomy (infrequently used).

Different types of segments of the intestinal tract have been used to reconstruct the urinary tract, including the stomach, ileum, colon and appendix [380].

Several studies have compared certain aspects of HRQoL such as sexual function, urinary continence and body image in patient cohorts with different types of urinary diversion [381]. However, further research evaluating the impact of pre-operative tumour stage, functional- and socio-economic status, and time interval to primary surgery are needed.

#### 7.3.6.1 Patient selection and preparations for surgery

In consultation with the patient, both an orthotopic neobladder and ileal conduit should be considered in case reconstructive surgery exposes the patient to excessive risk (as determined by comorbidity and age).

Ensuring that patients make a well-informed decision about the type of urinary diversion is associated with less decision regret post-operatively, independent of the method selected [382].

Diagnosis of an invasive urethral tumour prior to cystectomy leads to urethrectomy which could be a contraindication for a neobladder reconstruction. If indicated; in males, in case of CIS and extension of tumour in the prostatic urethra, urethral frozen section has to be performed on the cystoprostatectomy specimen just under the verumontanum and on the inferior limits of the bladder neck; in females a urethral frozen section has to be taken just below the bladder neck.

Non-muscle-invasive BC in prostatic urethra or bladder neck biopsies does not necessarily preclude orthotopic neobladder substitution, provided that patients undergo regular follow-up cystoscopy and urinary cytology [383].

In the presence of positive LNs, orthotopic neobladder can nevertheless be considered in case of N1 involvement (metastasis in a single node in the true pelvis) but not in N2 or N3 tumours [384].

Oncological results after orthotopic neobladder substitution or conduit diversion are similar in terms of local or distant metastasis recurrence, but secondary urethral tumours seem less common in patients with a neobladder compared to those with conduits or continent cutaneous diversions [385].

For cystectomy, general preparations are necessary as for any other major pelvic and abdominal surgery. If the urinary diversion is constructed from GI segments, the length or size of the respective segments and their pathophysiology when storing urine must be considered [386]. Despite the necessary interruption and re-anastomosis of the bowel, formal bowel preparation may not be necessary [387]. Bowel recovery time can be reduced by the use of early mobilisation and early oralisation, GI stimulation with metoclopramide and chewing gum [388]. Patients treated according to the ‘Fast tract’/ERAS (Early Recovery After Surgery) protocol have shown to score better on the emotional and physical functioning scores and suffer less from wound healing disorders, fever and thrombosis [389].

A cornerstone of the ERAS protocol is post-operative pain management, which involves significantly reducing the use of opioids; offering opioids mainly as breakthrough pain medication. Instead of patient-controlled analgesia and epidural opioids, most patients receive high-dose acetaminophen and/or ketorolac, starting intra-operatively. Patients on ERAS experience more pain as compared to patients on a traditional protocol (Visual Analogue Scale 3.1 vs. 1.1, p < 0.001), but post-operative ileus decreased from 22% to 7.3% (p = 0.003) [390].

A multicentre randomised placebo-controlled trial showed that patients receiving alvimopan, a peripherally acting μ-opioid receptor antagonist, had quicker bowel recovery compared to patients receiving placebo [391]. However, this drug is, as yet, not approved in Europe.

Venous thromboembolism (VTE) prophylaxis may be implemented as part of an ERAS protocol. A single-centre non-randomised study showed a significant lower 30-day VTE incidence rate in patients treated for 28 days with enoxaparin compared to patients without prophylaxis [392]. Data from the Ontario Cancer...
Registry including 4,205 cystectomy patients of whom 1,084 received NAC showed that VTE rates are higher in patients treated with NAC as compared to patients treated with cystectomy only (12% vs. 8%, p = 0.002) [393, 394].

Patients undergoing continent urinary diversion must be motivated to learn about their diversion and to be manually skilful in manipulating their diversion. Contraindications to more complex forms of urinary diversion include:

- debilitating neurological and psychiatric illnesses;
- limited life expectancy;
- severe impaired liver or renal function;
- urothelial carcinoma positive surgical margins.

Relative contraindications specific for an orthotopic neobladder are high-dose pre-operative RT, complex urethral stricture disease and severe urethral sphincter-related incontinence [395].

### 7.3.6.2 Different types of urinary diversion

Radical cystectomy and urinary diversion are the two steps of one operation. However, the literature uniformly reports complications of RC while ignoring the fact that most complications are diversion related [396]. Age alone is not a criterion for offering continent diversion [395, 397]. Comorbidity, cardiac- and pulmonary function and cognitive function are all important factors that should be considered, along with the patient’s social support and preference.

Age > 80 years is often considered to be the threshold after which neobladder reconstruction is not recommended. However, there is no exact age for a strict contraindication. In most large series from experienced centres, the rate of orthotopic bladder substitution after cystectomy for bladder tumour is up to 80% in men and 50% in women [398-401]. Nevertheless, no RCTs comparing conduit diversion with neobladder or continent cutaneous diversion have been performed.

A retrospective study including 1,383 patients showed that the risk of a decline in estimated glomerular filtration rate (eGFR) did not significantly differ after ileal conduit vs. neobladder in patients with pre-operative chronic kidney disease 2 (eGFR 60–89 mL/min/1.73 m²) or 3a (eGFR 45–59 mL/min/1.73 m²) [402]. Only age and anastomotic strictures were found to be associated with a decline in eGFR.

#### 7.3.6.2.1 Uretero-cutaneostomy

Ureteral diversion to the abdominal wall is the simplest form of cutaneous diversion. Operating time, complication rate, blood loss, transfusion rate, stay at intensive care and length of hospital stay are lower in patients treated with ureterocutaneostomy as compared to ileal conduit [403, 404]. Therefore, in frail patients and/or in those with a solitary kidney who need a supravesical diversion, uretero-cutaneostomy is the preferred procedure [405, 406]. Quality of life, which was assessed using the Bladder Cancer Index (BCI), showed equal urinary bother and function for patients treated with ileal conduit and uretero-cutaneostomy [403]. However, maintaining a catheter for stoma patency might relate to an elevated incidence of urinary tract infections and therefore impair QoL [407, 408]. Nevertheless, in carefully selected elderly patients, all other forms of wet and dry urinary diversions, including orthotopic bladder substitutions, are possible [409].

Technically, in case patients have both kidneys; either one ureter, to which the other shorter one is attached end-to-side, is connected to the skin (trans-uretero-cutaneostomy) or both ureters are directly anastomosed to the abdominal wall creating a stoma. Due to the smaller diameter of the ureters, stoma stenosis has been observed more frequently for this technique as compared to using small or large bowel to create an intestinal stoma [405].

In a retrospective multicentre study peri-operative morbidity was evaluated for urinary diversion using bowel as compared to uretero-cutaneostomy. Patients selected for a uretero-cutaneostomy were older and had a higher ASA score, while their mean Charlson score was lower (4.2 vs. 5.6, p < 0.001) [410].

Despite the limited comparative data available, it must be taken into consideration that older data and clinical experience suggest ureter stenosis at the skin level and ascending UTI are more frequent complications in uretero-cutaneostomy compared to an ileal conduit diversion. In a retrospective study comparing various forms of intestinal diversion, ileal conduits had fewer late complications than continent abdominal pouches or orthotopic neobladders [411].

#### 7.3.6.2.2 Ileal conduit

The ileal conduit is an established option with well-known/predictable results. However, up to 48% of patients develop early complications including UTIs, pyelonephritis, ureteroileal leakage and stenosis [411]. The main complications in long-term follow-up studies are stomal complications in up to 24% of patients and functional
and/or morphological changes of the UUT in up to 30% [411-413]. An increase in complications was seen with longer follow-up in the Berne series of 131 patients who were followed for a minimum of five years (median follow-up 98 months) [414]; the rate of complications increased from 45% at five years to 94% in those surviving > 15 years. In the latter group, 50% of patients developed UUT changes and 38% developed urolithiasis.

7.3.6.2.3 Orthotopic neobladder
According to Dutch-, German- and Spanish bladder cancer registry data, an orthotopic bladder substitution to the urethra is used in approximately 10–20% of both male and female patients. Contemporary reports document the safety and long-term reliability of this procedure. In several large centres, this has become the diversion of choice for most patients undergoing cystectomy [226, 286, 395]. However, in elderly patients (> 80 years) it is rarely performed even in high-volume expert centres [415, 416].

The terminal ileum is the GI segment most often used for bladder substitution. There is less experience with the ascending colon, including the caecum, and the sigmoid [286]. Emptying of the reservoir anastomosed to the urethra requires abdominal straining, intestinal peristalsis, and sphincter relaxation. Early and late morbidity in up to 22% of patients is reported [417, 418]. In two studies of 1,054 and 1,300 patients [395, 419], long-term complications included diurnal (8–10%) and nocturnal (20–30%) incontinence, uretero-intestinal stenosis (3–18%), metabolic disorders, and vitamin B12 deficiency. A study comparing cancer control and patterns of disease recurrence in patients with neobladder and ileal conduit showed no difference in CSS between the two groups when adjusting for pathological stage [420]. Urethral recurrence in neobladder patients seems rare (1.5–7% in both male and female patients) [395, 421]. These results indicate that neobladder in male and female patients does not compromise the oncological outcome of cystectomy. It remains debatable whether patient's QoL for neobladder is better compared to non-continent urinary diversion [422, 423].

Continent cutaneous urinary diversion (a low-pressure detubularised ileal reservoir for self-catheterisation) and uretero-rectosigmoidostomy are rarely used techniques nowadays, due to their high complication rates, including stomal stenosis, incontinence in the continent cutaneous diversion, UUT infections and stone formation in case of uretero-rectosigmoidostomy [424].

Various forms of UUT reflux protection, including a simple isoperistaltic tunnel, ileal intussusception, tapered ileal prolongation implanted subserosally, and direct (sub)mucosal or subserosal ureteral implantation, have been described [418, 425]. According to the long-term results, the UUT is protected sufficiently by either method.

A detailed investigation of the bladder neck prior to RC is important for women who are scheduled for an orthotopic bladder substitute [426]. In women undergoing RC the rate of concomitant urethral malignancy has been reported to range from 12–16% [427]. Localisation of the primary tumour at the bladder neck correlated strongly with concomitant urethral malignancy. In addition, tumour involving the bladder neck and urethra tended to be associated with a higher risk of advanced stage and nodal involvement [428].

Currently, it is not possible to recommend a particular type of urinary diversion. However, most institutions prefer ileal orthotopic neobladders and ileal conduits based on clinical experience [429, 430]. In selected patients, such as patients with a single kidney, uretero-cutaneostomy is surgically the least burdensome type of diversion. Recommendations related to RC and urinary diversions are listed in Section 7.3.10.

7.3.7 Morbidity and mortality
In three long-term studies and one population-based cohort study, the peri-operative mortality was reported as 1.2–3.2% at 30 days and 2.3–8.0% at 90 days [226, 396, 398, 431, 432]. In a large single-centre series early complications (within three months of surgery) were seen in 58% of patients [396]. Late morbidity was usually linked to the type of urinary diversion (see also above) [399, 433]. Early morbidity associated with RC for NMIBC (at high risk for disease progression) is similar and no less than that associated with muscle-invasive tumours [434]. In general, lower morbidity and (peri-operative) mortality have been observed by surgeons and in hospitals with a higher case load and therefore more experience [431, 435-439].

**Grade V**

Death of a patient

Suffix ‘d’

If the patient suffers from a complication at the time of discharge, the suffix “d” (for ‘disability’) is added to the respective grade of complication. This label indicates the need for a follow-up to fully evaluate the complication.

---

1 A systematic review showed that peri-operative blood transfusion (PBT) in patients who undergo RC correlates with increased overall mortality, CSM and cancer recurrence. The authors hypothesised that this may be caused by the suggested immunosuppressive effect of PBT. The foreign antigens in transfused blood induce immune suppression, which may lead to tumour cell spread, tumour growth and reduced survival in already immunosuppressed cancer patients. As other possible causes for this finding increased post-operative infections and blood incompatibility were mentioned [441]. Buchner and co-workers showed similar results in a retrospective study. The 5-year CSS decreased in cases where intra-operative blood transfusion (CSS decreased from 67% to 48%) or post-operative blood transfusion (CSS decreased from 63% to 48%) were given [442].

2 Intra-operative tranexamin acid infusion reduces peri-operative blood transfusion rates from 57.7% to 31.1%. There was no increase seen in peri-operative VTE [443].

3 Hammond and co-workers reviewed 20,762 cases of VTE after major surgery and found cystectomy patients to have the second highest rate of VTE among all cancers studied [444]. These patients benefit from 30 days low-molecular-weight heparin prophylaxis. Subsequently, it was demonstrated that BMI > 30 and non-urothelial BCs are independently associated with VTE after cystectomy. In these patients extended (90 days) heparin prophylaxis should be considered [445].

7.3.8 Survival

According to a multi-institutional database of 888 consecutive patients undergoing RC for BC, the 5-year RFS rate was 58% and CSS was 66% [413]. External validation of post-operative nomograms for BC-specific mortality showed similar results, with bladder-CSS of 62% [446].

Recurrence-free survival and OS in a large single-centre study of 1,054 patients was 68% and 66% at five years and 60% and 43%, at ten years, respectively [212]. However, the 5-year RFS in node-positive patients who underwent cystectomy was considerably less at 34–43% [447, 448]. In a surgery-only study, the 5-year RFS was 76% in patients with pT1 tumours, 74% for pT2, 52% for pT3, and 36% for pT4 [225].

A trend analysis based on 148,315 BC patients identified in the SEER database between 1973 and 2009 showed increased stage-specific 5-year survival rates for all stages, except for metastatic disease [449].

7.3.9 Impact of hospital and surgeon volume on treatment outcomes

In a systematic review including 40 retrospective studies and 560,00 patients, the impact of hospital and/or surgeon volume and peri-operative outcomes of RC was assessed [450]. A higher hospital volume was associated with lower in-hospital, 30-day and 90-day mortality. In addition, higher volume hospitals were more likely to have lower positive surgical margins, higher number of LNDs and neobladders and lower complication rates. For surgeon volume, less evidence was available. This study suggested performing at least 10 RCs per centre annually and preferably more than 20. Recently, a nationwide analysis of the Dutch Cancer Registry including almost 9,500 patients between 2008 and 2018 reported decreased 30- and 90-day mortality rates for annual hospital volumes of > 30 RCs. Furthermore, this study showed no true plateau curve for 30- and 90-day mortality beyond 30 RCs supporting the ‘more is better’ principle [451, 452].

7.4 Unresectable tumours

7.4.1 Palliative cystectomy

Unresectable locally advanced tumours (T4b, invading the pelvic or abdominal wall) may be accompanied by several debilitating symptoms, including bleeding, pain, dysuria and urinary obstruction. These patients are candidates for palliative treatments, such as palliative RT. If control of the symptoms is not possible by less invasive methods, patients may be offered a palliative cystectomy with urinary diversion or urinary diversion only. Palliative cystectomy carries the greatest morbidity, particularly in patients with a poor PS. In a series of 74 patients who underwent palliative cystectomy, severe complications (Clavien-Dindo grade ≥ 3) occurred in 30%. The 30-day mortality rate was 9% and at eight months follow-up, 70% had died [453].

</tr>
</tbody>
</table>

*Only statements which met the a priori consensus threshold across all three stakeholder groups are listed (defined as ≥ 70% agreement and ≤ 15% disagreement, or vice versa).*

7.4.2 Supportive care

7.4.2.1 Obstruction of the upper urinary tract

Unilateral (best kidney) or bilateral nephrostomy tubes provide the easiest solution for UUT obstruction, but patients find the tubes inconvenient and prefer ureteral stenting. However, stenting can be difficult to achieve. Stents must be regularly replaced and there is the risk of stent obstruction or displacement. Another possible solution is a urinary diversion with, or without, a palliative cystectomy.

7.4.2.2 Bleeding and pain

In the case of bleeding, the patient must be screened first for coagulation disorders or the patient’s use of anticoagulant drugs must be reviewed. Transurethral (laser) coagulation may be difficult in a bladder full of tumour or with a bleeding tumour. Intravesical rinsing of the bladder with 1% silver nitrate or 1–2% alum can be effective [454]. This can usually be done without any anaesthesia. The instillation of formalin (2.5–4% for 30 minutes) is a more aggressive and painful procedure, requiring anaesthesia. Formalin instillation has a higher risk of side-effects, e.g., bladder fibrosis, but is more likely to control the bleeding [454]. Vesicoureteral reflux should be excluded to prevent renal complications.

Radiation therapy is another common strategy to control bleeding and is also used to control pain. An older study reported control of haematuria in 59% of patients and pain control in 73% [455]. Irritative bladder and bowel complaints due to irradiation are possible, but are usually mild. Non-conservative options are embolisation of specific arteries in the small pelvis, with success rates as high as 90% [454]. Radical surgery is a last resort and includes cystectomy and diversion (see above, Section 7.4.1).

7.5 Bladder-sparing treatments for localised disease

7.5.1 Transurethral resection of bladder tumour

Transurethral resection of bladder tumour alone in MIBC patients is only possible as a therapeutic option if tumour growth is limited to the superficial muscle layer and if re-staging biopsies are negative for residual (invasive) tumour [456]. In general, approximately 50% of patients will still have to undergo RC for recurrent MIBC with a disease-specific mortality rate of up to 47% in this group [457]. A disease-free status at re-staging TURB appears to be crucial in making the decision not to perform RC [458, 459]. A prospective study by Solsona et al., including 133 patients with radical TURB and re-staging negative biopsies, reported a 15-year follow-up [459]. Thirty per cent of patients had recurrent NMIBC and went on to intravesical therapy, and 30% (n = 40) progressed, of which 27 died of BC. After five, ten, and fifteen years, the results showed CSS rates of 81.9%, 79.5%, and 76.7%, respectively and PFS rates with an intact bladder of 75.5%, 64.9%, and 57.8%, respectively.

In conclusion, TURB alone should only be considered as a therapeutic option for muscle-invasive disease after radical TURB, when the patient is unfit for cystectomy, or refuses open surgery, or as part of a trimodality (TMT) bladder-preserving approach.

7.5.1.1 Guideline for transurethral resection of bladder tumour

7.5.2 External beam radiotherapy

Current RT techniques with soft-tissue matching and image guidance result in superior bladder coverage and a reduced integral dose to the surrounding tissues. The target total dose (to bladder and/or bladder tumour) for curative EBRT in BC is 64–66 Gy [460, 461]. A reasonable alternative is moderately hypofractionated EBRT to 55 Gy in 20 fractions which has been suggested to be non-inferior to 64 Gy in 32 fractions in terms of invasive
locoregional control, OS, and late toxicity. In a phase II study, 55 patients (median age 86) with BC, unfit for cystectomy or even daily RT, were treated with 6-weekly doses of 6 Gy [462]. Forty-eight patients completed EBRT with acceptable toxicity and 17% showed local progression after two years demonstrating good local control with this more ultra-hypofractionated schedule.

Elective treatment to the LNs is optional and should take into account patient comorbidities and the risks of toxicity to adjacent critical structures. For node-positive disease, consider boosting grossly involved nodes to the highest achievable dose that does not violate normal tissue constraints based on the clinical scenario.

The use of modern standard EBRT techniques results in major related late morbidity of the urinary bladder or bowel in less than 5% of patients [463]. Acute diarrhoea is reduced even more with intensity-modulated RT [464]. Important prognostic factors for outcome include response to EBRT, tumour size, hydronephrosis, presence of CIS, and completeness of the initial TURB. Additional prognostic factors reported are age and stage [465].

With the use of modern EBRT techniques, efficacy and safely results seem to have improved over time. A 2002 Cochrane analysis demonstrated that RC has an OS benefit compared to RT [466], although this was not the case in a 2014 retrospective review using a propensity score analysis [467]. In a 2017 retrospective cohort study of U.S. National Cancer Data Base data, patients over 80 were identified with cT2–4, N0–3, M0 BC, who were treated with curative EBRT (60–70 Gy; n = 739) or concurrent chemoradiotherapy (n = 630) between 2004 and 2013 [468]. The 2-year OS was 42% for EBRT vs. 56% for chemoradiotherapy (p < 0.001). For EBRT a higher RT dose and a low stage were associated with improved OS.

In conclusion, although EBRT results seem to improve over time, EBRT alone does not seem to be as effective as surgery or TMT therapy (see Section 7.5.4). Factors that influence outcome should be considered. However, EBRT can be an alternative treatment in patients unfit for radical surgery or concurrent chemotherapy, and it can also be quite effective in helping control bleeding.

IGRT = image-guided radiotherapy; IMRT = intensity-modulated radiotherapy.

### 7.5.3 Chemotherapy

Chemotherapy alone rarely produces durable complete remissions. In general, a clinical complete response rate of up to 56% is reported in some series, which must be weighed against a staging error of > 60% [469, 470]. Response to chemotherapy is a prognostic factor for treatment outcome and eventual survival although it may be confounded by patient selection [471].

Several groups have reported the effect of chemotherapy on resectable tumours (neoadjuvant approach), as well as unresectable primary tumours [237, 254, 472, 473]. Neoadjuvant chemotherapy with two to three cycles
of MVAC or CMV has led to a down-staging of the primary tumour in various prospective series [237, 254, 472]. A bladder-conserving strategy with TURB and systemic cisplatin-based chemotherapy has been reported several years ago and could lead to long-term survival with intact bladder in a highly selected patient population [471].

A recent large retrospective analysis of a National Cancer Database cohort reported on 1,538 patients treated with TURB and multi-agent chemotherapy [474]. The two and 5-year OS for all patients was 49% and 32.9% and for cT2 patients it was 52.6% and 36.2%, respectively. While these data show that long-term survival with intact bladder can be achieved in a subset of patients it is not recommended for routine use.

7.5.4 Trimodality bladder-preserving treatment

Trimodality therapy combines TURB, chemotherapy and RT. The rationale to combine TURB with RT is to maximally achieve local tumour control in the bladder and adjacent nodes. The addition of radiosensitising chemotherapy or other radiosensitisers (mentioned below) is aimed at the potentiation of RT. Micrometastases are targeted by platinum-based combination chemotherapy (for details see Section 7.1). The aim of TMT is to preserve the bladder and QoL without compromising oncological outcome.

There are no successfully completed RCTs comparing the outcome of TMT with RC, but TMT using chemoradiation has been shown to be superior to RT alone [475-477]. Many of the reported series have differing characteristics as compared to the larger surgical series, which typically have median ages in the mid-to-late 60s compared to mid-70s in some large RT series (reviewed by James, et al. [475]). Data from a retrospective series, with some methodological caveats, comparing RT (n = 66) and chemoradiation (n = 208) showed an improved complete response of chemoradiation vs. RT (OR: 2.32; 95% CI: 1.05–5.12; p = 0.037), with a 64% 5-year OS for chemoradiation vs. 45% for RT (HR: 0.7; 95% CI: 0.50–0.99; p = 0.045) [477].

In the case of TMT, two distinct patterns of care emerge; treatment aimed at patients fit for cystectomy who elect TMT or refuse cystectomy, and treatment aimed at older, less fit, patients. For the former category, TMT presents selective bladder preservation and in this case the initial step is a radical TURB where as much tumour as possible should be resected. In this case appropriate patient selection (e.g., T2 tumours, no CIS) is critical [478, 479]. Even in case of an initial presumed complete resection, a second TUR has been suggested to reveal tumour in > 50% of patients and subsequently improves 5-year OS in case of TMT [480]. For patients who are not candidates for cystectomy, less stringent criteria can be applied, but extensive CIS and poor bladder function should both be regarded as relative contraindications.

A collaborative review has described the principles of TMT [481]. For radiation, two schedules are most commonly used; historically within the RTOG a split-course format with interval cystoscopy [476] and single-phase treatment which is now more commonly used [475]. A conventional radiation schedule includes EBRT to the bladder and limited pelvic LNs with an initial dose of 40-45 Gy, with a boost to the whole bladder of 50–54 Gy and a further tumour boost to a total dose of 60–66 Gy. If not boosting the tumour, it is also reasonable for the whole bladder to be treated to 59.4–66 Gy. For node-positive disease, consider boosting grossly involved nodes to the highest achievable dose that does not violate normal tissue constraints. Therefore, elective treatment to the LNs (when node negative) is optional and should take into account patient comorbidities and the risks of toxicity to adjacent critical structures.

In summary, reasonable radiation fields include pelvis (with bladder and/or bladder tumour boost), bladder only or partial bladder (tumour) only [475]. A reasonable radiation dosing alternative to conventional fractionation when treating the bladder-only fields is moderately hypofractionated EBRT to 55 Gy in 20 fractions which has been suggested to be non-inferior to 64 Gy in 32 fractions (fx) in terms of invasive loco-regional control, OS and late toxicity [460, 482].
Different chemotherapy regimens have been used, but most evidence exists for cisplatin [483] and mitomycin C plus 5-FU [475]. In addition to these agents, other regimens have also been used such as gemcitabine and hypoxic cell sensitisation with nicotinamide and carbogen, without clear preference for a specific radiosensitiser [8, 9]. In a recently published phase II RCT, twice-a-day radiation plus fluorouracil/cisplatin was compared to once-daily radiation plus gemcitabine [484]. Both arms were found to result in a > 75% freedom of distant metastases at 3 years (78% and 84%, respectively). Therefore, there are options for non-cisplatin candidates such as 5-FU/mitomycin C or low-dose gemcitabine.

To detect non-responders who should be offered salvage cystectomy, bladder biopsies should be performed after TMT [477].

Five-year CSS and OS rates vary between 50%–84% and 36%–74%, respectively, with salvage cystectomy rates of 10–30% [475, 478, 481, 483, 485, 486]. The Boston group reported on their experience in 66 patients with mixed variant histologies treated with TMT and found similar complete response, OS, DSS and salvage cystectomy rates as in UC [487]. The majority of recurrences post-TMT are non-invasive and can be managed conservatively [475]. In contemporary experiences, salvage cystectomy is required in about 10–15% of patients treated with TMT and can be curative [475, 478, 486]. Current data suggest that major late complication rates are slightly higher but remain acceptable for salvage- vs. primary cystectomy [488, 489].

A sub-analysis of two RTOG trials looked at complete response (T0) and near-complete response (Ta or Tis) after TMT [490]. After a median follow-up of 5.9 years 41/119 (35%) of patients experienced a bladder recurrence, and fourteen required salvage cystectomy. There was no difference between complete and near-complete responders. Non-muscle-invasive BC recurrences after complete response to TMT were reported in 25% of patients by the Boston group, sometimes over a decade after initial treatment [491]. A NMIBC recurrence was associated with a lower DSS, although in properly selected patients, intravesical BCG could avoid immediate salvage cystectomy.

The differential impact of RC vs. TMT on long-term OS is lacking a randomised comparison and rigorous prospective data. A propensity score matched institutional analysis has suggested similar DSS and OS between TMT and RC [486]. Two retrospective analyses of the National Cancer Database from 2004–2013 with propensity score matching compared RC to TMT. Ritch et al., identified 6,606 RC and 1,773 TMT patients [492]. Worse survival was linked to higher age, comorbidity and tumour stage. After modelling, TMT resulted in a lower mortality at one year (HR: 0.84, 95% CI: 0.74–0.96, p = 0.01). However, in years 2 and onwards, there was a significant and persistent higher mortality after TMT (year 2: HR: 1.4, 95% CI: 1.2–1.6, p < 0.001; and year 3 onwards: HR: 1.5, 95% CI: 1.2–1.8, p < 0.001). The second analysis was based on a larger cohort, with 22,680 patients undergoing RC; 2,540 patients received definitive EBRT and 1,489 TMT [493]. Survival after modelling was significantly better for RC compared to any EBRT, definitive EBRT and TMT (HR: 1.4, 95% CI: 1.2–1.6) at any time point. In older patients which are potentially less ideal candidates for radical surgery, Williams et al., found a significantly lower OS (HR :1.49, 1.31–1.69) and CSS (1.55, 1.32–1.83) for TMT as compared to surgery as well as increased costs [494]. This was a retrospective SEER database study which included 687 propensity-matched patients in each arm, however, the median number of radiation fractions was well below what is considered adequate for definitive therapy and as such the radiation patients may have been treated inadequately or palliatively. In general, such population-based studies are limited by confounding, misclassification, and selection bias. A systematic review including 57 studies and over 30,000 patients comparing RC and TMT found improved 10-year OS and DSS for TMT, but for the entire cohort OS and DSS did not significantly differ between RC and TMT [495]. Complete response after TMT resulted in significantly better survival, as did down-staging after TURB or NAC in case of RC.

Overall significant late pelvic (GI/genitourinary [GU]) toxicity rates after TMT are low and QoL is good [475, 496, 497]. A combined analysis of survivors from four RTOG trials with a median follow-up of 5.4 years showed that combined-modality therapy was associated with low rates of late grade 3 toxicity (5.7% GU and 1.9% GI). No late grade 4 toxicities or treatment-related deaths were recorded [496]. A retrospective study showed QoL to be good after TMT and in most domains better than after cystectomy, although prospective validations are needed [498]. One option to reduce side effects after TMT is the use of IMRT and image-guided radiotherapy (IGRT) [8, 9, 499].

A collaborative review came to the conclusion that data are accumulating, suggesting that bladder preservation with TMT leads to acceptable outcomes and therefore TMT may be considered a reasonable treatment option in well-selected patients as compared to RC [481]. Bladder preservation as an alternative to RC is generally reserved for patients with smaller solitary tumours, negative nodes, no extensive or multifocal CIS, no tumour-
related hydronephrosis, and good pre-treatment bladder function. Trimodality bladder-preserving treatment should also be considered in all patients with a contraindication for surgery, either a relative or absolute contraindication since the factors that determine fitness for surgery and chemoradiotherapy differ. There are no definitive contemporary data supporting the benefit of using neoadjuvant or adjuvant chemotherapy combined with chemoradiation. Patient selection is critical in achieving good outcomes [481]. Whether a node dissection should be performed before TMT as in RC remains unclear [8, 9].

A bladder-preserving trimodality strategy requires very close multidisciplinary cooperation [8, 9]. This was also highlighted by a Canadian group [500]. In Ontario between 1994 and 2008 only 10% (370/3,759) of patients with cystectomy had a pre-operative radiation oncology consultation, with high geographical variations. Independent factors associated with this consultation included advanced age (p < 0.001), greater comorbidity (p < 0.001) and earlier year of diagnosis (p < 0.001). A bladder-preserving trimodality strategy also requires a high level of patient compliance. Even if a patient has shown a clinical response to a trimodality bladder-preserving strategy, the bladder remains a potential source of recurrence, hence long-term life-long bladder monitoring is essential and patients should be counselled that this will be required.

7.6 Adjuvant therapy

7.6.1 Role of adjuvant platinum-based chemotherapy

Adjuvant chemotherapy after RC for patients with pT3/4 and/or LN positive (N+) disease without clinically detectable metastases (M0) is still under debate [488, 501]. The general benefits of adjuvant chemotherapy include:

- chemotherapy is administered after accurate pathological staging, therefore, treatment in patients at low risk for micrometastases is avoided;
- no delay in definitive surgical treatment.

The drawbacks of adjuvant chemotherapy are:

- assessment of in vivo chemosensitivity of the tumour is not possible and overtreatment is an unavoidable problem;
- delay of or intolerance to chemotherapy, due to post-operative morbidity [502].

There is limited evidence from adequately conducted and accrued phase III RCTs in favour of the routine use of adjuvant chemotherapy [501, 503-508]. An individual patient data meta-analysis [503] of survival data from six RCTs of adjuvant chemotherapy [485, 509-512] included 491 patients (unpublished data from Otto et al., were included in the analysis). All included trials suffered from significant methodological flaws including small sample size (underpowered), incomplete accrual, use of inadequate statistical methods and design flaws (irrelevant endpoints and failing to address salvage chemotherapy in case of relapse or metastases) [501]. In these trials, three or four cycles of CMV, cisplatin, cyclophosphamide, and adriamycin (CISCA), methotrexate, vinblastine, adriamycin or epirubicin, and cisplatin and methotrexate (CM) were used [513], and one trial used cisplatin monotherapy [511]. The data were not convincing to support an unequivocal recommendation for the use of adjuvant chemotherapy. In 2014, this meta-analysis was updated with an additional three studies [505-507] resulting in the inclusion of 945 patients from nine trials [504]. None of the trials had fully accrued and individual patient data were not used in the analysis [504]. For one trial only an abstract was available at the time of the meta-analysis [506] and none of the included individual trials were significantly positive for OS in favour of adjuvant chemotherapy. In two of the trials more modern chemotherapy regimens were used (gemcitabine/cisplatin and paclitaxel/gemcitabine/cisplatin) [505, 506]. The HR for OS was 0.77 (95% CI: 0.59–0.99, p = 0.049) and for DFS 0.66 (95% CI: 0.45–0.91, p = 0.014) with a stronger impact on DFS in case of nodal positivity.

A retrospective cohort analysis including 3,974 patients after cystectomy and LND showed an OS benefit in high-risk subgroups (extravesical extension and nodal involvement) (HR: 0.75, CI: 0.62–0.90) [514]. A recent publication of the largest RCT (European Organisation for Research and Treatment of Cancer [EORTC] 30994), although not fully accrued, showed a significant improvement of PFS for immediate, compared with deferred, cisplatin-based chemotherapy (HR: 0.54, 95% CI: 0.4–0.73, p < 0.0001), but there was no significant OS benefit [515].

Furthermore, a large observational study including 5,653 patients with pathological T3–4 and/or pathological node-positive BC, treated between 2003 and 2006 compared the effectiveness of adjuvant chemotherapy vs. observation. Twenty-three percent of patients received adjuvant chemotherapy with a 5-year OS of 37% for the adjuvant arm vs. 29.1% (HR: 0.70, 95% CI: 0.64–0.76) in the observation group [516].

Another large retrospective analysis based on National Cancer Data Base including 15,397 patients with locally advanced (pT3/4) or LN-positive disease also demonstrated an OS benefit in patients with UC histology [517]. In patients with concomitant variant or pure variant histology, however, no benefit was found.

From the currently available evidence it is still unclear whether immediate adjuvant chemotherapy or chemotherapy at the time of relapse is superior, or if the two approaches are equivalent with respect to the endpoint of OS. The most recent meta-analysis from 2014 showed a therapeutic benefit of adjuvant chemotherapy, but the level of evidence of this review is still very low, with significant heterogeneity and methodological flaws in the only nine included trials [504]. Patients should be informed about potential chemotherapy options before RC, including neoadjuvant and adjuvant chemotherapy, and the limited evidence for adjuvant chemotherapy.

7.6.2 Role of adjuvant immunotherapy

To determine the benefit of PD-1/PD-L1 checkpoint inhibitors, three phase III RCTs have evaluated checkpoint inhibitor monotherapy with atezolizumab, nivolumab or pembrolizumab in patients with muscle-invasive UC. The CheckMate 274 phase III multi-centre, double-blind, randomised, controlled trial of adjuvant nivolumab vs. placebo for up to 1 year in 709 patients with muscle-invasive UC (neoadjuvant cisplatin-based chemotherapy was allowed before trial entry) demonstrated a significant improvement in median DFS (20.8 months (95% CI:...
16.5–27.6) with nivolumab and 10.8 months (95% CI: 8.3–13.9) with placebo). The percentage of patients who were alive and disease-free at 6 months was 74.9% with nivolumab and 60.3% with placebo (HR for disease recurrence or death, 0.70; 96.22% CI: 0.55–0.90; p < 0.001). Among patients with a PD-L1 expression level of ≥ 1%, the percentage of patients was 74.5% and 55.7%, respectively (HR: 0.55; 96.72% CI: 0.35–0.85; p < 0.001) [518]. The primary endpoint of DFS was not achieved in a multi-centre RCT of adjuvant atezolizumab vs. observation (IMvigor010) Median DFS was 19.4 months (95% CI: 15.9–24.8) with atezolizumab and 16.6 months (11.2–24.8) with observation (stratified HR: 0.89, 95% CI: 0.74–1.08, p = 0.24) [519]. A similarly designed trial of pembrolizumab in the adjuvant setting has completed accrual with results awaited. The FDA has approved nivolumab for adjuvant treatment of patients with UC who are at high risk of recurrence after undergoing surgery [520]. A promising report (see Marker section) has suggested for a potential role for ctDNA to guide the use of adjuvant IO for UC [223].

7.7 Metastatic disease

7.7.1 Introduction

The treatment of metastatic UC had remained largely unchanged since pivotal trials published over 20 years ago set the standard of care for first-line treatment with cisplatin-based combinations demonstrating an OS benefit. In the past few years this longstanding paradigm has been challenged by several large studies investigating the benefit of immunotherapy using checkpoint inhibitors. Moreover, novel compounds including both targeted therapy and antibody-drug conjugates have been successfully tested and approved in later treatment lines.

7.7.2 First-line systemic therapy for metastatic disease

In general, patients with untreated metastatic UC can be divided into three broad categories: fit for cisplatin-based chemotherapy, fit for carboplatin-based chemotherapy (but unfit for cisplatin) and unfit for any platinum-based chemotherapy.

Definitions: ‘Fit for cisplatin, fit for carboplatin, unfit for any platinum-based chemotherapy’

An international survey among BC experts [521] was the basis for a consensus statement on how to classify patients unfit for cisplatin-based chemotherapy. At least one of the following criteria must be present: PS > 1; GFR ≤ 60 mL/min; grade ≥ 2 audiometric hearing loss; grade ≥ 2 peripheral neuropathy or New York Heart Association (NYHA) class II heart failure [522]. Around 50% of patients with BC are not eligible for cisplatin-based chemotherapy [522]. Renal function assessment is of utmost importance for treatment selection. Measuring GFR with radioisotopes (99mTc DTPA or 51Cr-EDTA) is recommended in equivocal cases.

Cisplatin has also been administered in patients with a lower GFR (40–60 mL/min) using different split-dose schedules. The respective studies were mostly small phase I and II trials in different settings (neoadjuvant and advanced disease) demonstrating that the use of split-dose cisplatin is feasible and appears
to result in encouraging efficacy [523-525]. However, no prospective RCT has compared split-dose cisplatin with conventional dosing.

Most patients that are deemed unfit for cisplatin are able to receive carboplatin-based chemotherapy. However, some patients are deemed unfit for any platinum-based chemotherapy, i.e. both cisplatin and carboplatin. Patient are unfit for any platinum-based chemotherapy in case of PS > 2, GFR < 30 mL/min or the combination of PS 2 and GFR < 60 mL/min since the outcome in this patient population is poor regardless of platinum-based treatment or not [526]. Patients with multiple comorbidities may also be poor candidates for platinum-based chemotherapy. Definitions of platinum-eligibility for first-line treatment of metastatic UC are summarised in Table 7.2.

ECOG = Eastern Cooperative Oncology Group; GFR = glomerular filtration rate; NYHA = New York Heart Association; PS = performance status.

7.7.2.1 First-line chemotherapy in patients fit for cisplatin
Cisplatin-containing combination chemotherapy has been the standard of care since the late 1980s demonstrating an OS of 12 to 14 months in different series (for a review see [527]). Methotrexate, vinblastine, adriamycin plus cisplatin and GC achieved survival of 14.8 and 13.8 months, respectively [528]. Overall response rates were 46% for MVAC and 49% for GC. The lower toxicity of GC [183] compared to standard MVAC has resulted in GC becoming the standard regimen.

Dose-dense MVAC combined with granulocyte colony-stimulating factor (G-CSF) is less toxic and more efficacious than standard MVAC in terms of, complete response (CR), and 2-year OS. However, there is no significant difference in median survival between the two regimens [529, 530]. Further intensification of treatment using paclitaxel, cisplatin and gemcitabine (PCG) triple regimen did not result in a significant improvement in OS in the intention-to-treat (ITT) population of a phase III RCT, comparing PCG to GC [531]. Similarly, the addition of the angiogenesis inhibitor bevacizumab to GC did not result in OS improvement [532].

The disease sites have an impact on long-term survival. In LN-only disease, 20.9% of patients were alive at five years compared to only 6.8% of patients with visceral metastases [528]. In the trials with long-term follow-up approximately 10-15% of patients with metastatic UC are alive at 5 years and longer, suggesting a sustained benefit from cisplatin-based chemotherapy in a minority of patients [528, 530].

Carboplatin-containing chemotherapy is not considered to be equivalent to cisplatin-based combinations, and should not be considered interchangeable or standard in patients fit for cisplatin. A comparative analysis of four randomised phase II trials of carboplatin vs. cisplatin combination chemotherapy demonstrated lower CR rates and shorter OS for the carboplatin arms [533]. Recently, a retrospective study highlighted the importance of applying cisplatin in cisplatin-eligible patients in order to maintain benefit [534].

7.7.2.2 First-line chemotherapy in patients fit for carboplatin (but unfit for cisplatin)
Up to 50% of patients are not fit for cisplatin-containing chemotherapy but most may be candidates for carboplatin [522]. The first randomised phase II/III trial in this setting was conducted by the EORTC and compared two carboplatin-containing regimens (methotrexate/carboplatin/vinblastine [M-CAVI] and gemcitabine/carboplatin [GemCarbo]) in patients unfit for cisplatin. The EORTC definitions for eligibility were GFR < 60 mL/min and/or PS 2. Severe acute toxicity was 13.6% with GemCarbo vs. 23% with M-CAVI, while the ORR was 42% for GemCarbo and 30% for M-CAVI, respectively [526]. Based on these results the combination of carboplatin and gemcitabine should be considered a standard of care in this patient group.
Combinations of gemcitabine and paclitaxel have been studied as first-line treatment and produced response rates between 38% and 60% but has never been tested in RCTs [535-537]. A randomised phase II trial assessed the efficacy and tolerability profile of two vinflunine-based regimens (vinflunine/gemcitabine vs. vinflunine/carboplatin). Both regimens showed equal ORR and OS with less haematologic toxicity for the combination of vinflunine/gemcitabine [538]. Non-platinum combination chemotherapy is nevertheless not recommended for first-line use in platinum-eligible patients.

The use of single-agent chemotherapy has been associated with varying response rates. Responses with single agents are usually short, complete responses are rare, and no long-term DFS/OS has been reported. It is not recommended for first-line treatment of metastatic UC.

7.7.2.3 Integration of immunotherapy in the first-line chemotherapy treatment of patients fit for platinum (cisplatin or carboplatin)

7.7.2.3.1 Immunotherapy combination approaches

In 2020, the results of three phase III trials have been published investigating the use of immunotherapy in the first-line setting for platinum-eligible patients. The first trial to report was IMvigor130 investigating the combination of the PD-L1 inhibitor atezolizumab plus platinum-gemcitabine chemotherapy vs. chemotherapy plus placebo vs. atezolizumab alone [539]. The primary endpoint of PFS benefit for the combination vs. chemotherapy alone in the ITT group was reached (8.2 months vs. 6.3 months [HR: 0.82, 95% CI: 0.70–0.96; one-sided, p = 0.007]) while OS was not significant at the interim analysis after a median follow-up of 11.8 months. The small PFS benefit in the absence of an OS benefit has raised questions of its clinical significance. Due to the sequential testing design, the comparison of chemotherapy vs. atezolizumab alone has not yet been formally performed.

The KEYNOTE 361 study had a very similar design using the PD-1 inhibitor pembrolizumab plus platinum-gemcitabine chemotherapy vs. placebo plus pembrolizumab. The results of the primary endpoints of PFS and OS for the comparison of pembrolizumab plus chemotherapy vs. chemotherapy plus placebo in the ITT population showed no benefit for the combination [540].

DANUBE compared the immunotherapy combination (IO-IO) of CTLA-4 inhibitor tremelimumab and PD-L1 inhibitor durvalumab with chemotherapy alone or durvalumab alone [541]. The co-primary endpoint of improved OS for the IO-IO combination vs. chemotherapy was not reached in the ITT group nor was the OS improved for durvalumab monotherapy vs. chemotherapy in the PD-L1-positive population.

In conclusion, these three trials do not support the use of combination of PD-1/L1 checkpoint inhibitors plus chemotherapy or the IO-IO combination as first-line treatment.

7.7.2.3.2 Use of first-line single-agent immunotherapy in patients unfit for cisplatinum-based chemotherapy

Based on the results of two single-arm phase II trials [542, 543] the checkpoint inhibitors pembrolizumab and atezolizumab have been approved by the U.S. FDA and the European Medicines Agency (EMA) for first-line treatment in cisplatin-unfit patients in case of positive PD-L1 status. PD-L1 positivity for use of pembrolizumab is defined by immunohistochemistry as a CPS of ≥ 10 using the Dako 22C33 platform and for atezolizumab as positivity of ≥ 5% tumour-infiltrating immune cells using Ventana SP142.

Pembrolizumab was tested in 370 patients with advanced or metastatic UC ineligible for cisplatin, showing an ORR of 29% and CR in 7% of patients [542]. Atezolizumab was evaluated in the same patient population in a phase II trial (n = 119) showing an ORR of 23% with 9% of patients achieving CR [543].

The trials IMvigor 130, Keynote 361 and DANUBE all included an experimental arm with immunotherapy alone using atezolizumab, pembrolizumab and durvalumab, respectively [539-541]. No benefit in terms of PFS or OS for the use of single-agent immunotherapy compared to platinum-based chemotherapy was found. The combination of carboplatin/gemcitabine therefore is considered the preferred first-line treatment choice for patients ineligible for cisplatin but eligible for carboplatin.

7.7.2.3.3 Switch maintenance with immunotherapy after platinum-based chemotherapy

A randomised phase II trial evaluated switch maintenance treatment with pembrolizumab in patients achieving at least stable disease on platinum-based first-line chemotherapy. The primary endpoint of PFS was met (5.4 months vs. 3.0 months, HR: 0.65, p = 0.04) but not the secondary endpoint of OS (22 months vs. 18.7 months, HR: 0.91, 95% CI: 0.52–1.59) [544].

The JAVELIN Bladder 100 study investigated the impact of switch maintenance with the PD-L1 inhibitor avelumab after initial treatment with platinum-gemcitabine chemotherapy. Patients achieving at least stable disease or better after 4–6 cycles of platinum-gemcitabine were randomised to avelumab or best supportive care (BSC). Overall survival was the primary endpoint which improved to 21.4 months with avelumab compared to 14.3 months with BSC (HR: 0.69, 95% CI: 0.56–0.86; p < 0.001). Of patients who
discontinued BSC and received subsequent treatment. 53% received immunotherapy. Immune-related AEs occurred in 29% of all patients and 7% experienced grade 3 complications [545]. In conclusion, maintenance IO with avelumab is a standard of care for all patients with disease stabilisation on first-line platinum-based chemotherapy.

7.7.2.4 Treatment of patients unfit for any platinum-based chemotherapy

Very limited data exist regarding the optimal treatment for this patient population which is characterised by severely impaired PS (PS > 2) and/or severely impaired renal function (GFR < 30 mL/min). Historically, the outcome in this patient group has been poor. Best supportive care has often been chosen instead of systemic therapy. Most trials evaluating alternative treatment options to cisplatinum-based chemotherapy did not focus specifically on this patient population thereby making interpretation of data difficult. The FDA (but not EMA) has approved pembrolizumab and atezolizumab as first-line treatment for patients not fit to receive any platinum-based chemotherapy regardless of PD-L1 status based on the results of two single-arm phase II trials [542, 543]. These trials have not reported how many patients were unfit for any platinum-based chemotherapy.

7.7.3 Second-line systemic therapy for metastatic disease

7.7.3.1 Second-line chemotherapy

Second-line chemotherapy data are highly variable and mainly derive from small single-arm phase II trials apart from a single phase III RCT. A reasonable strategy has been to re-challenge former platinum-sensitive patients if progression occurred at least six to twelve months after first-line platinum-based combination chemotherapy. Second-line response rates of single-agent treatment with paclitaxel (weekly), docetaxel, gemcitabine, nab-paclitaxel, oxaliplatin, ifosfamide, topotecan, pemetrexed, lapatinib, gefitinib and bortezomib have ranged between 0% and 28% in small phase II trials [546, 547].

The paclitaxel/gemcitabine combination has shown good response rates in small single-arm studies but no adequate phase III RCT has been conducted [548, 549]. Vinflunine was tested in a phase III RCT and compared against BSC in patients progressing after first-line treatment with platinum-based chemotherapy [550]. The results showed a very modest ORR (8.6%), a clinical benefit with a favourable safety profile and a survival benefit, which was however only statistically significant in the eligible patient population (not in the ITT population).

A randomised phase III trial evaluated the addition of the angiogenesis inhibitor ramucirumab to docetaxel chemotherapy vs. docetaxel alone, which resulted in improved PFS (4.1 vs. 2.8 months) and higher response rates (24.5% vs. 14%) but no OS benefit was achieved [551, 552].

7.7.3.2 Second-line immunotherapy for platinum-pre-treated patients

The immune checkpoint inhibitors pembrolizumab, nivolumab, atezolizumab, avelumab, and durvalumab have demonstrated similar efficacy and safety in patients progressing during, or after, previous platinum-based chemotherapy in phase I, II and III trials.

Pembrolizumab demonstrated a significant OS improvement as second-line treatment in a phase III RCT leading to EMA and FDA approval. Patients (n = 542) were randomised to receive either pembrolizumab monotherapy or chemotherapy (paclitaxel, docetaxel or vinflunine). The median OS with pembrolizumab was 10.3 months (95% CI: 8.0–11.8) vs. 7.4 months (95% CI: 6.1–8.3) with chemotherapy (HR 0.73, 95% CI: 0.59–0.91, p = 0.002) independent of PD-L1 expression levels [553].

Atezolizumab was the first checkpoint inhibitor approved by FDA for metastatic UC based on the results of phase I and II trials [215, 554]. The phase III RCT (IMvigor211) included 931 patients comparing atezolizumab with second-line chemotherapy (paclitaxel, docetaxel or vinflunine) did not meet its primary endpoint of improved OS for patients with high PD-L1 expression with 11.1 months (atezolizumab) vs. 10.6 (chemotherapy) months (stratified HR: 0.87, 95% CI: 0.63–1.21, p = 0.41) [555].

The PD-1 inhibitor nivolumab was approved by the FDA based on the results of a single-arm phase II trial (CheckMate 275), enrolling 270 platinum pre-treated patients. The primary endpoint of ORR was 19.6%, and OS was 8.74 months for the entire group [556].

Based on level 1 evidence from a RCT, pembrolizumab has emerged in clinic as the preferred standard of care immunotherapy in the second-line setting.

7.7.3.3 Side-effect profile of immunotherapy

Checkpoint inhibitors including PD-1 or PD-L1 antibodies and CTLA-4 antibodies have a distinct side-effect profile associated with their mechanism of action leading to enhanced immune system activity. These AEs
can affect any organ in the body leading to mild, moderate or severe side effects. The most common organs affected are the skin, GI tract, liver, lung, thyroid, adrenal and pituitary gland. Other systems that may be affected include musculoskeletal, renal, nervous, haematologic, ocular and cardiovascular system. Any change during immunotherapy treatment should raise suspicion about a possible relation to the treatment. The nature of immune-related AEs has been very well characterised and published [557]. The timely and appropriate treatment of immune-related side effects is crucial to achieve optimal benefit from the treatment while maintaining safety. Clear guidelines for side-effect management have been published [558]. Immunotherapy treatment should be applied and supervised by trained clinicians only to ensure early side effect recognition and treatment. In case of interruption of immunotherapy, re-challenge will require close monitoring for AEs [559].

7.7.4 Integration of novel agents
7.7.4.1 Antibody drug conjugates
The first antibody drug conjugate to report encouraging data was enfortumab vedotin, an antibody-drug conjugate targeting Nectin-4, a cell adhesion molecule which is highly expressed in UC conjugated to monomethyl auristatin E (MMAE). A phase-II single-arm study (EV-201) in 125 patients previously treated with platinum chemotherapy and checkpoint inhibition showed a confirmed objective response rate of 44%, including 12% complete responses [560]. This data led to accelerated FDA and EMA approval for enfortumab vedotin in locally advanced or metastatic UC patients who have previously received a PD-1 or PD-L1 inhibitor, and platinum-containing chemotherapy [561, 562]. Another cohort of the same EV-201 trial demonstrated similar promising results in a cohort of 91 patients that were cisplatin-ineligible and had received prior IO [563]. A phase III RCT (n = 608) comparing enfortumab vedotin with single-agent chemotherapy after prior platinum chemotherapy and checkpoint inhibitor immunotherapy demonstrated significant survival benefit of almost 4 months (12.88 months vs. 8.97 months; HR 0.7, 95% CI: 0.56–0.89) [564]. The most common treatment-related AEs included alopecia (45%), peripheral neuropathy (34%), fatigue (31%, 7.4% ≥ grade 3), decreased appetite (31%), diarrhoea (24%), nausea (23%), and skin rash (16%, 7.4% ≥ grade 3).

Preliminary results of the combination of enfortumab vedotin and pembrolizumab as first-line treatment in cisplatin-ineligible patients with locally advanced/metastatic UC have been reported resulting in ORR of 73.3% with 15.6% complete responses [565]. Treatment-related AEs of interest included any rash (48% all grade, 11% ≥ grade 3) and any peripheral neuropathy (50% all grade, 3% ≥ grade 3). This combination is currently under investigation in a phase III trial in the first-line setting for platinum-eligible patients (EV-302).

Based on these results enfortumab vedotin has been FDA approved for patients who have received prior platinum-containing chemotherapy and prior IO with PD-1 or PD-L1 inhibitor as well as for cisplatin-ineligible patients who have received one or more prior lines of therapy.

Another new and also promising antibody drug conjugate is sacituzumab govitecan, consisting of a humanised monoclonal antibody targeting trophoblast cell surface antigen 2 (Trop-2) conjugated to SN-38, the active metabolite of irinotecan. Sacituzumab govitecan was tested in 113 platinum and IO pre-treated metastatic UC (mUC) patients [560] and achieved an ORR of 27% and a total of 77% had a decrease in measurable disease, median PFS was 5.4 months and median OS 10.9 months [566]. Side effects consisted of haematological toxicities (neutropenia 34% ≥ grade 3; febrile neutropenia 10% ≥ grade 3), fatigue (52%), alopecia (47%), nausea (60%), diarrhoea (65%, 10% ≥ grade 3) and decreased appetite (36%) [566]. Sacituzumab govitecan has received accelerated FDA approval for metastatic UC with prior platinum and IO pre-treatment. Several trials using sacituzumab govitecan as monotherapy or in combinations are ongoing.

7.7.4.2 FGFR inhibition
Genomic profiling of UC has revealed common potentially actionable genomic alterations including alterations in FGFR [567]. Erdaftinib is a pan-FGFR tyrosine kinase inhibitor and the first FDA-approved targeted therapy for mUC with susceptible FGFR2/3 alterations following platinum-containing chemotherapy. The phase II trial of erdaftinib included 99 patients whose tumour harboured an FGFR3 mutation or FGFR2/3 fusion and who had disease progression following chemotherapy [213]. The confirmed ORR was 40% and an additional 39% of patients had stable disease. A total of 22 patients had previously received immunotherapy with only one patient achieving a response, yet the response rate for erdaftinib for this subgroup was 59%. At a median follow-up of 24 months, the median PFS was 5.5 months (95% CI: 4.0–6.0) and the median OS was 11.3 months (95% CI: 9.7–15.2) [213]. Treatment-related AEs of ≥ grade 3 occurred in 46% of patients. Common AEs of ≥ grade 3 were hyponatraemia (11%), stomatitis (10%), and asthenia (7%) and 13 patients discontinued erdaftinib due to AEs, including retinal pigment epithelial detachment, hand-foot syndrome, dry mouth, and skin/nail events. In addition to erdaftinib, several other FGFR inhibitors are being evaluated including infgratinib which
has demonstrated promising activity [214]. The increased identification of FGFR3 mutations/fusion has led to several ongoing trials with different agents and combination in different disease settings.

7.7.5 **Current status of predictive biomarkers**

The most important advance in recent years has been the recognition of alterations in FGFR3 including mutations and gene fusions as a predictive marker for response to FGFR inhibitors [213]. It is recommended to screen mUC patients ideally at diagnosis of metastatic disease for FGFR3 alterations to plan optimal treatment including trials.

Many efforts have focused on markers for predicting response to immune checkpoint inhibition. Programmed death-ligand 1 expression by immunohistochemistry has been evaluated in many studies with mixed and, so far, inconclusive results. This may in part be related to the use of different antibodies and various scoring systems evaluating different compartments i.e., tumour cells, immune cells, or both. A major limitation of PD-L1 staining relates to the significant proportion of PD-L1-negative patients that respond to immune checkpoint blockade. The predictive value of PD-L1 was not confirmed in large phase III trials evaluating the integration of immunotherapy in the first-line setting for mUC [539-541]. At present, the only indication for PD-L1 testing in mUC is dictated by current the FDA and EMA approvals and relates to the potential use of immune checkpoint inhibitors as first-line monotherapy in patients unfit for cisplatin-containing chemotherapy.

Another biomarker that has been evaluated for predicting response to immunotherapy is high TMB [217]. Neoantigen burden and TMB have been associated with response to immune checkpoint inhibitors in several malignancies. High TMB has been associated with response to immune checkpoint inhibitors in metastatic UC in small single arm trials [215, 218] but was not confirmed so far in RCTs. Other markers that have been evaluated in predicting response to immune checkpoint inhibitors include molecular subtypes, CD8 expression by immunohistochemistry and other immune gene cell signatures. Recent work has focused on the importance of stroma including the role of TGFs in predicting response to immune checkpoint blockade [221, 222].

In conclusion, apart from FGFR3 alterations, there are currently no further validated predictive molecular markers that are routinely used in clinical practice.

7.7.6 **Special situations**

7.7.6.1 **Impact of prior neoadjuvant/adjuvant therapy on treatment sequence**

Peri-operative systemic treatment is increasingly used in UC including cisplatin-based chemotherapy in the neoadjuvant setting for BC and adjuvant platinum-based chemotherapy for upper tract UC [568]. Many ongoing phase III trials investigate the use of immunotherapy in this setting as well. So far, one trial has reported a significant DFS benefit for adjuvant treatment with nivolumab compared with placebo whereas one trial reported no significant benefit using atezolizumab vs. placebo in the same setting whilst another trial reported negative findings [518, 519]. It is expected that an increased number of patients with metastatic UC will have received pre-treatment with platinum and/or immunotherapy agents. No prospective trials have investigated the treatment of such patients. The choice of treatment in these patients depends on the applied peri-operative treatment and the time until relapse. If at least 12 months have passed since the end of peri-operative treatment the same systemic treatment as in treatment-naïve patients is recommended. To help prevent early relapse within 12 months the peri-operative systemic therapy has to be taken into account when planning further treatment.

7.7.6.2 **Systemic treatment of metastatic disease with histology other than pure urothelial carcinoma**

Pure urothelial carcinoma (PUC) represents the predominant histology in over 90% of patients with mUC. Variant histologies (e.g. micropapillary, nested, sarcomatoid) and divergent differentiation (e.g. SCC, adenocarcinoma) can be found in addition to PUC in up to 33% of patients. Such patients were often excluded from large phase II and phase III trials and therefore the knowledge about the best management of such patients is limited. The respective literature was reviewed recently [68] and an expert Delphi survey and consensus conference provided guidance [9]. In case of predominant PUC it is recommended to treat patients with mixed histology the same way as patients with PUC histology. Patients with predominant non-urothelial differentiation such as small cell neuroendocrine carcinoma, urachal adenocarcinoma, SCC and adenocarcinoma should be treated individually.

7.7.7 **Treatment of patients with bone metastases**

The prevalence of metastatic bone disease (MBD) in patients with advanced/metastatic UC is 30–40% [569]. Skeletal complications due to MBD have a detrimental effect on pain and QoL and are also associated with increased mortality [570]. Bisphosphonates such as zoledronic acid reduce and delay skeletal-related events (SREs) due to bone metastases by inhibiting bone resorption, as shown in a small pilot study [571].
Denosumab, a fully human monoclonal antibody that binds to and neutralises RANKL (receptor activator of nuclear factor κB ligand), was shown to be non-inferior to zoledronic acid in preventing or delaying SREs in patients with solid tumours and advanced MBD, including patients with UC [572]. Patients with MBD, irrespective of the cancer type, should be considered for bone-targeted treatment [570].

Patients treated with zoledronic acid or denosumab should be informed about possible side effects including osteonecrosis of the jaw and hypocalcaemia. Supplementation with calcium and vitamin D is mandatory. Dosing regimens of zoledronic acid should follow regulatory recommendations and have to be adjusted according to pre-existing medical conditions, especially renal function [573]. For denosumab, no dose adjustments are required for variations in renal function.

7.7.8 Summary: treatment algorithm for metastatic urothelial cancer update 2021

Figure 7.2 summarises the treatment algorithm for metastatic BC based on the evidence discussed in the text above.

Patients with treatment-naïve mUC are grouped according to platinum-eligibility based on clear definitions. In general, first-line treatment consists of platinum-based chemotherapy in which cisplatin is to be preferred to carboplatin. Patients who are cisplatin-ineligible but carboplatin-eligible should receive carboplatin-gemcitabine combination chemotherapy. In case of positive PD-L1 status, treatment with checkpoint inhibitors (atezolizumab or pembrolizumab) could be an alternative option.

Patients unfit for both cisplatin and carboplatin (platinum-unfit) can be considered for immunotherapy (FDA approved irrespective of PD-L1 status, EMA approved only for PD-L1 positive patients) or receive BSC.

In cases of disease stabilization on platinum-based chemotherapy switch, maintenance treatment with IO (avelumab) is recommended. Alternatively, patients can be followed closely and receive second-line immunotherapy at the time of progression (pembrolizumab).

It is recommended to determine FGFR mutation status before deciding about second-line treatment. Patients with FGFR3 mutations are candidates for FGFR inhibitor treatment. Enfortumab vedotin therapy is the new standard in case of progression after platinum chemotherapy and IO but has not yet been approved in Europe. The optimal sequence of novel agents and potential combinations are the subject of many ongoing trials. It is generally recommended to treat patients within ongoing clinical trials.

Figure 7.2: Flow chart for the management of metastatic urothelial cancer

7.8 Quality of life
7.8.1 Introduction
The evaluation of HRQoL considers physical, psychological, emotional and social functioning. Several questionnaires have been validated for assessing HRQoL in patients with BC, including FACT-G [574], EORTC QLQ-C30 [575], EORTC QLQ-BLM30 [575], SF-36 [576] and recently the BCI questionnaire [577]. In spite of these validated questionnaires, there is heterogeneity in the measurements used to assess sexual health. A health questionnaire that covers the entire range of sexual health in bladder cancer patients is currently lacking [578]. In patients with bladder cancer, the overall HRQoL is lower compared to the general population and patients with other common pelvic cancers, independent of therapy received and disease stage [579].

In patients with MIBC, HRQoL appears to decline, particularly in the physical and social functioning domains [580]. Several questionnaires have been validated for assessing HRQoL in patients with BC, including...
FACT (Functional Assessment of Cancer Therapy)-G [574], EORTC QLQ-C30 [575], EORTC QLQ-BLM (MIBC module) [575], and SF (Short Form)-36 [576, 581] and recently the BCI questionnaire specifically designed and validated for BC patients [577].

7.8.2 Neoadjuvant chemotherapy
The impact of NAC on patient-reported outcomes (using EORTC QLQ questionnaires) was investigated by Feuerstein et al. [582]. A propensity-matched analysis of 101 patients who completed NAC and 54 patients who did not undergo NAC, showed no negative effect of NAC on patient-reported outcomes prior to RC. Recently, HRQoL data from two RCTs have been published [497, 583]. Huddart et al., analysed the subset of patients within the BC2001 trial who underwent NAC prior to (chemo)radiation. Using the FACT-BL questionnaire, no detrimental impact of NAC on HRQoL was observed [497]. Kitamura et al., reported on 64 patients included in the JCOG0209 study who underwent NAC (MVAC vs. MVAC and RC). An overall decline on HRQoL was reported directly following NAC using the FACT-BL questionnaire. However, no difference in HRQoL was observed after the consolidating RC.

7.8.3 Radical cystectomy and urinary diversion
Two systematic reviews and meta-analyses focused on HRQoL after RC and urinary diversion [381, 584]. Yang et al., compared HRQoL of incontinent and continent urinary diversions (all types) including 29 studies (n = 3,754) of which 9 had a prospective design (one of which was randomised) [381]. Only three studies reported HRQoL data both pre- and post-operatively. In these three studies, an initial deterioration in overall HRQoL was reported but general health, functional and emotional domains at 12 months post-surgery were equal or better than baseline. After 12 months, the HRQoL benefits diminished in all domains. Overall, no difference in HRQoL between continent and incontinent urinary diversion was reported although an ileal conduit may confer a small physical health benefit [584].

Cerruto et al., reported HRQoL comparing ileal conduit with orthotopic neobladder reconstruction [584]. A pooled analysis was performed including 18 studies (n = 1,553) of which the vast majority were retrospective studies. The analysis showed no statistical significant difference in overall HRQoL, but methodological limitations need to be considered.

Clifford et al., prospectively evaluated continence outcomes in male patients undergoing orthotopic neobladder diversion [585]. Day-time continence increased from 59% at less than three months post-operatively to 92% after 12 to 18 months. Night-time continence increased from 28% at less than three months post-operatively to 51% after 18 to 36 months. Also of interest is the urinary bother in females with an orthotopic neobladder. Bartsch and co-workers reported day-time and night-time continence rates of 70.4% and 64.8%, respectively, in 56 female neobladder patients. Thirty-five patients (62.5%) performed clean intermittent catheterisation, which is much worse when compared to male neobladder patients. Moreover, patients with non-organ-confined disease (p = 0.04) and patients with a college degree (p = 0.001) showed worse outcomes on HRQoL scores [586].

Altogether, there is no superior type of urinary diversion in terms of overall HRQoL but it is rather a result of proper patient selection. An older and isolated patient is probably better served with an ileal conduit, whereas a younger patient with a higher level of interest in body image and sexuality is better off with an orthotopic diversion. The patient’s choice is the key to the selection of reconstruction method [381].

A number of RCTs comparing ORC with RARC (with either intra- or extracorporeal urinary diversion) have reported their HRQoL data [375, 376, 587, 588]. All studies reported no statistical significant difference in HRQoL outcomes between surgical techniques.

7.8.4 Bladder-sparing trimodality therapy
The only HRQoL data in bladder sparing treatment collected in a RCT setting was published by Huddart et al. [497]. The primary endpoint was the change in the Bladder Cancer Subscale (BLCS), as part of the FACT-BL questionnaire, at one year post-treatment. Questionnaire return rate at one and five years was 70% and 60%, respectively. The remaining patients did mostly not respond as a result of recurrence or RC. A reduction in HRQoL was seen in the majority of the domains immediately following RT, however, in most patients the HRQoL scores returned to baseline 6 months after RT and maintained at this level for five years. Approximately 33% of patients reported persistent lower Bladder Cancer Subscale scores after five years. Addition of chemotherapy did not affect the HRQoL outcomes.
7.8.5 Non-curative or metastatic bladder cancer
In non-curative or metastatic BC, HRQoL is reduced because of associated micturition problems, bleeding, pain and therefore disturbance of social and sexual life [589]. Beneficial impact of palliative surgery [590], RT [591], and/or chemotherapy on bladder-related symptoms have been described [592].

A HRQoL analysis was performed in platinum-refractory patients who were randomised to pembrolizumab vs. another line of chemotherapy (KEYNOTE-45 trial) [593]. It was reported that patients treated with pembrolizumab had stable or improved global health status/QoL, whereas those treated with investigators’ choice of chemotherapy experienced declines in global health [593].

8. FOLLOW-UP

8.1 Follow-up in muscle invasive bladder cancer
An appropriate schedule for disease monitoring should be based on natural timing of recurrence; probability and site of recurrence; functional monitoring after urinary diversion and the potential available management options [594].

Nomograms on CSS following RC have been developed and externally validated, but their wider use cannot be recommended until further data become available [595, 596].

Current surveillance protocols are based on patterns of recurrence drawn from retrospective series only. Combining this data is not possible since most retrospective studies use different follow-up regimens and imaging techniques. Additionally, reports of asymptomatic recurrences diagnosed during routine oncological follow-up and results from retrospective studies are contradictory [597-599]. From the Volkmer B, et al., series of 1,270 RC patients, no differences in OS were observed between asymptomatic and symptomatic recurrences [598]. Conversely, in the Giannarini, et al., series of 479 patients; those with recurrences detected during routine follow-up (especially in the lungs) and with secondary urothelial tumours as the site of recurrence, had a slightly higher survival [597]. Boorjian, et al., included 1,599 RC patients in their series, with 77% symptomatic recurrences. On multivariate analysis, patients who were symptomatic at recurrence had a 60% increased risk of death as compared to asymptomatic patients [599].

However, at this time, no data from prospective trials demonstrating the potential benefit of early detection of recurrent disease and its impact on OS are available [600].
8.2 Site of recurrence

8.2.1 Local recurrence
Local recurrence takes place in the soft tissues of the original surgical site or in LNs. Contemporary cystectomy has a 5–15% probability of pelvic recurrence which usually occurs during the first 24 months, most often within 6 to 18 months after surgery. However, late recurrences can occur up to five years after RC. Risk factors described are pathological stage, LNs, positive margins, extent of LND and peri-operative chemotherapy [601].

Patients generally have a poor prognosis after pelvic recurrence. Even with treatment, median survival ranges from four to eight months following diagnosis. Definitive therapy can prolong survival, but mostly provides significant palliation of symptoms. Trimodality management generally involves a combination of chemotherapy, radiation and surgery [600].

8.2.2 Distant recurrence
Distant recurrence is seen in up to 50% of patients treated with RC for MIBC. As with local recurrence, pathological stage and nodal involvement are risk factors [602]. Systemic recurrence is more common in locally advanced disease (pT3/4), ranging from 32 to 62%, and in patients with LN involvement (range 52–70%) [603]. The most likely sites for distant recurrence are LNs, lungs, liver and bone. Nearly 90% of distant recurrences appear within the first three years after RC, mainly in the first two years, although late recurrence has been described after more than 10 years. Median survival of patients with progressive disease treated with platinum-based chemotherapy is 9–26 months [604-606]. However, longer survival (28–33% at 5 years) has been reported in patients with minimal metastatic disease undergoing trimodality management, including metastasectomy [607, 608].

8.2.3 Urothelial recurrences
After RC, the incidence of new urethral tumours was 4.4% (1.3–13.7%). Risk factors for secondary urethral tumours are urethral malignancy in the prostatic urethra/prostate (in men) and bladder neck (in women). Orthotopic neobladder was associated with a significant lower risk of urethral tumours after RC (OR: 0.44) [609].

There is limited data, and agreement, about urethral follow-up, with some authors recommending routine surveillance with urethral wash and urine cytology and others doubting the need for routine urethral surveillance. However, there is a significant survival advantage in men with urethral recurrence diagnosed asymptptomatically vs. symptomatically, so follow-up of the male urethra is indicated in patients at risk of urethral recurrence [600]. Treatment is influenced by local stage and grade of urethral occurrence. In urethral CIS, BCG instillations have success rates of 83% [610]. In invasive disease, urethrectomy should be performed if the urethra is the only site of disease; in case of distant disease, systemic chemotherapy is indicated [3].

Upper urinary tract UCs occur in 4–10% of cases and represent the most common sites of late recurrence (3-year DFS following RC) [611]. Median OS is 10–55 months, and 60–67% of patients die of metastatic disease [600]. A meta-analysis found that 38% of UTUC recurrence was diagnosed by follow-up investigations, whereas in the remaining 62%, diagnosis was based on symptoms. When urine cytology was used during surveillance, the rate of primary detection was 7% vs. 29.6% with UUT imaging. The meta-analysis concluded that patients with non-invasive cancer are twice as likely to have UTUC as patients with invasive disease [612]. Multifocality increases the risk of recurrence by three-fold, while positive ureteral or urethral margins increase the risk by seven-fold. Radical nephroureterectomy can prolong survival [613].

8.3 Time schedule for surveillance
Although, based on low level evidence only, some follow-up schedules have been suggested, guided by the principle that recurrences tend to occur within the first years following initial treatment. A schedule suggested by the EAU Guidelines Panel includes a CT scan (every 6 months) until the third year, followed by annual imaging thereafter. Patients with multifocal disease, NMIBC with CIS or positive ureteral margins are at higher risk of developing UTUC, which can develop late (> 3 years). In those cases, monitoring of the UUT is mandatory during follow-up. Computed tomography is to be used for imaging of the UUT [612].

The exact time to stop follow-up is not well known and recently a risk-adapted schedule has been proposed, based on the interaction between recurrence risk and competing health factors that could lead to individualised recommendations and may increase recurrence detection. Elderly and very low-risk patients (those with NMIBC or pT0 disease at final cystectomy report) showed a higher competing risk of non-BC mortality when compared with their level of BC recurrence risk. On the other hand, patients with locally-advanced disease or LN involvement are at a higher risk of recurrence for more than 20 years [614]. However, this model has not been validated, does not differentiate between pure UC or variant histologies, and does not incorporate several risk factors related to non-BC mortality. Variant histology tumours (including urothelial variants,
non-urothelial variants, and mixed variants) might be associated with a greater recurrence risk than PUC. Interestingly, a different follow-up scheme for patients with variant histology tumours has been proposed [615]. In case of pT0 patients with previous variant histology in TURB or in those in the age range between 60 and 79 years, the follow-up should be longer than in PUC since the risk of recurrence persists over time. Similar to PUC, patients older than 80 years with variant histology tumours might not need oncologic surveillance given the higher risk of non-BC mortality compared to the risk of recurrence whereas patients younger than 60 years should be offered extended surveillance (> 10 years) since the risk of recurrence will exceed that of non-BC mortality [615]. Future prospective studies are needed to answer the question whether a more intense follow-up for variant histologies should be considered.

Furthermore, the prognostic implications of the different sites of recurrence should be considered. Local and systemic recurrences have a poor prognosis and early detection of the disease will not influence survival [616]. Despite this, the rationale for a risk-adapted schedule for BC surveillance appears to be promising and deserves further investigation.

Since data for follow-up strategies are sparse, a number of key questions were included in a recently held consensus project [8, 9]. Outcomes for all statements for which consensus was achieved are listed in Section 8.6.

8.4 Follow-up of functional outcomes and complications
Apart from oncological surveillance, patients with a urinary diversion need functional follow-up. Complications related to urinary diversion are detected in 45% of patients during the first five years of follow-up. This rate increases over time, and exceeds 54% after 15 years of follow-up. In a single-centre series of 259 male patients, long-term follow-up after orthotopic bladder substitution (median 121 months [range 60–267]), showed that excellent long-term functional outcomes can be achieved in high-volume centres with dedicated teams [617]. A smaller multi-centre series including women only (n = 102) showed complication rates between 5–12% after orthotopic neobladder (median follow-up of 24 months [range 1.5–100 months]). Both early (5%) and late (12%) complications related to the urinary diversion [618].

The functional complications are diverse and include: vitamin B12 deficiency, metabolic acidosis, worsening of renal function, urinary infections, urolithiasis, ureteroenteric stricture [619], stoma complications in patients with ileal conduit, neobladder continence problems, and emptying dysfunction [600]. Benign ureteroenteric strictures may occur in up to 20% of patients [619]. Functional complications are especially common in women: approximately two-thirds need to catheterise their neobladder, while almost 45% do not void spontaneously at all [586]. There seems to be a correlation between voiding patterns and nerve preservation; in 66 women bilateral preservation of autonomic nerves decreased the need for catheterisation to between 3.4–18.7% (CI: 95%) [618].

Based on SEER data, cystectomy was found to be associated with a 21% increased risk of fractures compared to no RC due to chronic metabolic acidosis and subsequent long-term bone loss [616]. Since low vitamin B12 levels have been reported in 17% of patients with bowel diversion, in case of cystectomy and bowel diversion, vitamin B12 levels should be measured annually [8, 9, 411].

1. INTRODUCTION

1.1 Aims and scope
The aim of these guidelines is to deliver current evidence-based information on the diagnosis and treatment of patients with primary urethral carcinoma. When the first carcinoma in the urinary tract is detected in the urethra, this is defined as primary urethral carcinoma, in contrast to secondary urethral carcinoma, which presents as recurrent carcinoma in the urethra after prior diagnosis and treatment of carcinoma elsewhere in the urinary tract. Most often, secondary urethral carcinoma is reported after radical cystectomy for bladder cancer [1, 2] (see Chapter 7.3 of the European Association of Urology [EAU] Guidelines on Muscle-invasive and Metastatic Bladder Cancer [MIBC]) [2].

It must be emphasised that clinical guidelines present the best evidence available to the experts but following guideline recommendations will not necessarily result in the best outcome. Guidelines can never replace clinical expertise when making treatment decisions for individual patients, but rather help to focus decisions - also taking personal values and preferences/individual circumstances of patients into account. Guidelines are not mandates and do not purport to be a legal standard of care.

1.2 Panel composition
The EAU Guidelines Panel on MIBC is responsible for this publication. This is an international multidisciplinary group of clinicians, including urologists, oncologists, a pathologist, a radiotherapist and a radiologist. Members of this panel have been selected based on their expertise to represent the professionals treating patients suspected of suffering from urethral carcinoma. In the course of 2021 two patient representatives have formally joined the MIBC Guidelines Panel. All experts involved in the production of this document have submitted potential conflict of interest statements, which can be viewed on the EAU Website Uroweb: https://uroweb.org/guideline/primary-urethral-carcinoma/.

1.3 Available publications
A quick reference document (Pocket guidelines) is available in print and as an app for iOS and Android devices, presenting the main findings of the Primary Urethral Carcinoma Guidelines. These are abridged versions which may require consultation together with the full text version. The most recent scientific summary was published in 2020 [3].

1.4 Publication history & summary of changes
The Primary Urethral Carcinoma Guidelines were first published in 2013. This is the ninth update of this document.

1.4.1 Summary of changes
The literature for the complete document has been assessed and updated, where relevant. In particular for:

2. METHODS

2.1 Data identification
For the 2022 Primary Urethral Carcinoma Guidelines, new and relevant evidence has been identified, collated, and appraised through a structured assessment of the literature. An updated systematic literature search was
For each recommendation within the guidelines there is an accompanying online strength rating form, based on a modified GRADE methodology [4, 5]. These forms address a number of key elements namely:

1. the overall quality of the evidence which exists for the recommendation, references used in this text are graded according to a classification system modified from the Oxford Centre for Evidence-Based Medicine Levels of Evidence [6];
2. the magnitude of the effect (individual or combined effects);
3. the certainty of the results (precision, consistency, heterogeneity and other statistical or study related factors);
4. the balance between desirable and undesirable outcomes;
5. the impact of patient values and preferences on the intervention;
6. the certainty of those patient values and preferences.

These key elements are the basis which panels use to define the strength rating of each recommendation. The strength of each recommendation is represented by the words ‘strong’ or ‘weak’ [7]. The strength of each recommendation is determined by the balance between desirable and undesirable consequences of alternative management strategies, the quality of the evidence (including certainty of estimates), and nature and variability of patient values and preferences. The strength rating forms will be available online.

Additional information can be found in the general Methodology section of this print, and online at the EAU website; http://www.uroweb.org/guideline/.

A list of Associations endorsing the EAU Guidelines can also be viewed online at the above address.

2.2 Review
This document was peer-reviewed prior to publication in 2021.

3. EPIDEMIOLOGY, AETIOLOGY AND PATHOLOGY

3.1 Epidemiology
Primary urethral carcinoma is considered a rare cancer, accounting for < 1% of all genitourinary malignancies [8] (ICD-O3 topography code: C68.0) [9]. In 2013, the prevalence of urethral carcinoma in the 28 European Union countries was 3,986 cases with an estimated annual incidence of 1,504 new cases, with a male/female prevalence of 2.9: 1 [10]. Likewise, in an updated analysis of the Surveillance, Epidemiology and End Results (SEER) database (2004-2016), the incidence of primary urethral carcinoma peaked in the > 75 years age group (7.6/million). The age-standardised rate was 4.3/million in men and 1.5/million in women and was almost negligible in those aged < 55 years (0.2/million) [11]. After matching for tumour and patient characteristics, women present with higher disease stage and exhibited higher cancer-specific mortality [12].

3.2 Aetiology
For male primary urethral carcinoma, various predisposing factors have been reported, including urethral strictures [13, 14], chronic irritation after intermittent catheterisation/urethroplasty [15-17], external beam irradiation therapy (EBRT) [18], radioactive seed implantation [19], chronic urethral inflammation/urethritis following sexually transmitted diseases (i.e., condylomata associated with human papilloma virus 16) [20, 21] and lichen sclerosis [14]. In female urethral carcinoma, urethral diverticula [22-24] and recurrent urinary tract infections [25] have been associated with primary urethral carcinoma. Mid-urethral sling meshes have not been associated with an increased risk of primary urethral carcinoma [26]. Clear-cell adenocarcinoma (AC) may also have a congenital origin [27, 28].
3.3 **Histopathology**

Both the Surveillance of Rare Cancers in Europe (RARECARE) project and SEER database have reported that urothelial carcinoma (UC) of the urethra is the predominant histological type of primary urethral cancer (54–65%), followed by squamous cell carcinoma (SCC) (16–22%) and AC (10–16%) [10, 29].

A SEER analysis of 2,065 men with primary urethral carcinoma (mean age 73 years) found that UC was most common (78%), and SCC (12%) and AC (5%) were significantly less frequent [30]. In women, AC is the more frequent histology (38–46.7%) followed by SCC (25.4–28%), UC (24.9–28%) and other histological entities (6%) [31, 32].

4. **STAGING AND CLASSIFICATION SYSTEMS**

4.1 **Tumour, Node, Metastasis (UICC/TNM) staging system**

In men and women, urethral carcinoma is classified according to the 8th edition of the TNM classification [9] (Table 4.1). It should be noted that there is a separate TNM staging system for prostatic UC [9]. Of note, for cancers occurring in the urethral diverticulum, stage T2 is not applicable as urethral diverticula are lacking periurethral muscle [33].

**Urethra (male and female)**

| Ta | Non-invasive papillary, polypoid, or verrucous carcinoma |
| Tis | Carcinoma in situ |
| T1 | Tumour invades subepithelial connective tissue |
| T2 | Tumour invades any of the following: corpus spongiosum, prostate, periurethral muscle |
| T3 | Tumour invades any of the following: corpus cavernosum, beyond prostatic capsule, anterior vagina, bladder neck (extraprostatic extension) |
| T4 | Tumour invades other adjacent organs (invasion of the bladder) |

**Urothelial (transitional cell) carcinoma of the prostate**

| Tis pu | Carcinoma in situ, involvement of prostatic urethra |
| Tis pd | Carcinoma in situ, involvement of prostatic ducts |
| T1 | Tumour invades subepithelial connective tissue (for tumours involving prostatic urethra only) |
| T2 | Tumour invades any of the following: prostatic stroma, corpus spongiosum, periurethral muscle |
| T3 | Tumour invades any of the following: corpus cavernosum, beyond prostatic capsule, bladder neck (extraprostatic extension) |
| T4 | Tumour invades other adjacent organs (invasion of the bladder or rectum) |

**N - Regional Lymph Nodes**

| NX | Regional lymph nodes cannot be assessed |
| N0 | No regional lymph node metastasis |
| N1 | Metastasis in a single lymph node |
| N2 | Metastasis in multiple lymph nodes |

**M - Distant Metastasis**

| M0 | No distant metastasis |
| M1 | Distant metastasis |

4.2 **Tumour grade**

Non-urothelial urethral carcinoma is graded by a trinomial system that differentiates between well-differentiated (G1), moderately-differentiated (G2), and poorly-differentiated tumours (G3). Table 4.2 lists the different grading systems according to the WHO 1973 and 2004 systems [34]. The 2004 classification corresponds to the 2016 WHO classification [35].

5. **DIAGNOSTIC EVALUATION AND STAGING**

5.1 **History**
When becoming clinically apparent, most patients (45–57%) with primary urethral carcinoma present with symptoms associated with locally advanced disease (T3/T4) [37]. At initial presentation visible haematuria or bloody urethral discharge is reported in up to 62% of the cases. Further symptoms of locally advanced disease include; an extra-urethral mass (52%), bladder outlet obstruction (48%), pelvic pain (33%), urethrocystaneous fistula (10%), abscess formation (5%) or dyspareunia [37].

5.2 **Clinical examination**
In men, physical examination should comprise palpation of the external genitalia for suspicious indurations or masses and digital rectal examination [38]. In women, further pelvic examination and palpation of the urethra should be performed. In addition, bimanual examination, when necessary under general anaesthesia, should be performed for local clinical staging and to assess whether colorectal or gynaecological malignancies are present. Bilateral inguinal palpation should be done to assess the presence of enlarged LNs, describing location, size, and mobility [39].

5.3 **Urinary cytology**
Urinary cytology is part of the standard work-up of a patient with suspected primary urethral carcinoma. Reporting of urinary cytology findings should follow the Paris system [40]. However, the role of urinary cytology in primary urethral carcinoma is limited since its sensitivity ranges between 55% and 59% [41]. Detection rates depend on the underlying histological entity. In male patients, the sensitivity for UC and SCC was reported to be 80% and 50%, respectively, whereas in female patients, sensitivity was found to be 77% for SCC and 50% for UC [41].

5.4 **Diagnostic urethrocystoscopy and biopsy**
Diagnostic urethrocystoscopy and biopsy enables primary assessment of a urethral tumour in terms of tumour extent, location, and underlying histology [38]. Cystoscopic examination is necessary to exclude the presence of concomitant bladder tumours [42]. A cold-cup biopsy enables accurate tissue retrieval for histological analysis and avoids artificial tissue damage. In patients with larger lesions, transurethral resection (optionally in men under penile blood arrest using a tourniquet) can be performed for histological diagnosis [43]. In patients with suspected UC of the prostatic urethra or ducts, resectoscope loop biopsy of the prostatic urethra (between the five and seven o’clock position from the bladder neck and distally around the area of the verumontanum) can contribute to an improved detection rate [44].

To enable accurate pathological assessment of surgical margins, biopsy sites (proximal/distal end) should be marked and sent together with clinical information to the pathologist. To obtain all relevant information, the collection, handling, and evaluation of biopsy specimen should follow the recommendations provided by the International Collaboration on Cancer Reporting (see Table 4.3) [36].

5.5 **Imaging for diagnosis and staging**
Radiological imaging of urethral carcinoma aims to assess local staging and to detect lymphatic and distant metastatic spread. In a recent multicentre study, the accuracy of cross-sectional imaging for clinical tumour and nodal staging predicting final pathological staging was found to be 72.9% and 70.6%, respectively [45]. Imaging work-up should include computed tomography of the chest, abdomen and pelvis for staging, including some form of CT urography with designated phases for optimal urothelial evaluation. Magnetic resonance imaging can be used to evaluate tumour location and size, as well as local tumour extent and presence of regional LN metastases, focusing in particular on inguinal and pelvic LNs [46-50].

For local staging, there is evidence that MRI is an accurate tool for monitoring tumour response to neoadjuvant chemoradiotherapy and evaluating the extent of local disease prior to exenterative surgery [51].

\[18F\]-Fluorodeoxglucose positron emission tomography/magnetic resonance imaging has shown to improve the diagnostic evaluation in patients with metastatic disease [52].

5.6 **Regional lymph nodes**
In urethral carcinoma enlarged LNs often represent metastatic disease (~84% of patients) [54-56], which is in contrast to penile cancer where this is the case in ~41% of patients [53]. In men, lymphatics from the anterior urethra drain into the superficial- and deep inguinal LNs and, subsequently, to the pelvic (external, obturator...
and internal iliac) LNs. Conversely, lymphatic vessels of the posterior urethra drain into the pelvic LNs. In women, the lymph of the proximal third drains into the pelvic LN chains, whereas the distal two-thirds initially drain into the superficial and deep inguinal nodes [57, 58].

6. PROGNOSIS

6.1 Long-term survival after primary urethral carcinoma

According to the RARECARE project, the one- and 5-year relative overall survival (OS) rates in patients with urethral carcinoma in Europe are 71% and 54%, respectively [10]. Based on longer follow-up, an analysis of the SEER database, comparing prognostic factors in rare pathological types of primary urethral carcinoma (n = 257) and common pathological groups (n = 2,651), reported 10-year OS rates of 42.4% and 31.9%, respectively [59]. Cancer-specific survival (CSS) rates at five and ten years were 68% and 60%, respectively [60]. Age (> 60 years), race (others vs. whites), T-stage (T3/T4 vs. Ta-T2) and M-stage (M1 vs. M0) were independent prognostic risk factors for OS and CSS in rare pathological variants [59].

6.2 Predictors of survival in primary urethral carcinoma

In Europe, 5-year OS rate does not substantially differ between the sexes [10, 32]. Prognostic factors of worse survival in patients with primary urethral carcinoma are:

- advanced age (> 65 years) and black race [10, 32, 61, 62];
- higher stage, grade, nodal involvement [55, 62] and metastasis [30];
- increased tumour size and proximal tumour location [30];
- underlying (non-urothelial) histology [10, 30, 61-64];
- presence of concomitant bladder cancer [42];
- extent of surgical treatment and treatment modality [30, 61, 62];
- treatment in academic centres [65];
- location of recurrence (urethral vs. non-urethral) [66].

Some limitations have to be considered when interpreting these results as the number of patients included in most studies were low [63].

7. DISEASE MANAGEMENT

7.1 Treatment of primary urethral carcinoma in males

Previously, treatment of male distal urethral carcinoma followed the procedure for penile cancer, with surgical excision of the primary lesion with a wide safety margin [38]. Distal urethral tumours exhibit significantly improved survival rates compared with proximal tumours [67]. Therefore, in the treatment of distal urethral carcinoma the focus of clinicians has shifted towards improving functional outcomes and quality of life (QoL), while preserving oncological safety. A retrospective series found no evidence of local recurrence, even with < 5 mm resection margins (median follow-up: 17–37 months), in men with pT1-3N0-2 distal urethral carcinoma treated with well-defined penile-preserving surgery and additional iliac/inguinal lymphadenectomy (LND) for clinically suspected LN disease [68]. Similar results for the feasibility of penile-preserving surgery have also been reported in recent series [69, 70]. However, a series on patients treated with penile-preserving surgery for distal urethral carcinoma reported a higher risk of progression in patients with positive proximal margins, which was also more frequently observed in cases with lymphovascular and peri-neural invasion of the primary tumour [71].

<td>Strong</td>
</tr>
</tbody>
</table>

7.2 Treatment of localised primary urethral carcinoma in females

7.2.1 Urethrectomy and urethra-sparing surgery

In women with localised urethral carcinoma, to provide the highest chance of local cure, primary radical urethrectomy should include removal of all the peri-urethral tissue from the bulbocavernosus muscle bilaterally and distally, with a cylinder of all adjacent soft tissue up to the pubic symphysis and bladder neck. Bladder neck closure and appendicovesicostomy for primary distal urethral lesions has been shown to provide satisfactory functional results in women [38].

Previous series have reported outcomes in women with mainly distal urethral tumours undergoing primary treatment with urethra-sparing surgery with or without additional radiotherapy (RT) compared to primary urethrectomy, with the aim of maintaining integrity and function of the lower urinary tract [72, 73]. In longer-term series with a median follow-up of 153–175 months, local recurrence rates in women undergoing partial urethrectomy with intra-operative frozen section analysis were 22–60%, and distal sleeve resection of > 2 cm resulted in secondary urinary incontinence in 42% of patients who subsequently required additional reconstructive surgery [72, 73].

Ablative surgical techniques, i.e., transurethral resection (TUR) or laser, used for small distal urethral tumours, have also resulted in considerable local failure rates of 16%, with a CSS rate of 50%. This emphasises the critical role of local tumour control in women with distal urethral carcinoma to prevent local and systemic progression [72].

7.2.2 Radiotherapy

In women, RT was investigated in several older series with a medium follow up of 91–105 months [74]. With a median cumulative dose of 65 Gy (range 40–106 Gy), the 5-year local control rate was 64% and 7-year CSS was 49% [74]. Most local failures (95%) occurred within the first two years after primary treatment [74]. The extent of urethral tumour involvement was found to be the only parameter independently associated with local tumour control but the type of RT (EBRT vs. interstitial brachytherapy) was not [74]. In one study, the addition of brachytherapy to EBRT reduced the risk of local recurrence by a factor of 4.2 [75]. Of note, pelvic toxicity in those achieving local control was considerable (49%), including urethral stenosis, fistula, necrosis, cystitis and/or haemorrhage, with 30% of the reported complications graded as severe [74].

7.3 Multimodal treatment in locally advanced urethral carcinoma in both males and females

7.3.1 Introduction
Multimodal therapy in primary urethral carcinoma consists of definitive surgery plus chemotherapy with additional RT [76]. Multimodal therapy was often underutilised as shown by Cahn and colleagues (only 16%) in locally advanced disease notwithstanding promising results [76-79]. In a recent study monotherapy was associated with decreased local recurrence-free survival after adjusting for stage, histology, sex, and year of treatment (p = 0.017). Its use has decreased over time [80]. Treatment in academic centres was reported to result in higher utilisation of neoadjuvant- and multimodal treatment and improved OS in patients with locally advanced urothelial- and squamous cell primary urethral carcinoma [65].

7.3.2 Preoperative cisplatin-based chemotherapy
Retrospective studies reported that modern cisplatin-based combination chemotherapy regimens can be effective in advanced primary urethral carcinoma providing prolonged survival even in LN-positive disease. Moreover, they emphasised the critical role of surgery after chemotherapy to achieve long-term survival in patients with locally advanced urethral carcinoma.

In a series of 124 patients, 39 (31%) were treated with peri-operative platinum-based chemotherapy for advanced primary urethral carcinoma (twelve patients received neoadjuvant chemotherapy, six received neoadjuvant chemoradiotherapy and 21 adjuvant chemotherapy). Patients who received neoadjuvant chemotherapy or chemoradiotherapy for locally advanced primary urethral carcinoma (≥ cT3 and/or cN+) appeared to demonstrate improved survival compared to those who underwent upfront surgery with or without adjuvant chemotherapy [81]. Another retrospective series including 44 patients with advanced primary urethral carcinoma, reported outcomes on 21 patients who had preoperatively received cisplatin-based combination chemotherapy according to the underlying histologic subtype. The overall response rate for the various regimens was 72% and the median OS 32 months [54].

7.3.3 Chemoradiotherapy in locally advanced squamous cell carcinoma of the urethra
The clinical feasibility of local RT with concurrent chemotherapy as an alternative to surgery in locally advanced SCC has been reported in several series. This approach offers a potential for genital preservation [82-86]. The largest, and recently updated, retrospective series reported outcomes in 25 patients with primary locally advanced SCC of the urethra treated with two cycles of 5-fluorouracil and mitomycin C with concurrent EBRT. A complete clinical response was observed in ~80% of patients. The 5-year OS and disease-specific survival was 52% and 68%, respectively. In this updated series, salvage surgery, initiated only in non-responders or in case of local failure, was not reported to be associated with improved survival [82].

A large retrospective cohort study in patients with locally advanced urethral carcinoma treated with adjuvant RT and surgery vs. surgery alone demonstrated that the addition of RT improved OS [87].

7.3.4 Salvage treatment in recurrent primary urethral carcinoma after surgery for primary treatment
A multicentre study reported that patients who were treated with surgery as primary therapy and underwent surgery or RT-based salvage treatment for recurrent solitary or concomitant urethral disease, demonstrated similar survival rates compared to patients who never developed recurrence after primary treatment [66].
7.3.5 Treatment of regional lymph nodes

Nodal control in urethral carcinoma can be achieved either by regional LN dissection [38], RT [74] or chemotherapy [54]. Currently, there is still no clear evidence supporting prophylactic bilateral inguinal and/or pelvic LND in all patients with urethral carcinoma [56]. However, in patients with clinically enlarged inguinal/pelvic LNs or invasive tumours, regional LND should be considered as initial treatment since cure might still be achievable with limited disease [38]. It was recently shown that in patients with invasive urethral SCC and cN1-2 disease, inguinal LND conferred an OS benefit [56].

7.4 Treatment of urothelial carcinoma of the prostate

Local conservative treatment with extensive TUR and subsequent BCG instillation is effective in patients with Ta or Tis prostatic urethral carcinoma [88]. Likewise, patients undergoing TUR of the prostate prior to BCG experience improved complete response rates compared with those who do not [89]. Risk of understaging local extension of prostatic urethral cancer at TUR is high in patients with ductal or stromal involvement [90]. In smaller series, response rates to BCG in patients with prostatic duct involvement have been reported to vary between 57% and 75% [88, 91]. Some earlier series have reported superior oncological results for the initial use of radical cystoprostatectomy as a primary treatment option in patients with ductal involvement [92, 93]. In 24 patients with prostatic stromal invasion treated with radical cystoprostatectomy, a LN mapping study found that twelve patients had positive LNs, with an increased proportion located above the iliac bifurcation [94].

7.5 Metastatic disease

There is no data addressing management of metastatic disease in primary urethral carcinoma patients. Systemic therapy in metastatic disease should be selected based on the histology of the tumour. The EAU Guidelines on Muscle-invasive and Metastatic Bladder Cancer can be followed if UC is the predominant histology [2]. Even though urethral carcinoma patients have been included in large clinical trials on immunotherapy, so far, in terms of response rates, no subgroup analyses are available [95].

In addition, there is an urgent clinical need to better address the role of local palliative treatment strategies in primary urethral carcinoma including surgery, which has shown to impact positively on QoL aspects in selected patients with advanced genital cancers [96].

Figure 7.1: Management of primary urethral carcinoma

* Ensure complete circumferential assessment if penile-preserving/urethra-sparing surgery or partial urethrectomy is intended.
** Squamous cell carcinoma.
Regional lymphadenectomy should be considered in clinically enlarged lymph nodes.

Consider neoadjuvant chemotherapy.

In extensive or BCG-unresponsive disease: consider (primary) cystoprostatectomy +/- urethrectomy + lymphadenectomy.

BCG = bacillus Calmette-Guérin; CT = computed tomography; MRI = magnetic resonance imaging; PUC = primary urethral carcinoma; TUR = transurethral resection.

8. FOLLOW-UP

Given the low incidence of primary urethral carcinoma, follow-up has not been systematically investigated. Therefore, it seems reasonable to tailor surveillance regimens to patients’ individual risk factors (see Section 6.2). In patients undergoing urethra-sparing surgery, it seems prudent to advocate a more extensive follow-up with urinary cytology, urethrocystoscopy and cross-sectional imaging despite the lack of specific data.

8.1 Research priorities

There are clear gaps in the clinical literature related to the diagnosis, management and follow-up of patients with primary urethral carcinoma. As this is a rare disease, data will likely become available through quality registries and datasets, similar to those currently being set up by the eUrogen initiative.

The Panel identified the following topics as of interest:

• The (long-term) efficacy of urethral-sparing surgery and chemoradiotherapy for genital preservation in localised and locally advanced tumours;
• The prognostic impact of neoadjuvant and adjuvant treatment modalities in locally advanced disease;
• The therapeutic benefit and clinical safety of programmed cell death (ligand)-1 inhibitors for the treatment of advanced primary urethral carcinoma.

9. REFERENCES

10. CONFLICT OF INTEREST

All members of the Muscle-invasive and Metastatic Bladder Cancer Guidelines Panel have provided disclosure statements of all relationships that they have that might be perceived as a potential source of a conflict of interest. This information is open access available on the European Association of Urology website: http://www.uroweb.org/guidelines/primary-urethral-carcinoma/. This guidelines document was developed with the financial support of the European Association of Urology. No external sources of funding and support have been involved. The EAU is a non-profit organisation and funding is limited to administrative assistance and travel and meeting expenses. No honoraria or other reimbursements have been provided.

11. CITATION INFORMATION

The format in which to cite the EAU Guidelines will vary depending on the style guide of the journal in which the citation appears. Accordingly, the number of authors or whether, for instance, to include the publisher, location, or an ISBN number may vary.

The compilation of the complete Guidelines should be referenced as:

If a publisher and/or location is required, include:

References to individual guidelines should be structured in the following way:
Contributors’ names. Title of resource. Publication type. ISBN. Publisher and publisher location, year.

6.3.8 Guidelines for second-line therapy after treatment with curative intent

6.4 Treatment: Metastatic prostate cancer
6.4.1 Introduction
6.4.2 Prognostic factors
6.4.3 First-line hormonal treatment
   6.4.3.1 Non-steroidal anti-androgen monotherapy
   6.4.3.2 Intermittent versus continuous androgen deprivation therapy
   6.4.3.3 Early versus deferred androgen deprivation therapy
6.4.4 Combination therapies
   6.4.4.1 ‘Complete’ androgen blockade with older generation NSAA
   6.4.4.2 Androgen deprivation combined with other agents
       6.4.4.2.1 Androgen deprivation therapy combined with chemotherapy
       6.4.4.2.2 Combination with the new hormonal treatments (abiraterone, apalutamide, enzalutamide)
6.4.5 Treatment selection and patient selection
6.4.6 Treatment of the primary tumour in newly diagnosed metastatic disease
6.4.7 Metastasis-directed therapy in M1-patients
6.4.8 Guidelines for the first-line treatment of metastatic disease

6.5 Treatment: Castration-resistant PCa (CRPC)
6.5.1 Definition of CRPC
6.5.2 Management of mCRPC - general aspects
   6.5.2.1 Molecular diagnostics
6.5.3 Treatment decisions and sequence of available options
6.5.4 Non-metastatic CRPC
6.5.5 Metastatic CRPC
   6.5.5.1 Conventional androgen deprivation in CRPC
6.5.6 First-line treatment of metastatic CRPC
   6.5.6.1 Abiraterone
   6.5.6.2 Enzalutamide
   6.5.6.3 Docetaxel
   6.5.6.4 Sipuleucel-T
   6.5.6.5 Ipatasertib
6.5.7 Second-line treatment for mCRPC and sequence
   6.5.7.1 Cabazitaxel
   6.5.7.2 Abiraterone acetate after prior docetaxel
   6.5.7.3 Enzalutamide after docetaxel
   6.5.7.4 Radium-223
6.5.8 Treatment after docetaxel and one line of hormonal treatment for mCRPC
   6.5.8.1 PARP inhibitors for mCRPC
   6.5.8.2 Sequencing treatment
       6.5.8.2.1 ARTA -> ARTA (chemotherapy-naive patients)
       6.5.8.2.2 ARTA -> PARP inhibitor/olaparib
       6.5.8.2.3 Docetaxel for mHSPC -> docetaxel rechallenge
       6.5.8.2.4 ARTA -> docetaxel or docetaxel -> ARTA followed by PARP inhibitor
       6.5.8.2.5 ARTA before or after docetaxel
       6.5.8.2.6 ARTA -> docetaxel -> cabazitaxel or docetaxel -> ARTA -> cabazitaxel
6.5.9 Second-line treatment for mCRPC and sequencing of therapy
   6.5.9.1 Background
   6.5.9.2 PSMA-based therapy
6.5.10 Immunotherapy for mCRPC
6.5.11 Platinum chemotherapy
6.5.12 Monitoring of treatment
6.5.13 When to change treatment
6.5.14 Symptomatic management in metastatic CRPC
   6.5.14.1 Common complications due to bone metastases
   6.5.14.2 Preventing skeletal-related events
       6.5.14.2.1 Bisphosphonates
6.5.14.2.2 RANK ligand inhibitors 123
6.5.15 Summary of evidence and guidelines for life-prolonging treatments of castrate-resistant disease 123
6.5.16 Guidelines for systematic treatments of castrate-resistant disease 124
6.5.17 Guidelines for supportive care of castrate-resistant disease 124
6.5.18 Guideline for non-metastatic castrate-resistant disease 124
6.6 Summary of guidelines for the treatment of prostate cancer 125
6.6.1 General guidelines recommendations for treatment of prostate cancer 125
6.6.2 Guidelines recommendations for the various disease stages 126
6.6.3 Guidelines for metastatic disease, second-line and palliative treatments 129

7. FOLLOW-UP 131
7.1 Follow-up: After local treatment 131
7.1.1 Definition 131
7.1.2 Why follow-up? 131
7.1.3 How to follow-up? 131
7.1.3.1 Prostate-specific antigen monitoring 131
7.1.3.1.1 Active surveillance follow-up 131
7.1.3.1.2 Prostate-specific antigen monitoring after radical prostatectomy 131
7.1.3.1.3 Prostate-specific antigen monitoring after radiotherapy 132
7.1.3.1.4 Digital rectal examination 132
7.1.3.1.5 Transrectal ultrasound, bone scintigraphy, CT, MRI and PET/CT 132
7.1.4 How long to follow-up? 132
7.1.5 Summary of evidence and guidelines for follow-up after treatment with curative intent 132
7.2 Follow-up: During first line hormonal treatment (androgen sensitive period) 133
7.2.1 Introduction 133
7.2.2 Purpose of follow-up 133
7.2.3 General follow-up of men on ADT 133
7.2.3.1 Testosterone monitoring 133
7.2.3.2 Liver function monitoring 133
7.2.3.3 Serum creatinine and haematological parameters 133
7.2.3.4 Monitoring of metabolic complications 134
7.2.3.5 Monitoring bone problems 134
7.2.3.6 Monitoring lifestyle, cognition and fatigue 134
7.2.4 Methods of follow-up in men on ADT without metastases 134
7.2.4.1 Prostate-specific antigen monitoring 134
7.2.4.2 Imaging 134
7.2.5 Methods of follow-up in men under ADT for metastatic hormone-sensitive PCa 134
7.2.5.1 PSA monitoring 135
7.2.5.2 Imaging as a marker of response in metastatic PCa 135
7.2.6 Guidelines for follow-up during hormonal treatment 135

8. QUALITY OF LIFE OUTCOMES IN PROSTATE CANCER 136
8.1 Introduction 136
8.2 Adverse effects of PCa therapies 136
8.2.1 Surgery 136
8.2.2 Radiotherapy 136
8.2.2.1 Side-effects of external beam radiotherapy 136
8.2.2.2 Side effects from brachytherapy 137
8.2.3 Local primary whole-gland treatments other than surgery or radiotherapy 137
8.2.3.1 Cryosurgery 137
8.2.3.2 High-intensity focused ultrasound 137
8.2.4 Hormonal therapy 137
8.2.4.1 Sexual function 137
8.2.4.2 Hot flushes 137
8.2.4.3 Non-metastatic bone fractures 138
8.2.4.4 Metabolic effects 138
8.2.4.5 Cardiovascular morbidity 138
8.2.4.6 Fatigue 139
8.2.4.7 Neurological side effects 139

8.3 Overall quality of life in men with PCa 139
8.3.1 Long-term (> 12 months) quality of life outcomes in men with localised disease 140
  8.3.1.1 Men undergoing local treatments 140
  8.3.1.2 Guidelines for quality of life in men undergoing local treatments 141
8.3.2 Improving quality of life in men who have been diagnosed with PCa 141
  8.3.2.1 Men undergoing local treatments 141
  8.3.2.2 Men undergoing systemic treatments 141
  8.3.2.3 Decision regret 142
  8.3.2.4 Decision aids in prostate cancer 143
  8.3.2.5 Guidelines for quality of life in men undergoing systemic treatments 143
1. INTRODUCTION

1.1 Aims and scope
The Prostate Cancer (PCa) Guidelines Panel have prepared this guidelines document to assist medical professionals in the evidence-based management of PCa.

It must be emphasised that clinical guidelines present the best evidence available to the experts but following guideline recommendations will not necessarily result in the best outcome. Guidelines can never replace clinical expertise when making treatment decisions for individual patients, but rather help to focus decisions - also taking personal values and preferences/individual circumstances of patients into account. Guidelines are not mandates and do not purport to be a legal standard of care.

1.2 Panel composition
The PCa Guidelines Panel consists of an international multidisciplinary group of urologists, radiation oncologists, medical oncologists, radiologists, a pathologist, a geriatrician and a patient representative.

All imaging sections in the text have been developed jointly with the European Society of Urogenital Radiology (ESUR) and the European Association of Nuclear Medicine (EANM). Representatives of the ESUR and the EANM in the PCa Guidelines Panel are (in alphabetical order): Dr. A. Farolfi, Dr. D. Oprea-Lager, Prof.Dr. O. Rouvière and Dr. I.G. Schoots.

All radiotherapy (RT) sections have been developed jointly with the European Society for Radiotherapy & Oncology (ESTRO). Representatives of ESTRO in the PCa Guidelines Panel are (in alphabetical order): Prof.Dr. A.M. Henry, Prof.Dr. M.D. Mason and Prof.Dr. T. Wiegel.

The International Society of Urological Pathology is represented by Prof.Dr. T. van der Kwast.

Dr. S. O’Hanlon, consultant geriatrician, representing the International Society of Geriatric Oncology (SOIG) contributed to the sections addressing life expectancy, health status and quality of life in particular.

Dr. E. Briers, expert Patient Advocate Hasselt-Belgium representing the patient voice as delegated by the European Prostate Cancer Coalition/Europa UOMO.

All experts involved in the production of this document have submitted potential conflict of interest statements which can be viewed on the EAU website Uroweb: https://uroweb.org/guideline/prostate-cancer/.

1.3 Available publications
A quick reference document (Pocket guidelines) is available, both in print and as an app for iOS and Android devices. These are abridged versions which may require consultation together with the full text version. Several scientific publications are available [1, 2] as are a number of translations of all versions of the PCa Guidelines. All documents can be accessed on the EAU website: http://uroweb.org/guideline/prostate-cancer/.

1.4 Publication history and summary of changes
1.4.1 Publication history
The EAU PCa Guidelines were first published in 2001. This 2022 document presents a limited update of the 2021 EAU-EANM-ESTRO-ESUR-ISUP-SIOG PCa Guidelines publication.

1.4.2 Summary of changes
The literature for the complete document has been assessed and updated based upon a review of all recommendations and creation of appropriate GRADE forms. Evidence summaries and recommendations have been amended throughout the current document and several new sections have been added.

All chapters of the 2022 PCa Guidelines have been updated. New data have been included in the following sections, resulting in new sections, and new and revised recommendations:

- 4.3 Clinically significant prostate cancer
- 4.5.1.2.4 Risk assessment to determine the need for biopsy
- 4.5.2.1.2 Repeat PSA testing - Table 5.5: Risk data table of clinically significant prostate cancer (csPCa), related to PI-RADS score and PSA-D categories in biopsy-naive men, clinically suspected of having significant disease
- Section 5.2.7.1.4 Towards ‘extended’ MRI-directed biopsy?
5.2.3.4 Guidelines for risk-assessment of asymptomatic men

<table>

<td>Weak</td>
</tr>
</tbody>
</table>

5.2.8 Summary of evidence and guidelines for prostate biopsies

**Summary of evidence**

| Literature review including multiple biopsy schemes suggests that a 10 to 12-core scheme is optimal in the majority of initial and repeat biopsy patients, dependent on prostate size. These biopsy schemes should be heavily weighted towards the lateral aspect and the apex of the prostate to maximize peripheral zone sampling [3]. | LE | 3 |
| A systematic review and meta-analysis comparing MRI-targeted transrectal biopsy to MRI-targeted transperineal biopsy, analysing 8 studies, showed a higher sensitivity for detection of csPCa when the transperineal approach was used (86% vs. 73%). | LE | 2 |
| Current literature, including systematic reviews and meta-analyses, does not show a clear superiority of one image-guided technique (cognitive guidance, US/MR fusion software or direct in-bore guidance) over the other. | LE | 2 |

**Recommendations**

| At least 8 systematic biopsies are recommended in prostates with a size of about 30 cc and 10 to 12 core biopsies are recommended in larger prostates, with > 12 cores not being significantly more conclusive. | Strength rating | Strong |
| Transperineal biopsies are preferred over transrectal biopsies. | Strength rating | Strong |
| Where MRI has shown a suspicious lesion MR-targeted biopsy can be obtained through cognitive guidance, US/MR fusion software or direct in-bore guidance. | Strength rating | Weak |

5.2.8.2.1 Recommended terminology for reporting prostate biopsies

| Adenocarcinoma, provide type and subtype, and presence or absence of cribriform pattern. | Strength rating | Strong |

5.3.5 Summary of evidence and guidelines for staging of prostate cancer

| PSMA PET/CT is more accurate for staging than CT and bone scan for high-risk disease but to date no outcome data exist to inform subsequent management. | LE | 1b |

**Recommendation**

| High-risk localised disease/locally advanced disease | Strength rating |
| When using PSMA PET or whole body MRI to increase sensitivity, be aware of the lack of outcome data of subsequent treatment changes. | Strong |

- 6.1.4.1.3.4. Radiopharmaceutical therapy

6.1.6 General guidelines for the treatment of prostate cancer

| Surgical treatment | Strength rating |
| Do not perform nerve-sparing surgery when there is a risk of ipsilateral extracapsular extension (based on cT stage, ISUP grade, magnetic resonance imaging, or with this information combined into a nomogram). | Weak |
Radiotherapeutic treatment

Offer low-dose rate (LDR) brachytherapy monotherapy to patients with good urinary function and low- or intermediate-risk disease with ISUP grade 2 and ≤ 33% of biopsy cores involved. **Strong**

Offer LDR or high-dose rate (HDR) brachytherapy boost combined with IMRT/VMAT plus IGRT to patients with good urinary function intermediate-risk disease with ISUP G3 and/or PSA 10-20 ng/mL. **Weak**

Offer LDR or HDR brachytherapy boost combined with IMRT /VMAT plus IGRT to patients with good urinary function and high-risk and/or locally advanced disease. **Weak**

- **6.2.1.2.1 ADT monotherapy**

6.2.1.3 Summary of evidence and guidelines for the treatment of low-risk disease

</tbody>
</table>

**Strength rating**

Strong

2. METHODS

2.1 Data identification

For the 2022 PCa Guidelines, new and relevant evidence has been identified, collated and appraised through a structured assessment of the literature. A broad and comprehensive literature search, covering all sections of the PCa Guideline was performed. The search was limited to English language publications. Databases searched included Medline, EMBASE and the Cochrane Libraries, covering a time frame between May 1st 2020 and April 14th 2021. A total of 2,536 unique records were identified, retrieved and screened for relevance resulting in 193 new publications having been included in the 2022 print. A detailed search strategy is available online: https://uroweb.org/guideline/prostate-cancer/?type=appendices-publications.

Changes in recommendations were only considered on the basis of high-level evidence (i.e. systematic reviews with meta-analysis, randomised controlled trials [RCTs], and prospective comparative studies) published in the English language. A total of 193 new references were added to the 2022 PCa Guidelines. Additional information can be found in the general Methodology section of this print and online at the EAU website: https://uroweb.org/guidelines/policies-and-methodological-documents/.
For each recommendation within the guidelines there is an accompanying online strength rating form, the basis of which is a modified GRADE methodology [4, 5]. These forms address a number of key elements namely:
1. the overall quality of the evidence which exists for the recommendation, references used in this text are graded according to a classification system modified from the Oxford Centre for Evidence-Based Medicine Levels of Evidence [8];
2. the magnitude of the effect (individual or combined effects);
3. the certainty of the results (precision, consistency, heterogeneity and other statistical or study related factors);
4. the balance between desirable and undesirable outcomes;
5. the impact of patient values and preferences on the intervention;
6. the certainty of those patient values and preferences.

These key elements are the basis which panels use to define the strength rating of each recommendation. The strength of each recommendation is represented by the words ‘strong’ or ‘weak’ [7]. The strength of each recommendation is determined by the balance between desirable and undesirable consequences of alternative management strategies, the quality of the evidence (including certainty of estimates), and nature and variability of patient values and preferences. The strength rating forms will be available online.

A list of Associations endorsing the EAU Guidelines can also be viewed online at the above address. In addition, the International Society of Geriatric Oncology (SIOG), the European Society for Radiotherapy & Oncology (ESTRO), the European Society for Urogenital Radiology (ESUR), the European Association of Nuclear Medicine (EANM) and the International Society of Urological Pathology (ISUP) have endorsed the PCa Guidelines.

2.2 Review
All RT sections from the 2021 print were peer-reviewed prior to publication, as were Sections 5.4 (Evaluating life expectancy and health status) and Chapter 8 (Quality of life). Publications ensuing from systematic reviews have all been peer-reviewed.

2.3 Future goals
Results of ongoing and new systematic reviews will be included in the 2022 update of the PCa Guidelines:
• A systematic review on progression criteria and quality of life (QoL) of patients diagnosed with PCa;
• A systematic review assessing the performance of risk stratification tools incorporating imaging, biomarkers, biopsy involvement and/or MRI-targeted biopsies, compared to the classical risk classifications (d’Amico, EAU, CAPRA and NCCN) recommended in current guidelines for predicting biochemical recurrence, metastasis or death after local treatment for prostate cancer. Are the new stratification tools preferred above the classical risk classifications?
• A systematic review assessing the outcomes of brachytherapy boost combined with external beam RT for PCa.
• Care pathways for the various stages of PCa management are being developed. These pathways will, in due time, inform treatment flowcharts and an interactive app.
• Assessment of individual patient life expectancy – development of a calculator.

3. EPIDEMIOLOGY AND AETIOLOGY

3.1 Epidemiology
Prostate cancer is the second most commonly diagnosed cancer in men, with an estimated 1.4 million diagnoses worldwide in 2020 [8, 9]. The frequency of autopsy-detected PCa is roughly the same worldwide [10]. A systematic review of autopsy studies reported a prevalence of PCa at age < 30 years of 5% (95% confidence interval [CI]: 3–8%), increasing by an odds ratio (OR) of 1.7 (1.6–1.8) per decade, to a prevalence of 59% (48–71%) by age > 79 years [11].

The incidence of PCa diagnosis varies widely between different geographical areas, being highest in Australia/New Zealand and Northern America (age-standardised rates [ASR] per 100,000 of 111.6 and 97.2, respectively), and in Western and Northern Europe (ASRs of 94.9 and 85, respectively), largely due to the use of prostate-specific antigen (PSA) testing and the aging population. The incidence is low in Eastern and South-Central Asia (ASRs of 10.5 and 4.5, respectively), but rising [12]. Rates in Eastern and Southern Europe were low but have also shown a steady increase [9, 10]. Incidence and disease stage distribution patterns
follow biological-, genetic-, and/or lifestyle factors, but are also influenced by (inter)national organisations’ recommendations on screening and diagnosis (see Section 5.1) [13].

There is relatively less variation in mortality rates worldwide, although rates are generally high in populations of African descent (Caribbean: ASR of 29 and Sub-Saharan Africa: ASRs ranging between 19 and 14), intermediate in the USA and very low in Asia (South-Central Asia: ASR of 2.9) [9].

3.2 Aetiology
3.2.1 Family history/hereditary prostate cancer
Family history and ethnic background are associated with an increased PCa incidence suggesting a genetic predisposition [14, 15]. Only a small subpopulation of men with PCa have true hereditary disease. Hereditary PCa (HPCa) is associated with a six to seven year earlier disease onset but the disease aggressiveness and clinical course does not seem to differ in other ways [14, 16].

In a large USA population database, HPCa (in 2.18% of participants) showed a relative risk (RR) of 2.30 for diagnosis of any PCa, 3.93 for early-onset PCa, 2.21 for lethal PCa, and 2.32 for clinically significant PCa (csPCa) [17]. These increased risks of HPCa were higher than for familial PCa (≥ 2 first- or second-degree relatives with PCa on the same side of the pedigree), or familial syndromes such as hereditary breast and ovarian cancer and Lynch syndrome. The probability of high-risk PCa at age 65 was 11.4% (vs. a population risk of 1.4%) in a Swedish population-based study [18].

3.2.1.1 Germline mutations and prostate cancer
Genome-wide association studies have identified more than 100 common susceptibility loci contributing to the risk for PCa [19-21]. Clinical cohort studies have reported rates of 15% to 17% of germline mutations independent of stage [22, 23]. Giri et al., studied clinical genetic data from men with PCa unselected for metastatic disease undergoing multigene testing across the US [22]. The authors found that 15.6% of men with PCa have pathogenic variants identified in genes tested (BRCA1, BRCA2, HAX13, MLH1, MSH2, PMS2, MSH6, EPCAM, ATM, CHEK2, NBN, and TP53), and 10.9% of men have germline pathogenic variants in DNA repair genes (see Table 5.2). Pathogenic variants were most commonly identified in BRCA2 (4.5%), CHEK2 (2.2%), ATM (1.8%), and BRCA1 (1.1%) [22].

Castro et al., found a carrier rate of 16.2% in unselected patients at diagnosis of metastatic castrate-resistant PCa (mCRPC) who were screened for DNA damage repair (DDR) mutations in 107 genes [24].

Nicolosi et al., reported frequency and distribution of positive germline variants in 3,607 unselected PCa patients and found that 620 (17.2%) had a pathogenic germline variant [23]. Among unselected men with metastatic PCa, an incidence of 11.8% was found for germline mutations in genes mediating DNA-repair processes [25].

Targeted genomic analysis of genes associated with an increased risk of PCa could offer options to identify families at high risk [26, 27].

Nyberg et al., presented results of a prospective cohort study of male BRCA1 and BRCA2 carriers and their PCa risk confirming BRCA2 association with aggressive PCa [28]. Castro et al., analysed the outcomes of 2,019 patients with PCa (18 BRCA1 carriers, 61 BRCA2 carriers, and 1,940 non-carriers). Prostate cancers with germline BRCA1/2 mutations were more frequently associated with ISUP ≥ 4, T3/T4 stage, nodal involvement, and metastases at diagnosis than PCa in non-carriers [29]. BRCA-susceptibility gene mutation carriers were reported to have worse outcome when compared to non-carriers after local therapy [30].

In a retrospective study of 313 patients who died of PCa and 486 patients with low-risk localised PCa, the combined BRCA1/2 and ATM mutation carrier rate was significantly higher in lethal PCa patients (6.07%) than in localised PCa patients (1.44%) [31].

The Identification of Men With a Genetic Predisposition to Prostate Cancer (IMPACT) study, which evaluated targeted PCa screening (annually, biopsy recommended if PSA > 3.0 ng/mL) using PSA in men aged 40-69 years with germline BRCA1/2 mutations found that after 3 years of screening, BRCA2 mutation carriers were associated with a higher incidence of PCa, a younger age of diagnosis, and more clinically significant tumours compared with non-carriers [32]. The influence of BRCA1 mutations on PCa remained unclear. No differences in age or tumour characteristics were detected between BRCA1 carriers and BRCA1 non-carriers. Limitations of the IMPACT study include the lack of magnetic resonance imaging (MRI) data and targeted biopsies as it was initiated before that era.

Similarly, Mano et al., reported on an Israeli cohort in which men with BRCA1 and BRCA2 mutations had a significantly higher incidence of malignant disease. In contrast to findings of the IMPACT study, the rate of PCa among BRCA1 carriers was more than twice as high (8.6% vs. 3.8%) compared to the general population [33].
3.2.2 **Risk factors**

A wide variety of exogenous/environmental factors have been discussed as being associated with the risk of developing PCa or as being aetiologically important for the progression from latent to clinical PCa [34]. Japanese men have a lower PCa risk compared to men from the Western world. However, as Japanese men move from Japan to California, their risk of PCa increases, approaching that of American men, implying a role of environmental or dietary factors [35]. However, currently there are no known effective preventative dietary or pharmacological interventions.

3.2.2.1 **Metabolic syndrome**

The single components of metabolic syndrome (MetS), hypertension ($p = 0.035$) and waist circumference $> 102$ cm ($p = 0.007$), have been associated with a significantly greater risk of PCa, but in contrast, having $\geq 3$ components of MetS is associated with a reduced risk (OR: 0.70, 95% CI: 0.60–0.82) [36, 37].

3.2.2.1.1 **Diabetes/metformin**

The association between metformin use and PCa is controversial. At population level, metformin users (but not other oral hypoglycaemic agents) were found to be at a decreased risk of PCa diagnosis compared with never-users (adjusted OR: 0.84, 95% CI: 0.74–0.96) [38]. In 540 diabetic participants of the Reduction by Dutasteride of Prostate Cancer Events (REDUCE) study, metformin use was not significantly associated with PCa and therefore not advised as a preventive measure (OR: 1.19, $p = 0.50$) [39]. The ongoing Systemic Therapy in Advancing or Metastatic Prostate Cancer: Evaluation of Drug Efficacy (STAMPEDE) trial assesses metformin use in advanced PCa (Arm K) [40].

3.2.2.1.2 **Cholesterol/statins**

A meta-analysis of 14 large prospective studies did not show any association between blood total cholesterol, high-density lipoprotein cholesterol, low-density lipoprotein cholesterol levels and the risk of either overall PCa or high-grade PCa [36]. Results from the REDUCE study also did not show a preventive effect of statins on PCa risk [37].

3.2.2.1.3 **Obesity**

Within the REDUCE study, obesity was associated with lower risk of low-grade PCa in multivariable analyses (OR: 0.79, $p = 0.01$), but increased risk of high-grade PCa (OR: 1.28, $p = 0.042$) [41]. This effect seems mainly explained by environmental determinants of height/body mass index (BMI) rather than genetically elevated height or BMI [42].

3.2.2.2 **Dietary factors**

The association between a wide variety of dietary factors and PCa have been studied, but there is still a paucity of quality evidence (Table 3.1).

<table>

</table>
A U-shaped association has been observed, with both low- and high vitamin-D concentrations being associated with an increased risk of PCa, and more strongly for high-grade disease [55, 56].

An inverse association of low blood levels of selenium and vitamin E, but mainly nail selenium levels (reflecting long-term exposure) with aggressive PCa have been found [57, 58]. Selenium and Vitamin E supplementation were, however, found not to affect PCa incidence [59].

3.2.2.3 Hormonally active medication

3.2.2.3.1 5-alpha-reductase inhibitors (5-ARIs)

Although it seems that 5-ARIs have the potential of preventing or delaying the development of PCa (~25%, for ISUP grade 1 cancer only), this must be weighed against treatment-related side effects as well as the potential small increased risk of high-grade PCas, although these do not seem to impact PCa mortality [60-63]. None of the available 5-ARIs have been approved by the European Medicines Agency (EMA) for chemoprevention.

3.2.2.3.2 Testosterone

Hypogonadal men receiving testosterone supplements do not have an increased risk of PCa [64]. A pooled analysis showed that men with very low concentrations of free testosterone (lowest 10%) have a below-average risk (OR: 0.77) of PCa [65].

3.2.2.4 Other potential risk factors

A significantly higher rate of ISUP > 2 PCa (hazard ratio [HR]: 4.04) was found in men with inflammatory bowel disease when compared with the general population [66]. Balding was associated with a higher risk of PCa death [67]. Gonorrhoea was significantly associated with an increased incidence of PCa (OR: 1.31, 95% CI: 1.14–1.52) [68]. Occupational exposure may also play a role, based on a meta-analysis which revealed that night-shift work is associated with an increased risk (2.8%, p = 0.030) of PCa [69]. Current cigarette smoking was associated with an increased risk of PCa death (RR: 1.24, 95% CI: 1.18–1.31) and with aggressive tumour features and worse prognosis, even after cessation [70, 71]. A meta-analysis on Cadmium (Cd) found a positive association (magnitude of risk unknown due to heterogeneity) between high Cd exposure and risk of PCa for occupational exposure, but not for non-occupational exposure, potentially due to higher Cd levels during occupational exposure [72]. Men positive for human papillomavirus-16 may be at increased risk [73]. Plasma concentration of the estrogenic insecticide chlordecone is associated with an increase in the risk of PCa (OR: 1.77 for highest tertile of values above the limit of detection) [74].

A number of other factors previously linked to an increased risk of PCa have been disproved including vasectomy [75] and self-reported acne [76]. There are conflicting data about the use of aspirin or non-steroidal anti-inflammatory drugs and the risk of PCa and mortality [77, 78].

Ultraviolet radiation exposure decreased the risk of PCa (HR: 0.91, 95% CI: 0.88–0.95) [79]. A review found a small but protective association of circumcision status with PCa [80]. Higher ejaculation frequency (≥ 21 times a month vs. 4 to 7 times) has been associated with a 20% lower risk of PCa [81].

To date the current body of evidence will not support a causal relationship between specific (dietary and otherwise) factors and the development of PCa. Consequently, no effective preventative strategies can be suggested.

4. CLASSIFICATION AND STAGING SYSTEMS

4.1 Classification
The objective of a tumour classification system is to combine patients with a similar clinical outcome. This allows for the design of clinical trials on relatively homogeneous patient populations, the comparison of clinical and pathological data obtained from different hospitals across the world, and the development of recommendations for the treatment of these patient populations. Throughout these Guidelines the 2017 Tumour, Node, Metastasis (TNM) classification for staging of PCa (Table 4.1) [82] and the EAU risk group classification, which is essentially based on D’Amico’s classification system for PCa, are used (Table 4.2) [83]. The latter classification is based on the grouping of patients with a similar risk of biochemical recurrence (BCR) after radical prostatectomy (RP) or external beam radiotherapy (EBRT). Magnetic resonance imaging and targeted biopsy may cause a stage shift in risk classification systems [84].

</tr>
</tbody>
</table>

1 Metastasis no larger than 0.2 cm can be designated pNmi.
2 When more than one site of metastasis is present, the most advanced category is used. (p)M1c is the most advanced category.

Clinical T stage only refers to digital rectal examination (DRE) findings; local imaging findings are not considered in the TNM classification. Pathological staging (pTNM) is based on histopathological tissue assessment and largely parallels the clinical TNM, except for clinical stage T1 and the T2 substages. Pathological stages pT1a/b/c do not exist and histopathologically confirmed organ-confined PCas after RP are pathological stage pT2. The current Union for International Cancer Control (UICC) no longer recognises pT2 substages [82].

Of note: the EANM recently proposed a ‘miTNM’ (molecular imaging TNM) classification, taking into account prostate-specific membrane antigen positron emission tomography–computed tomography (PSMA PET/CT) findings [85]. The prognosis of the miT, miN and miM substages is likely to be better to their T, N and M counterparts due to the ‘Will Rogers phenomenon’; the extent of this prognosis shift remains to be assessed as well as its practical interest and impact [86].
4.2 Gleason score and International Society of Urological Pathology 2014 grade

In the original Gleason grading system, 5 Gleason grades (ranging from 1–5) based on histological tumour architecture were distinguished, but in the 2005 and subsequent 2014 International Society of Urological Pathology (ISUP) Gleason score (GS) modifications Gleason grades 1 and 2 were eliminated [87, 88]. The 2005 ISUP modified GS of biopsy-detected PCa comprises the Gleason grade of the most extensive (primary) pattern, plus the second most common (secondary) pattern, if two are present. If one pattern is present, it needs to be doubled to yield the GS. For three grades, the biopsy GS comprises the most common grade plus the highest grade, irrespective of its extent. The grade of intraductal carcinoma should also be incorporated in the GS [89]. In addition to reporting of the carcinoma features for each biopsy, an overall (or global) GS based on the carcinoma-positive biopsies can be provided. The global GS takes into account the extent of each grade from all prostate biopsies. The 2014 ISUP endorsed grading system limits the number of PCa grades, ranging them from 1 to 5 (see Table 4.2) [88, 90].

Further sub-stratification of the intermediate-risk group can be made and specifically the National Cancer Center Network (NCCN) Guidelines subdivide intermediate-risk disease into favourable intermediate-risk and unfavourable intermediate-risk, with unfavourable features including ISUP grade 3, and/or ≥ 50% positive biopsy cores and/or at least two intermediate-risk factors [91].

4.3 Clinically significant prostate cancer

The descriptor ‘clinically significant’ is widely used to differentiate PCa that may cause morbidity or death from types of PCa that do not. This distinction is particularly important as insignificant PCa that does not cause harm is so common [11]. Unless this distinction is made, such cancers are at high risk of being overtreated, with the treatment itself risking harmful side effects to patients. The over-treatment of insignificant PCas has been criticised as a major drawback of PSA testing [92].

However, defining what is clinically significant and what is insignificant PCa is difficult. In large studies of RP specimens which showed only ISUP grade 1 disease, extraprostatic extension (EPE) was extremely rare (0.28% of 2,502 cases) and seminal vesicle (SV) invasion or lymph node (LN) metastasis did not occur at all [93, 94]. International Society for Urological Pathology grade 1 disease itself can therefore be considered clinically insignificant. Whilst ISUP grade 1 bears the hallmarks of cancer histologically, ISUP grade 1 itself does not behave in a clinically malignant fashion.

However, ISUP grade 1 is first diagnosed at biopsy and guides management decisions, not after the prostate has been removed. The current standard practice of MRI-targeted and template biopsies has reduced diagnostic inaccuracy [95], however sampling error may still occur such that higher grade cancer could be missed. This should be especially considered if the prior MRI showed a suspicious lesion, but only ISUP grade 1 was found at biopsy.
Another complexity in defining insignificant cancer is that ISUP grade 1 may progress to higher grades over time, becoming clinically significant at a later biopsy [96]. Therefore, although ISUP grade 1 itself can be described as clinically insignificant, it is important to take into account other factors, including imaging prior to biopsy and adequate sampling core number. When combined with low-risk clinical factors (see Table 4.2), ISUP grade 1 represents low-risk PCa, with its recommendation of preferred management being active surveillance (AS) or watchful waiting (WW) (see Sections 6.1.1.2 & 6.1.1.3). It should be noted, therefore, that defining ISUP grade 1 as insignificant cancer does not mean it should be ignored, but safely observed.

Epidemiological and autopsy data also suggest that a proportion of ISUP grade 2 PCas would remain undetectable during a man’s life [97] and therefore may be overtreated. In current guidelines deferred treatment may be offered to select patients with intermediate-risk PCa [91], but evidence is lacking for appropriate selection criteria [98].

Recent papers have defined clinically significant cancer differently, commonly using ISUP grade 2 and above and even ISUP grade 3 and above, demonstrating the lack of consensus and evolution of its definition [99-102]. Some papers even provide more than one definition within a single study [103, 104]. Although there is insufficient evidence to define clearly what clinically significant (cs)PCa is, it is imperative that authors define and state it in their own studies, including exactly how the disease was diagnosed.

4.4 Prognostic relevance of stratification
A more precise stratification of the clinically heterogeneous subset of intermediate-risk group patients could provide a better framework for their management [105, 106]. However, as yet, the best stratification and optimal treatment remain controversial.

5. DIAGNOSTIC EVALUATION

5.1 Screening and early detection
5.1.1 Screening
Population or mass screening is defined as the ‘systematic examination of asymptomatic men to identify individuals ‘at risk’ and is usually initiated by health authorities. The co-primary objectives are:
- reduction in mortality due to PCa;
- a maintained QoL as expressed by QoL-adjusted gain in life years (QALYs).

Prostate cancer mortality trends range widely from country to country in the industrialised world [107]. Mortality due to PCa has decreased in most Western nations but the magnitude of the reduction varies between countries. Currently, screening for PCa still remains one of the most controversial topics in the urological literature [108].

Initial widespread aggressive screening in USA was associated with a decrease in mortality [109]. In 2012 the US Preventive Services Task Force (USPSTF) released a recommendation against PSA-based screening [92], which was adopted in the 2013 AUA Guidelines [110] and resulted in a reduction in the use of PSA for early detection [111]. This reduction in the use of PSA testing was associated with higher rates of advanced disease at diagnosis (e.g., a 6% increase in the number of patients with metastatic PCa) [13, 112-115]. While PCa mortality had decreased for two decades since the introduction of PSA testing [116], the incidence of advanced disease and, possibly, cancer-related mortality slowly increased from 2008 and accelerated in 2012 [117]. Moreover, additional evidence suggests a long-term benefit of PSA population screening in terms of reduction of cancer-specific mortality [118, 119]. However, the temporal relationship between PSA testing and decreased mortality, as well as a rising mortality following immediately after the USPSTF and AUA Guidelines recommendation against PSA testing questions the direct causative link between both points.
In 2017 the USPSTF issued an updated statement suggesting that men aged 55–69 should be informed about the benefits and harms of PSA-based screening as this might be associated with a small survival benefit. The USPSTF has now upgraded this recommendation to a grade C [120], from a previous grade ‘D’ [120-122]. They highlighted the fact that the decision to be screened should be an individual one. The grade D recommendation remains in place for men over 70 years old. This represents a major switch from discouraging PSA-based screening (grade D) to offering early diagnosis to selected men depending on individual circumstances.

A comparison of systematic and opportunistic screening suggested over-diagnosis and mortality reduction in the systematic screening group compared to a higher over-diagnosis with a marginal survival benefit, at best, in the opportunistic screening regimen [123].

A Cochrane review published in 2013 [124], which has since been updated [125], presents the main overview to date. The findings of the updated publication (based on a literature search until April 3, 2013) are almost identical to the 2009 review:

- Screening is associated with an increased diagnosis of PCa (RR: 1.3, 95% CI: 1.02–1.65).
- Screening is associated with detection of more localised disease (RR: 1.79, 95% CI: 1.19–2.70) and less advanced PCa (T3–4, N1, M1) (RR: 0.80, 95% CI: 0.73–0.87).
- From the results of 5 RCTs, randomising more than 341,000 men, no PCa-specific survival benefit was observed (RR: 1.00, 95% CI: 0.86–1.17). This was the main endpoint in all trials.
- From the results of four available RCTs, no overall survival (OS) benefit was observed (RR: 1.00, 95% CI: 0.96–1.03).

The included studies applied a range of different screening measures and testing intervals in patients who had undergone prior PSA testing, to various degrees. None included the use of risk calculators, MRI prior to biopsy (vs. a single PSA threshold) or AS (as an alternative to RP) which no longer reflects current standard practice.

The diagnostic tool (i.e. biopsy procedure) was not associated with increased mortality within 120 days after biopsy in screened men as compared to controls in the two largest population-based screening populations (ERSPC and PLCO), in contrast to a 120-day mortality rate of 1.3% in screened vs. 0.3% in controls, respectively, in a Canadian population-based screening study [126]. Increased diagnosis has historically led to over-treatment with associated side effects. However, despite this, the impact on the patient’s overall QoL is still unclear. Population level screening has never been shown to be detrimental [127-129]. Nevertheless, all these findings have led to strong advice against systematic population-based screening in most countries, including those in Europe.

In case screening is considered, a single PSA test is not enough based on the Cluster Randomized Trial of PSA Testing for Prostate Cancer (CAP) trial. The CAP trial evaluated a single PSA screening vs. controls not undergoing PSA screening on PCa detection in men aged 50 to 69 years old. The single PSA screening intervention detected more low-risk PCa cases but had no significant effect on PCa mortality after a median follow-up of 10 years [130].

Since 2013, the European Randomized Study of Screening for Prostate Cancer (ERSPC) data have been updated with 16 years of follow-up (see Table 5.1) [131]. The key message is that with extended follow-up, the mortality reduction remains unchanged (21%, and 29% after non-compliance adjustment). However, the number needed to screen (NNS) and to treat is decreasing and is now below the NNS observed in breast cancer trials [131, 132]. Long-term follow-up of the PLCO (Prostate, Lung, Colon, Ovarian cancer screening trial) showed no survival benefit for screening at a median follow-up of 16.7 years but a significant 17% increase in Gleason score 2–6 cancers and 11% decrease in Gleason score 8–10 cancers [133].

Table 5.1: Follow-up data from the ERSPC study [131]

Most screening trials include PSA and prostate biopsies to screen for PCa. Data on screening trials incorporating MRI are emerging. The role of MRI in PSA screening was studied in two RCTs. The STHLM3 trial randomised men with a PSA > 3 ng/mL between standard biopsies (10–12 cores) or MRI and standard plus targeted biopsies in the presence of a suspicious MRI. The percentage of men that underwent prostate
biopsies in the standard group was double that of the MRI group. In this non-inferiority trial, the intention-to-treat (ITT) analysis found 18% and 21% clinically significant (ISUP > 1) disease and 12% and 4% insignificant disease in the standard and the MRI group, respectively [134]. The second trial, the IP1-PROSTAGRAM study (PSA > 3 ng/mL; MRI Prostate Imaging – Reporting and Data System (PI-RADS) > 2), showed highest detection of csPCa for MRI compared to transrectal ultrasound-guided prostate (TRUS) biopsy [135].

The integration of MRI in the biopsy protocol may reduce the number of men that undergo biopsies while detecting more clinically significant and less clinically insignificant PCa [134, 135].

Currently there is insufficient evidence to support systematic screening; but there is an increased interest in early individualised detection.

5.1.2 Early detection
An individualised risk-adapted strategy for early detection may still be associated with a substantial risk of over-diagnosis. It is essential to remember that breaking the link between diagnosis and active treatment is the only way to decrease over-treatment, while still maintaining the potential benefit of individual early diagnosis for men requesting it [15, 136].

5.1.2.1 Risk factors
Men at elevated risk of having PCa are those > 50 years [137] or at age > 45 years with a family history of PCa (either paternal or maternal) [138] or of African descent [139, 140]. Men of African descent are more likely to be diagnosed with more advanced disease [141] and upgrade was more frequent after prostatectomy as compared to Caucasian men (49% vs. 26%) [142].

Germline mutations are associated with an increased risk of the development of aggressive PCa, i.e., BRCA2 [143, 144]. Prostate-specific antigen screening in male BRCA1 and 2 carriers detected more significant cancers at a younger age compared to non-mutation carriers [32, 33].

Men with a baseline PSA < 1 ng/mL at 40 years and < 2 ng/mL at 60 years are at decreased risk of PCa metastasis or death from PCa several decades later [145, 146].

5.1.2.2 Initial risk assessment by PSA and DRE
Informed men requesting an early diagnosis should be given a PSA test and undergo a DRE [147]. The use of DRE alone in the primary care setting had a sensitivity and specificity below 60%, possibly due to inexperience, and can therefore not be recommended to exclude PCa [148].

Prostate-specific antigen measurement and DRE need to be repeated [130], but the optimal intervals for PSA testing and DRE follow-up are unknown as they varied between several prospective trials. A risk-adapted strategy might be a consideration, based on the initial PSA level. This could be every 2 years for those initially at risk, or postponed up to 8 years in those not at risk with an initial PSA < 1 ng/mL at 40 years and a PSA < 2 ng/mL at 60 years of age and a negative family history [149]. An analysis of ERSPC data supports a recommendation for an 8-year screening interval in men with an initial PSA concentration < 1 μg/L; fewer than 1% of men with an initial PSA concentration < 1 ng/mL were found to have a concentration above the biopsy threshold of 3 ng/mL at 4-year follow-up; the cancer detection rate by 8 years was close to 1% [150]. The long-term survival and QoL benefits of extended PSA re-testing (every 8 years) remain to be proven at a population level.

5.1.2.3 Risk assessment, co-morbidity and life-expectancy
Data from the Goteborg arm of the ERSPC trial suggest that the age at which early diagnosis should be stopped remains controversial, but an individual’s life expectancy must definitely be taken into account. Men who have less than a 15-year life expectancy are unlikely to benefit, based on data from the Prostate Cancer Intervention Versus Observation Trial (PIVOT) and the ERSPC trials. Furthermore, although there is no simple tool to evaluate individual life expectancy; co-morbidity is at least as important as age. A detailed review can be found in Section 5.4 ‘Estimating life expectancy and health status’ and in the SIOG Guidelines [151].

5.1.2.4 Risk assessment to determine the need for biopsy
Multiple diagnostic tools are now available to determine the need for a biopsy to establish the diagnosis of a PCa.

Risk calculators, combining clinical data (age, DRE findings, PSA level, etc.) may be useful in helping to determine (on an individual basis) what the potential risk of cancer may be, thereby reducing the number of unnecessary biopsies. Several tools developed from cohort studies are available including (among others):
• the ERSPC cohort: [http://www.prostatecancer-riskcalculator.com/seven-prostate-cancer-risk-calculators](http://www.prostatecancer-riskcalculator.com/seven-prostate-cancer-risk-calculators);
  An updated version was presented in 2017 including prediction of low and high risk now also based on the ISUP grading system and presence of cribriform growth in histology [152];
• the PCPT cohort: PCPTRC 2.0 [http://myprostatecancerrisk.com/];
• a local Canadian cohort: [https://sunnybrook.ca/content/?page=asure-calc](https://sunnybrook.ca/content/?page=asure-calc) (among others).

Prostate MRI stratifies suspected PCa in lower- and higher risk, based on a 1- to 5- risk scale of having csPCa [PI-RADS v2.1 guidelines 2019]. A recent meta-analysis of this risk assessment tool showed (on a patient level) a significant cancer detection rate of 9% (5–13%) for PI-RADS 2 scores, 16% (7–27%) for PI-RADS 3 scores, 59% (39–78%) for PI-RADS 4 scores, and 85% (73–94%) for PI-RADS 5 scores [153]. Men with PI-RADS assessment scores of 3 to 5 are recommended to undergo biopsy [154]. Prostate MRI and related MRI-directed biopsies have shown to be at least as diagnostically effective as systematic biopsies alone in diagnosing significant cancers [155]. However, if the MRI-directed biopsy decision strategy (without performing systematic biopsies) can reduce the number of unnecessary biopsy procedures, this will be at the expense of missing a small percentage of csPCas [156] (see Section 5.2.4.2.4).

PSA-density (PSA-D) is the strongest predictor in risk calculators. Combinations of PSA-D and MRI have been explored [157-162], showing guidance in biopsy-decisions whilst safely avoiding redundant biopsy testing (see Section 5.2.4.2.6.3).

Urine and serum biomarkers as well as tissue-based biomarkers have been proposed for improving detection and risk stratification of PCa patients, potentially avoiding unnecessary biopsies. However, further studies are necessary to validate their efficacy [163]. At present there is too limited data to implement these markers into routine screening programmes (see Section 5.2.3).

5.1.3 **Genetic testing for inherited prostate cancer**

Increasing evidence supports the implementation of genetic counselling and germline testing in early detection and PCa management [164]. Several commercial screening panels are now available to assess main PCa risk genes [165]. However, it remains unclear when germline testing should be considered and how this may impact localised and metastatic disease management. Germline *BRCA1* and *BRCA2* mutations occur in approximately 0.2% to 0.3% of the general population [166]. It is important to understand the difference between somatic testing, which is performed on the tumour, and germline testing, which is performed on blood or saliva and identifies inherited mutations. Genetic counselling is required prior to and after undergoing germline testing.

Germline mutations can drive the development of aggressive PCa. Therefore, the following men with a personal or family history of PCa or other cancer types arising from DNA repair gene mutations should be considered for germline testing:

• Men with metastatic PCa;
• Men with high-risk PCa and a family member diagnosed with PCa at age < 60 years;
• Men with multiple family members diagnosed with csPCa at age < 60 years or a family member who died from PCa cancer;
• Men with a family history of high-risk germline mutations or a family history of multiple cancers on the same side of the family.

Further research in this field (including not so well-known germline mutations) is needed to develop screening, early detection and treatment paradigms for mutation carriers and family members.

5.2 Clinical diagnosis

Prostate cancer is usually suspected on the basis of DRE and/or PSA levels. Definitive diagnosis depends on histopathological verification of adenocarcinoma in prostate biopsy cores.
5.2.1 Digital rectal examination
In ~18% of cases, PCa is detected by suspect DRE alone, irrespective of PSA level [179]. A suspect DRE in patients with a PSA level ≤ 2 ng/mL has a positive predictive value (PPV) of 5–30% [180]. In the ERSPC trial, an abnormal DRE in conjunction with an elevated PSA more than doubled the risk of a positive biopsy (48.6% vs. 22.4%) [181]. An abnormal DRE is associated with an increased risk of a higher ISUP grade, predicts csPCa in men under AS [182] and is an indication for MRI and biopsy [181, 183]. cT staging is dependent on DRE and a strong predictor of advanced PCa (OR: 11.12 for cT3 and OR: 5.28 for cT4) [184].

5.2.2 Prostate-specific antigen
The use of PSA as a serum marker has revolutionised PCa diagnosis [185]. Prostate-specific antigen is organ- but not cancer specific; therefore, it may be elevated in benign prostatic hypertrophy (BPH), prostatitis and other non-malignant conditions. As an independent variable, PSA is a better predictor of cancer than either DRE or TRUS [186].

There are no agreed standards defined for measuring PSA [187]. It is a continuous parameter, with higher levels indicating greater likelihood of PCa. Many men may harbour PCa despite having low serum PSA [188]. Table 5.3 demonstrates the occurrence of ISUP ≥ grade 2 PCa in systematic biopsies at low PSA levels, precluding an optimal PSA threshold for detecting non-palpable but csPCa. The use of nomograms and biomarkers may help in predicting indolent PCa [134, 189, 190]. In case of an elevated PSA (up to 10 ng/mL), a repeated test should be considered to confirm the increase before going to the next step.

Table 5.3: Risk of PCa identified by systemic PCa biopsy in relation to low PSA values [160]

</table>

5.2.2.1 Repeat PSA testing
A repeat PSA test before prostate biopsies in men with an initial PSA 3–10 ng/mL reduced the indication for biopsies in 16.8% of men while missing 5.4% ISUP grade > 1 in the STHLM3 trial [191]. Similarly, in the Prostate Testing for Cancer and Treatment (ProtecT) trial men with a more than 20% lower repeat-PSA analysis within 7 weeks had a lower risk of PCa (OR: 0.43, 95% CI: 0.35–0.52) as well as a lower risk of ISUP grade ≥ 2 (OR: 0.29, 95% CI: 0.19–0.44) [192]. A study with a PSA interval of 4 weeks showed similar findings of a reduced risk of PCa and ISUP grade > 1 [193]. These observations indicate that an early repeat-PSA prior to the decision of prostate biopsies has prognostic information.

5.2.2.2 PSA density
Prostate-specific antigen density is the level of serum PSA divided by the prostate volume. The higher the PSA-D, the more likely it is that the PCa is clinically significant; in particular in smaller prostates when a PSA-D cut-off of 0.15 ng/mL/cc was applied [194] (see Section 5.2.4.2.6.3). Several studies found a PSA-D over 0.1–0.15 ng/mL/cc predictive of cancer [195, 196]. Patients with a PSA-D below 0.09 ng/mL/cc were found unlikely (4%) to be diagnosed with csPCa [197]. A systematic review showed heterogeneity among studies using PSA-D to select men with PI-RADS 3 category on MRI reading for biopsies but suggest a cut-off of 0.15 ng/mL/cc [195]. Others found its added value to biparametric (bp) MRI-guided biopsies unclear with an area under the curve (AUC) of 0.87–0.95 for the direction of csPCa based on bpMRI and 0.91–0.95 for the combined test of bpMRI and PSA-D [198].

5.2.2.3 PSA velocity and doubling time
Various PSA kinetics definitions have been proposed with different methods of calculation (log transformed or not) and eligible PSAs:

• PSA velocity (PSAV): absolute annual increase in serum PSA (ng/mL/year) [199];
• PSA doubling time (PSA-DT): which measures the exponential increase in serum PSA over time [200].

Prostate-specific antigen velocity is more simple to calculate by subtracting the initial value from the final value, dividing by time. However, by ignoring middle values, not all PSA values are accurately taken into account.
Prostate-specific antigen-DT is calculated assuming an exponential rise in serum PSA. The formula takes into account the natural logarithm of 2 divided by the slope obtained from fitting a linear regression of the natural log of PSA over time [201]. However, many different PSA-DT calculations have been assessed according to the mathematical formula used and to the included PSA values (number, time period, intervals) [202]. For example, the ‘MSKCC’ method calculates a regression slope integrating all PSA values. Other methods transform PSA before calculating the slope and do not include all PSA values (different time frames and minimal intervals) [203]. Thus, O’Brien and colleagues identified more than 20 different definitions of PSAV and PSA-DT and demonstrated that obtained values could vary widely between definitions [203].

However, some rules can be considered for PSA-DT calculation:

- At least 3 PSA measurements are required [201];
- A minimum time period between measurements (4 weeks) is preferable due to potential statistical ‘noise’ when PSA values are obtained too close together (this statement can be reconsidered in case of very active disease);
- All PSA values should be ≥ 0.20 ng/mL and follow a global rising trend;
- All included PSA values should be obtained within the past 12 months at most, to reflect the current disease activity;
- PSA-DT is often mentioned in months, or in weeks in very active disease.

Prostate-specific antigen velocity and PSA-DT may have a prognostic role in treating PCa but have limited diagnostic use because of background noise (total prostate volume, and BPH), different intervals between PSA determinations, and acceleration/deceleration of PSAV and PSA-DT over time [201]. These measurements do not provide additional information compared with PSA alone [203-206]. Prostate-specific antigen-DT has been linked with metastasis-free- and OS in non-metastatic CRPC (nmCRPC) and identifies patients with high-risk nmCRPC who could benefit from intensified therapy (PSA-DT threshold < 10 months) [207].

5.2.2.4 Free/total PSA ratio

Free/total (f/t) PSA must be used cautiously because it may be adversely affected by several pre-analytical and clinical factors (e.g., instability of free PSA at 4°C and room temperature, variable assay characteristics, and concomitant BPH in large prostates) [208]. Prostate cancer was detected in men with a PSA 4–10 ng/mL by biopsy in 56% of men with f/t PSA < 0.10, but in only 8% with f/t PSA > 0.25 ng/mL [209]. A systematic review including 14 studies found a pooled sensitivity of 70% in men with a PSA of 4–10 ng/mL [210]. Free/total PSA is of no clinical use if the total serum PSA is > 10 ng/mL or during follow-up of known PCa. The clinical value of f/t PSA is limited in light of the new diagnostic pathways incorporating MRI (see Section 5.2.4.2).

5.2.3 Biomarkers

5.2.3.1 Blood based biomarkers: PHI/4K score/IsoPSA

Several assays measuring a panel of kallikreins in serum or plasma are now commercially available, including the U.S. Food and Drug Administration (FDA) approved Prostate Health Index (PHI) test (combining free and total PSA and the [–2]pro-PSA isoform [p2PSA]), and the four kallikrein (4K) score test (measuring free, intact and total PSA and kallikrein-like peptidase 2 [hK2] in addition to age, DRE and prior biopsy status). Both tests are intended to reduce the number of unnecessary prostate biopsies in PSA-tested men. A few prospective multi-centre studies demonstrated that both the PHI and 4K score test out-performed f/t PSA PCa detection, with an improved prediction of csPCa in men with a PSA between 2–10 ng/mL [211-214]. In a head-to-head comparison both tests performed equally [215].

In contrast to the 4K score and PHI, which focus on the concentration of PSA isoforms, IsoPSA utilises a novel technology which focuses on the structure of PSA [216]. Using an aqueous two-phase solution, it partitions the isoforms of PSA and assesses for structural changes in PSA. In a multi-centre prospective validation in 271 men the assay AUC was 0.784 for high-grade vs. low-grade cancer/benign histology, which was superior to the AUCs of total PSA and percent free PSA [217]. In men with a negative mpMRI, PSA-D, 4K score and family history predicted the risk of csPCa on biopsy and using a nomogram reduced the number of negative biopsies and indolent cancers by 47% and 15%, respectively, while missing 10% of csPCAs [218].

The Stockholm3 test is a prediction model that is based on several clinical variables (age, first-degree family history of PCa, and previous biopsy), blood biomarkers (total PSA, free PSA, ratio of free PSA to total PSA, human kallikrein 2, macrophage inhibitory cytokine-1, and microsémminoprotein-ß [MSMB]), and a polygenic risk score for predicting the risk of PCa with ISUP ≥ 2, and was shown to reduce the percent of clinically insignificant cancers when used on combination of MRI in a PSA screening population [134].
5.2.3.2 Urine biomarkers: PCA3/SelectMDX/Mi Prostate score (MiPS)/ExoDX

Prostate cancer gene 3 (PCA3) is an overexpressed long non-coding RNA (lncRNA) biomarker that is detectable in urine sediments obtained after three strokes of prostatic massage during DRE. The commercially available Progensa urine test for PCA3 is superior to total and percent-free PSA for the detection of PCs in men with elevated PSA as it shows significant increases in the area under the receiver-operator characteristic curve (AUC) for positive biopsies [219-222]. PCA3 score increases with PCa volume, but there are conflicting data about whether it independently predicts the ISUP grade [223]. Currently, the main indication for the Progensa test is to determine whether repeat biopsy is needed after an initially negative biopsy, but its clinical effectiveness for this purpose is uncertain [224]. Wei et al., showed 42% sensitivity at a cut-off of 60 in the primary biopsy setting with a high specificity (91%) and a PPV of 80% suggesting that the assay may be used in the primary setting [225].

The SelectMDX test is similarly based on mRNA biomarker isolation from urine. The presence of HOXC6 and DLX1 mRNA levels is assessed to provide an estimate of the risk of both presence of PCa on biopsy as well as presence of high-risk cancer [226]. A multi-centre trial evaluated SelectMDX in men with a MRI PI-RADS score < 4 or PI-RADS score < 3, and the percentage of missed csPCas was 6.5% and 3.2%, respectively, whereas 45.8% and 40% of biopsies were avoided [227]. Hendriks et al., found more biopsies were avoided and more high-grade PCas detected in a MRI-based biopsy strategy compared to a SelectMDX strategy. When both tests were combined, more GG > 1 lesions were found, but the number of negative or low-grade cancer biopsies more than doubled [190]. Combining SelectMDX and MRI in men with a PSA between 3–10 ng/mL had a negative predictive value (NPV) of 93% [228].

TMPRSS2-ERG fusion, a fusion of the trans-membrane protease serine 2 (TMPRSS2) and the ERG gene can be detected in 50% of PCas [229]. When detection of TMPRSS2-ERG in urine was added to PCA3 expression and serum PSA (Mi(chigan)Prostate Score [MiPS]), cancer prediction improved [230]. Exosomes secreted by cancer cells may contain mRNA diagnostic for high-grade PCa [231, 232]. Use of the ExoDx Prostate IntelliScore urine exosome assay resulted in avoiding 27% of unnecessary biopsies when compared to standard of care (SOC). However, currently, both the MiPS-score and ExoDx assay are considered investigational.

In 6 head-to-head comparison studies of PCA3 and PHI, only Seisen et al., found a significant difference; PCA3 detected more cancers, but for the detection of significant disease, defined as ISUP grade > 2, more than three positive cores, or > 50% cancer involvement in any core, PHI proved superior [233]. Russo et al., suggested in their systematic review that, based on moderate quality data, PHI and the 4K panel had a high diagnostic accuracy and showed similar performance in predicting the detection of significant disease with an AUC of 0.82 and 0.81, respectively [234]. However, in the screening population of the ERSPC study the use of both PCA3 and 4K panel when added to the risk calculator led to an improvement in AUC of less than 0.03 [235]. Based on the available evidence, some biomarkers could help in discriminating between aggressive and non-aggressive tumours with an additional value compared to the prognostic parameters currently used by clinicians [236]. However, upfront MRI is also likely to affect the utility of above-mentioned biomarkers (see Section 5.2.4).

5.2.3.3 Biomarkers to select men for a repeat biopsy

In men with an elevated risk of PCa with a prior negative biopsy, additional information may be gained by the Progensa-PCA3 and SelectMDX DRE urine tests, the serum 4Kscore and PHI tests or a tissue-based epigenetic test (ConfirmMDX). The role of PHI, Progensa PCA3, and SelectMDX in deciding whether to take a repeat biopsy in men who had a previous negative biopsy is uncertain and probably not cost-effective [224]. The ConfirmMDx test is based on the concept that benign prostatic tissue in the vicinity of a PCa focus shows distinct epigenetic alterations. In case PCa is missed at biopsy, demonstration of epigenetic changes in the benign tissue would indicate the presence of carcinoma. The ConfirmMDx test quantifies the methylation level of promoter regions of three genes (Methylated APC, RASSF1, and GSTP1) in benign prostatic tissue. A multi-centre study found a NPV of 88% when methylation was absent in all three markers, implying that a repeat biopsy could be avoided in these men [237]. Given the limited available data and the fact that the role of MRI in tumour detection was not accounted for, no recommendation can be made regarding the routine application of ConfirmMDx, in particular in the light of current use of MRI before biopsy.

5.2.3.4 Guidelines for risk-assessment of asymptomatic men

</tr>
</tbody>
</table>
In asymptomatic men with a PSA level between 2–10 ng/mL and a normal DRE, use one of the following tools for biopsy indication:

- risk-calculator;
- Magnetic resonance imaging of the prostate
- an additional serum, urine or tissue-based biomarker test.

### 5.2.4 Imaging

#### 5.2.4.1 Transrectal ultrasound and ultrasound-based techniques

Standard TRUS is not reliable at detecting PCa [238] and the diagnostic yield of additional biopsies performed on hypoechoic lesions is negligible [100]. Prostate HistoScanning™ provided inconsistent results across studies [239]. New sonographic modalities such as micro-Doppler, sonoelastography contrast-enhanced US or high-resolution micro-US provided promising preliminary findings, either alone, or combined into the so-called ‘multiparametric US’. However, these techniques still have limited clinical applicability due to lack of standardisation, lack of large-scale evaluation of inter-reader variability and unclear results in transition zones [240-242].

#### 5.2.4.2 Magnetic resonance imaging

##### 5.2.4.2.1 Magnetic resonance imaging performance in detecting PCa

Correlation with RP specimens shows that MRI has good sensitivity for the detection and localisation of ISUP grade ≥ 2 cancers, especially when their diameter is larger than 10 mm [243-245]. This good sensitivity was further confirmed in patients who underwent template biopsies. In a Cochrane meta-analysis which compared MRI to template biopsies (≥ 20 cores) in biopsy-naive and repeat-biopsy settings, MRI had a pooled sensitivity of 0.91 (95% CI: 0.83–0.95) and a pooled specificity of 0.37 (95% CI: 0.29–0.46) for ISUP grade ≥ 2 cancers [155]. For ISUP grade ≥ 3 cancers, MRI pooled sensitivity and specificity were 0.95 (95% CI: 0.87–0.99) and 0.35 (95% CI: 0.26–0.46), respectively. Magnetic resonance imaging is less sensitive in identifying ISUP grade 1 PCa. It identifies less than 30% of ISUP grade 1 cancers smaller than 0.5 cc identified on RP specimens by histopathology analysis [243]. In series using template biopsy findings as the reference standard, MRI has a pooled sensitivity of 0.70 (95% CI: 0.59–0.80) and a pooled specificity of 0.27 (95% CI: 0.19–0.37) for identifying ISUP grade 1 cancers [155].

The probability of detecting malignancy by MRI-identified lesions was standardised first by the use of a 5-grade Likert score [246], and then by the PI-RADS score which has been updated several times since its introduction [247, 248]. In a meta-analysis of 17 studies involving men with suspected or biopsy-proven PCa, the average PPVs for ISUP grade ≥ 2 cancers of lesions with a PI-RADSv2.1 score of 3, 4 and 5 were 16% (7–27%), 59% (39–78%), and 85% (73–94%), respectively, but with significant heterogeneity among studies [249].

##### 5.2.4.2.2 Targeted biopsy improves the detection of ISUP grade ≥ 2 cancer as compared to systematic biopsy

In pooled data of 25 reports on agreement analysis (head-to-head comparisons) between systematic biopsy (median number of cores: 8–15) and MRI-targeted biopsies (median number of cores: 2–7), the detection ratio (i.e. the ratio of the detection rates obtained by MRI-targeted biopsy alone and by systematic biopsy alone) was 1.12 (95% CI: 1.02–1.23) for ISUP grade ≥ 2 cancers and 1.20 (95% CI: 1.06–1.36) for ISUP grade ≥ 3 cancers, and therefore in favour of MRI-targeted biopsy.

Another meta-analysis of RCTs limited to biopsy-naive patients with a positive MRI found that MRI-targeted biopsy detected significantly more ISUP grade ≥ 2 cancers than systematic biopsy (risk difference, -0.11 [95% CI: -0.2 to 0.0]; p = 0.05), in prospective cohort studies (risk difference, -0.18 [95% CI: -0.24 to -0.11]; p < 0.00001), and in retrospective cohort studies (risk difference, -0.07 [95% CI: -0.12 to -0.02]; p = 0.004).

Three prospective multi-centre trials evaluated MRI-targeted biopsy in biopsy-naive patients. In the Prostate Evaluation for Clinically Important Disease: Sampling Using Image-guidance Or Not? (PRECISION) trial, 500 biopsy-naive patients were randomised to either MRI-targeted biopsy only or TRUS-guided systematic biopsy only. The detection rate of ISUP grade ≥ 2 cancers was significantly higher in men assigned to MRI-targeted biopsy (38%) than in those assigned to systemic biopsy (26%, p = 0.005, detection ratio 1.46) [99]. In the Assessment of Prostate MRI Before Prostate Biopsies (MRI-FIRST) trial, 251 biopsy-naive patients underwent TRUS-guided systematic biopsy by an operator who was blinded to MRI findings, and MRI-targeted biopsy by another operator. Magnetic resonance Imaging-targeted biopsy detected ISUP grade ≥ 2 cancers in a higher percentage of patients, but the difference was not significant (32.3% vs. 29.9%, p = 0.38; detection ratio: 1.08) [100]. However, MRI-targeted biopsy detected significantly more ISUP grade ≥ 3 cancers than systematic biopsy (19.9% vs. 15.1%, p = 0.0095; detection ratio: 1.32). A similar trend for improved detection of ISUP grade ≥ 3 cancers by MRI-targeted biopsy was observed in the Cochrane analysis; however, it was not statistically significant (detection ratio 1.11 [0.88–1.40]) [155]. The Met Prostaat MRI Meer Mans (4M) study included 626 biopsy-naive patients; all patients underwent systematic biopsy, and those with a positive MRI (PI-RADSv2 score of 3–5, 51%) underwent additional in-bore MRI-targeted biopsy. The results were close to those of the MRI-FIRST trial with a detection ratio for ISUP grade ≥ 2 cancers of 1.09 (detection rate: 25% for
MRI-targeted biopsy vs. 23% for systematic biopsy) [101]. However, in this study, MRI-targeted biopsy and systematic biopsy detected an equal number of ISUP grade ≥ 3 cancers (11% vs. 12%; detection ratio: 0.92).

The Targeted Biopsy Techniques Based on Magnetic Resonance Imaging in the Diagnosis of Prostate Cancer in Patients with Prior Negative Biopsies (FUTURE) randomised trial compared three techniques of MRI-targeted biopsy in the repeat-biopsy setting [250]. In the subgroup of 152 patients who underwent both MRI-targeted biopsy and systematic biopsy, MRI-targeted biopsy detected significantly more ISUP grade ≥ 2 cancers than systematic biopsy (34% vs. 16%; p < 0.001, detection ratio of 2.1), which is a finding consistent with the Cochrane agreement analysis (detection ratio: 1.44). An ISUP grade ≥ 2 cancer would have been missed in only 1.3% (2/152) of patients, had systematic biopsy been omitted [251]. These findings support that MRI-targeted biopsy significantly out-performs systematic biopsy for the detection of ISUP grade ≥ 2 in the repeat-biopsy setting. In biopsy-naive patients, the difference appears to be less marked but remains in favour of MRI-targeted biopsy.

5.2.4.2.3 MRI-targeted biopsy without systematic biopsy reduces the detection of ISUP grade 1 PCa as compared to systematic biopsy

In pooled data of 25 head-to-head comparisons between systematic biopsy and MRI-targeted biopsy, the detection ratio for ISUP grade 1 cancers was 0.62 (95% CI: 0.44–0.88) in patients with prior negative biopsy and 0.83 (95% CI: 0.54–0.74) in biopsy-naive patients [155]. In the PRECISION and 4M trials, the detection rate of ISUP grade 1 patients was significantly lower in the MRI-targeted biopsy group as compared to systematic biopsy (9% vs. 22%, p < 0.001, detection ratio of 0.41 for PRECISION; 14% vs. 25%, p < 0.001, detection ratio of 0.56 for 4M) [99, 101]. In the MRI-FIRST trial, MRI-targeted biopsy detected significantly fewer patients with clinically insignificant PCa (defined as ISUP grade 1 and maximum cancer core length < 6 mm) than systematic biopsy (5.6% vs. 19.5%, p < 0.0001, detection ratio of 0.29) [100]. Consequently, MRI-targeted biopsy without systematic biopsy significantly reduces over-diagnosis of low-risk disease, as compared to systematic biopsy.

5.2.4.2.4 Added value combining systematic biopsy and targeted biopsy

Magnetic resonance imaging-targeted biopsies can be used in two different diagnostic pathways: 1) the ‘combined pathway’, in which patients with a positive MRI undergo combined systematic and targeted biopsy, and patients with a negative MRI undergo systematic biopsy; 2) the ‘MRI pathway’, in which patients with a positive MRI undergo only MRI-targeted biopsy, and patients with a negative MRI who are not biopsied at all.

Data from the Cochrane meta-analysis and from the MRI-FIRST and 4M trials suggest that the absolute added value of systemic biopsy for detecting ISUP grade ≥ 2 cancers is lower than that of MRI-targeted biopsy (see Table 5.4).

*Intervals in parenthesis are 95% CI.
The absolute added value of a given biopsy technique is defined by the percentage of patients of the entire cohort diagnosed only by this biopsy technique.

ISUP = International Society for Urological Pathology (grade); MRI-TBx = magnetic resonance imaging-targeted biopsies; ND = not defined.
In Table 5.4, the absolute added values refer to the percentage of patients in the entire cohort; if the cancer prevalence is taken into account, the ‘relative’ percentage of additional detected PCa can be computed. Adding MRI-targeted biopsy to systematic biopsy in biopsy-naive patients increases the number of ISUP grade ≥ 2 and grade ≥ 3 PCa by approximately 20% and 30%, respectively. In the repeat-biopsy setting, adding MRI-targeted biopsy increases detection of ISUP grade ≥ 2 and grade ≥ 3 PCa by approximately 40% and 50%, respectively. Omitting systematic biopsy in biopsy-naive patients would miss approximately 16% of all detected ISUP grade ≥ 2 PCa and 18% of all ISUP grade ≥ 3 PCa. In the repeat-biopsy setting, it would miss approximately 10% of ISUP grade ≥ 2 PCa and 9% of ISUP grade ≥ 3 PCa.

5.2.4.2.5 Avoiding biopsies in the ‘MR pathway’
The diagnostic yield and number of biopsy procedures potentially avoided by the ‘MR pathway’ depends on the Likert/PI-RADS threshold used to define a positive MRI. In pooled studies on biopsy-naive patients and patients with prior negative biopsies, a Likert/PI-RADS threshold of ≥ 3 would have avoided 30% (95% CI: 23–38) of all biopsy procedures while missing 11% (95% CI: 6–18) of all detected ISUP grade ≥ 2 cancers (relative percentage) [155]. Increasing the threshold to ≥ 4 would have avoided 59% (95% CI: 43–78) of all biopsy procedures while missing 28% (95% CI: 14–48) of all detected ISUP grade ≥ 2 cancers [155]. Of note, the percentages of negative MRI (Likert/PI-RADS score ≤ 2) in the MRI-FIRST, PRECISION and 4M trials were 21.1%, 28.9% and 49%, respectively [99-101].

5.2.4.2.6 Practical considerations
5.2.4.2.6.1 Prostate magnetic resonance imaging reproducibility
Despite the use of the PI-RADSv2 scoring system [247], MRI inter-reader reproducibility remains moderate at best which currently limits its broad use by non-dedicated radiologists [252]. However, significant improvement in the accuracy of MRI and MRI-targeted biopsy can be observed over time, both in academic and community hospitals, especially after implementation of PI-RADSv2 scoring and multidisciplinary meetings using pathological correlation and feedback [253-256]. An updated version of the PI-RADS score (PI-RADSv2.1) has been recently published to improve reader reproducibility, showing improved diagnostic performance [153] but it has not yet been fully evaluated [248]. It is still too early to predict whether quantitative approaches and computer-aided diagnostic systems will improve the characterisation of lesions seen at MRI [257]. Standardisation of MRI interpretation and quality check of acquisition and of MRI-targeted biopsy technique is required to optimise the ‘MRI pathway’ in large-volume and small-volume (non-expert) centres [258-260].

5.2.4.2.6.2 Targeted biopsy accuracy and reproducibility
Clinically significant PCa not detected by the ‘MRI pathway’ can be missed because of MRI failure (invisible cancer or reader’s misinterpretation) or because of targeting failure (target missed or under sampled by MRI-targeted biopsy). In two retrospective studies of 211 and 116 patients with a unilateral MRI lesion, targeted biopsy alone detected 73.5–85.5% of all csPCa (ISUP grade ≥ 2); combining MRI-targeted biopsy with systematic biopsy of the lobe with the MRI lesion detected 96–96.4% of all csPCas and combined targeted and systematic biopsy of the contralateral lobe only identified 81.6–92.7% of csPCas [261, 262]. The difference may reflect targeting errors leading to undersampling of the tumour. The accuracy of MRI-targeted biopsy is substantially impacted by the experience of the biopsy operator [252]. Increasing the number of cores taken per target may partially compensate for guiding imprecision. In a retrospective study of 479 patients who underwent MRI-targeted biopsy with 4 cores per target that were sequentially labelled, the first 3 cores detected 95.1% of csPCa [263]. In two other retrospective studies of 330 and 744 patients who underwent MRI-targeted biopsy with up to 5 cores per target, the one-core and 3-core sampling strategies detected 63–75% and 90–93%, respectively, of the ISUP grade ≥ 2 PCa detected by the 5-core strategy [264, 265]. These percentages are likely to be influenced by the lesion size and location, the prostate volume or the operator’s experience, but no study has quantified the impact of these factors yet.

5.2.4.2.6.3 Risk-stratification
Using risk-stratification to avoid biopsy procedures
Prostate-specific antigen density may help refine the risk of csPCa in patients undergoing MRI as PSA-D and the PI-RADS score are significant independent predictors of csPCa at biopsy [266, 267]. In a meta-analysis of 8 studies, pooled MRI NPV for ISUP grade ≥ 2 cancer was 84.4% (95% CI: 81.3–87.2) in the whole cohort, 82.7% (95% CI: 80.5–84.7) in biopsy-naive men and 88.2% (95% CI: 85–91.1) in men with prior negative biopsies. In the subgroup of patients with PSA-D < 0.15 ng/mL, NPV increased to respectively 90.4% (95% CI: 86.8–93.4), 88.7% (95% CI: 83.1–93.3) and 94.1% (95% CI: 90.9–96.6) [268]. In contrast, the risk of csPCa is as high as 27–40% in patients with negative MRI and PSA-D > 0.15–0.20 ng/mL/cc [101, 159, 267, 269-271].
Based on a meta-analysis of > 3,000 biopsy-naïve men, a risk-adapted data table of csPCa was developed, linking PI-RADS score (1–2, 3, and 4–5) to PSA-D categories (< 0.10, 0.10–0.15, 0.15–0.20 and > 0.20 ng/mL) (Table 5.5) [157]. For example, the risk of having ISUP grade ≥ 2 cancer in biopsy-naïve men with a PI-RADS 1–2 assessment score and PSA-D below 0.10 is 3–4%, in a below-average-risk population of < 5% [157]. This risk-adapted matrix table based on PSA-D and on MRI risk assessments may guide the decision to perform a biopsy.

These data are applicable for a mean ISUP grade ≥ 2 cancer prevalence of 35% (range 28–46%) in biopsy-naïve men, and would need to be adjusted to other populations’ prevalence. Awaiting validation of MRI-based multivariate risk-prediction tools, corroboration linking MRI findings to PSA-D values for biopsy decisions is beginning to emerge which may promote their routine use in clinical practice [16, 272]. It must be emphasised, however, that the use of PSA-D remains currently limited due to the lack of standardisation of prostate volume measurement (assessed by DRE or by imaging [TRUS or MRI using various techniques such as ellipsoid formula or planimetry]). The impact of this lack of standardisation on the volume estimation remains under-evaluated.

Table 5.5: Risk data table of clinically significant prostate cancer, related to PI-RADS score and PSA-D categories in biopsy-naïve men, clinically suspected of having significant disease [157]*

| Detection of clinically significant prostate cancer (ISUP grade 2 and higher) | PSA-density risk groups |
|---|---|---|---|---|
| PI-RADS risk categories | Prevalence ISUP ≥ 2 PCa | Low | Intermediate-low | Intermediate-high | High |
| | | < 0.10 | 0.10–0.15 | 0.15–0.20 | ≥ 0.20 |
| PI-RADS 1–2 | 31% (678/2199) | 28% (612/2199) | 16% (360/2199) | 25% (553/2199) |
| PI-RADS 3 | 6% (48/839) | 3% (11/411) | 7% (17/256) | 8% (8/104) | 18% (12/68) |
| PI-RADS 4–5 | 16% (41/254) | 4% (3/74) | 13% (11/88) | 29% (12/41) | 29% (15/51) |

| Compiled totals of csPCa risk | | | | | |
| PI-RADS 1–2 | 31% (678/2199) | 28% (612/2199) | 16% (360/2199) | 25% (553/2199) |
| PI-RADS 3 | 6% (48/839) | 3% (11/411) | 7% (17/256) | 8% (8/104) | 18% (12/68) |
| PI-RADS 4–5 | 16% (41/254) | 4% (3/74) | 13% (11/88) | 29% (12/41) | 29% (15/51) |
| All PI-RADS | 62% (687/1106) | 31% (59/189) | 54% (144/268) | 69% (148/215) | 77% (336/434) |

Risk-adapted matrix table for biopsy decision management

| PI-RADS 1–2 | No biopsy | No biopsy | No biopsy | Consider biopsy |
| PI-RADS 3 | No biopsy | Consider biopsy | Highly consider biopsy | Perform biopsy |
| PI-RADS 4–5 | Perform biopsy | Perform biopsy | Perform biopsy | Perform biopsy |

very low | 0–5% csPCa (below population risk) #
low | 5–10% csPCa (acceptable risk) ##
Intermediate-low | 10–20% csPCa
Intermediate-high | 20–30% csPCa
High | 30–40% csPCa
Very high | > 40% csPCa

## 2019 EAU guidelines: csPCa 9% (95%CI: 6–14%).

Table adapted from: Schouts, IG and Padhani AR. BJU Int 2021 127(2):175. Risk-adapted biopsy decision based on prostate magnetic resonance imaging and prostate-specific antigen density for enhanced biopsy avoidance in first prostate cancer diagnostic evaluation, with permission from Wiley.
Combining MRI findings with the PCA3 score may also improve risk stratification [273]. Several groups have developed comprehensive risk calculators which combine MRI findings with simple clinical data as a tool to predict subsequent biopsy results [274]. At external validation, they tended to outperform risk calculators not incorporating MRI findings (ERSPC and Prostate Cancer Prevention Trial) with good discriminative power (as measured by the AUC). However, they also tended to be miscalibrated with under- or over-prediction of the risk of ISUP grade ≥ 2 cancer [275, 276]. In one study that externally assessed four risk calculators combining MRI findings and clinical data, only two demonstrated a distinct net benefit when a risk of false-negative prediction of 15% was accepted. The others were harmful for this risk level, as compared to the ‘biopsy all’ strategy [275]. This illustrates the prevalence-dependence of risk models. Recalibrations taking into account the local prevalence are possible, but this approach is difficult in routine clinical practice as the local prevalence is difficult to estimate and may change over time.

Using risk-stratification to avoid MRI and biopsy procedures

A retrospective analysis including 200 men from a prospective database of patients who underwent MRI and combined systematic and targeted biopsy showed that upfront use of the Rotterdam Prostate Cancer Risk Calculator would have avoided MRI and biopsy in 73 men (37%). Of these 73 men, 10 had ISUP grade 1 cancer and 4 had ISUP grade ≥ 2 cancer [277]. A prospective multi-centre study evaluated several diagnostic pathways in 545 biopsy-naive men who underwent MRI and systematic and targeted biopsy. Using a PHI threshold of ≥ 30 to perform MRI and biopsy would have avoided MRI and biopsy in 25% of men at the cost of missing 8% of the ISUP grade ≥ 2 cancers [278]. Another prospective multi-centre trial including 532 men (with or without history of prostate biopsy) showed that using a threshold of ≥ 10% for the Stockholm3 test to perform MRI and biopsy would have avoided MRI and biopsy in 38% of men at the cost of missing 8% of ISUP grade ≥ 2 cancers [279].

5.2.4.2.6.4 Potential cancer grade shift, induced by improved diagnosis by MRI and MRI-targeted biopsy

Magnetic resonance imaging findings are significant predictors of adverse pathology features on prostatectomy specimens, and of survival-free BCR after RP or RT [84, 280-282]. In addition, tumours visible on MRI are enriched in molecular hallmarks of aggressivity, as compared to invisible lesions [283]. Thus, MRI does identify aggressive tumours.

Nonetheless, as MRI-targeted biopsy is more sensitive than systematic biopsy in detecting areas of high-grade cancer, ISUP grade ≥ 2 cancers detected by MRI-targeted biopsy are, on average, of better prognosis than those detected by the classical diagnostic pathway (Will Rogers phenomenon [86]). This is illustrated in a retrospective series of 1,345 patients treated by RP which showed that, in all risk groups, patients diagnosed by MRI-targeted biopsy had better BCR-free survival than those diagnosed by systematic biopsy only [84]. To mitigate this grade shift, in case of targeted biopsies, the 2019 ISUP consensus conference recommended using an aggregated ISUP grade summarizing the results of all biopsy cores from the same MR lesion, rather than using the result from the core with the highest ISUP grade [89]. When long-term follow-up of patients who underwent MRI-targeted biopsy is available, a revision of the risk-groups definition will become necessary. In the meantime, results of MRI-targeted biopsy must be interpreted in the context of this potential grade shift [284].

5.2.4.2.7 MRI and MRI-targeted biopsy results depend on the a priori risk of csPCa

The ‘MRI pathway’ is appealing since it could decrease the number of biopsy procedures, reduce the detection of low-grade PCa while maintaining (or even improving) the detection of csPCa, as compared to systematic biopsy. However, MRI findings must be interpreted in the light of the a priori risk of csPCa. Risk stratification combining clinical data, MRI findings and (maybe) other biomarkers will help, in the future, defining those patients that can safely avoid biopsy. Second, the inter-reader reproducibility of MRI is moderate at best. Current biopsy-targeting methods remain imprecise and their accuracy is substantially impacted by the operator’s experience. As a result, 3 to 5 biopsy cores per target may be needed to reduce the risk of missing or undersampling the lesion, even with US/MR fusion systems. Other ‘extended’ MRI-targeted and perilesional biopsy templates are being investigated (see Section 5.2.7.1.4). Third, the use of pre-biopsy MRI may induce grade shift, even with the use of an aggregated ISUP grade for each MR lesion targeted at biopsy (see Section 5.2.4.2.6). Clinicians must interpret MRI-targeted biopsy results in the context of this potential grade shift. A revision of the definitions of the risk groups will be needed in the future to take into account wider use of MRI and MRI-targeted biopsy.

Finally, it must be emphasized that the ‘MRI pathway’ has only been evaluated in patients in whom the risk of csPCa was judged high enough to deserve biopsy based on standard clinical assessment including PSA. Magnetic resonance imaging in individuals without any suspicion of PCa is likely to result in an increase in false-positive findings and subsequent unnecessary biopsies.
5.2.4.3 Guidelines for MRI imaging in biopsy decision

### Introductory statement

Systematic biopsy is an acceptable approach in case MRI is unavailable.

### Baseline biopsy decision

The need for prostate biopsy is based on PSA level, other biomarkers and/or suspicious DRE and/or imaging (see Section 5.2.4). Age, potential co-morbidity and therapeutic consequences should also be considered and discussed beforehand [253]. Risk stratification is a potential tool for reducing unnecessary biopsies [285].

Limited PSA elevation alone should not prompt immediate biopsy. Prostate-specific antigen level should be verified after a few weeks, in the same laboratory using the same assay under standardised conditions (i.e. no ejaculation, manipulations, and urinary tract infections [UTIs]) [286, 287]. Empiric use of antibiotics in an asymptomatic patient in order to lower the PSA should not be undertaken [288].

Ultrasound (US)-guided and/or MRI-targeted biopsy is now the SOC. Prostate biopsy is performed by either the transrectal or transperineal approach. Cancer detection rates, when performed without prior imaging with MRI, are comparable between the two approaches [257], however, some evidence suggests reduced infection risk with the transperineal route (see Section 5.2.8.1.1) [289, 290]. Transurethral resection of the prostate (TURP) should not be used as a tool for cancer detection [291].

### Repeat biopsy decision

#### 5.2.6.1 Repeat biopsy after previously negative biopsy

Men with a previous negative systematic biopsy should be offered a prostate MRI and in case of PIRADS > 3 findings, a repeat (targeted) biopsy has to be done. Other indications for repeat biopsy are:

- rising and/or persistently elevated PSA (see Table 5.3 for risk estimates);
- suspicious DRE, 5–30% PCa risk [179, 180];
- intraductal carcinoma as a solitary finding, > 90% risk of associated high-grade PCa [292];

In a contemporary series of biopsies the likelihood of finding a csPCa after follow-up biopsy after a diagnosis of atypical small acinar proliferation and high-grade prostatic intraepithelial neoplasia (PIN) was only 6-8%, not significantly different from follow-up biopsies after a negative biopsy [293, 294]. The added value of other biomarkers remains unclear (see Sections 5.2.3.1 and 5.2.3.2).

#### 5.2.6.2 Saturation biopsy

The incidence of PCa detected by saturation repeat biopsy (≥ 20 cores) is 30–43% and depends on the number of cores sampled during earlier biopsies [295]. Saturation biopsy may be performed with the transperineal technique, which detects an additional 38% of PCa. The rate of urinary retention varies substantially from 1.2% to 10% [296-299].
5.2.7 **Prostate biopsy procedure**

5.2.7.1 **Sampling sites and number of cores**

5.2.7.1.1 Ultrasound-guided systematic biopsy

For systematic biopsies, the sample sites should be bilateral from apex to base, as far posterior and lateral as possible in the peripheral gland regardless of the approach used. Sextant biopsy is no longer considered adequate. At least 8 systematic biopsies are recommended in prostates with a size of about 30 cc [3]. Ten to 12 core biopsies are recommended in larger prostates, with > 12 cores not being significantly more conclusive [300, 301].

Additional cores should be obtained from suspect areas identified by DRE or on pre-biopsy MRI; multiple (3–5) cores should be taken from each MRI-visible lesion (see Section 5.2.4.2.7.2). They can be obtained through cognitive guidance, US/MR fusion software or direct in-bore guidance. Current literature, including systematic reviews and meta-analyses, does not show a clear superiority of one image-guided technique over another [250, 302-305].

5.2.7.1.2 Ultrasound-guided saturation biopsy

In the setting of a positive MRI with targeted biopsy cores being taken, the addition of template cores may increase the detection of significant cancer slightly, but also increases the detection of insignificant cancer [103, 307]. The rationale for this must be carefully considered on an individual patient basis.

5.2.7.1.3 MRI-directed targeted biopsy

Where MRI has shown a suspicious lesion MR-targeted biopsy can be obtained through cognitive guidance, US/MR fusion software or direct in-bore guidance. Current literature, including systematic reviews and meta-analyses, does not show a clear superiority of one image-guided technique over another [250, 302-305]. However, regarding approach, the only systematic review and meta-analysis comparing MRI-targeted transrectal biopsy to MRI-targeted transperineal biopsy, analysing 8 studies, showed a higher sensitivity for detection of csPCa when the transperineal approach was used (86% vs. 73%) [306]. This benefit was especially pronounced for anterior tumours. Multiple (3–5) cores should be taken from each lesion (see Section 5.2.4.2.7.2).

5.2.7.1.4 Towards ‘extended’ MRI-directed biopsy?

As detailed in Section 5.2.4.2.6.2, the added value of systematic biopsy is partially explained by the fact that they compensate for guiding imprecisions of targeted biopsy. Therefore, biopsy strategies with multiple perilesional (regional) targeted cores obtained in addition of MRI-directed targeted cores are being investigated [261, 262, 307-310]. Prospective clinical trials are needed to evaluate whether these strategies can replace the combination of systematic and targeted biopsy currently recommended as the diagnostic work-up in men with positive MRI scans.

5.2.8.1 Antibiotics prior to biopsy

5.2.8.1.1 Transperineal prostate biopsy

A total of seven randomised studies including 1,330 patients compared the impact of biopsy route on infectious complications. Infectious complications were significantly higher following transrectal biopsy (37 events among 657 men) compared to transperineal biopsy (22 events among 673 men) (RR: 1.81 [range 1.09–3.00], 95% CI) [311-318]. In addition, a systematic review including 165 studies with 162,577 patients described sepsis rates of 0.1% and 0.9% for transperineal and transrectal biopsies, respectively [319]. Finally, a population-based study from the UK, including 486,467 biopsies over more than a decade from 2008-2019, showed lower rates of sepsis and infection with transperineal vs. transrectal biopsy (0.53% vs. 0.31%, p ≤ 0.001) [320]. The available evidence demonstrates that the transrectal approach should be abandoned in favour of the transperineal approach despite any possible logistical challenges.

To date, no RCT has been published investigating different antibiotic prophylaxis regimens for transperineal prostate biopsy. However, as it is a clean procedure that avoids rectal flora, quinolones or other antibiotics to cover rectal flora may not be necessary. A single dose of cephalosporin only to cover skin commensals has been shown to be sufficient in multiple single cohort series [299, 321]. Prior negative mid-stream urine test and routine surgical disinfecting preparation of the perineal skin are mandatory. In one of the largest studies to date, 1,287 patients underwent transperineal biopsy under local anaesthesia only [322]. Antibiotic prophylaxis consisted of a single oral dose of either cefuroxime or cephalexin. Patients with cardiac valve replacements received amoxycillin and gentamicin, and those with severe penicillin allergy received sulphamethoxazole. No quinolones were used. Only one patient developed a UTI with positive urine culture and there was no urosepsis requiring hospitalisation.

In another study of 577 consecutive patients undergoing transperineal biopsy using single dose IV cephalozin prophylaxis, one patient (0.2%) suffered prostatitis not requiring hospitalisation [299]. There were no incidences of sepsis. In a further study of 485 patients using only cephazolin, 4 patients (0.8%) suffered infectious complications [323].

5.2.8.1.2 Transrectal prostate biopsy

Meta-analysis of eight RCTs including 1,786 men showed that use of a rectal povidone-iodine preparation before biopsy, in addition to antimicrobial prophylaxis, resulted in a significantly lower rate of infectious complications (RR: 0.55, 95% CI: 0.41–0.72) [318, 324-329]. Single RCTs showed no evidence of benefit for perineal skin disinfection [330], but reported an advantage for rectal povidone-iodine preparation before biopsy compared to after biopsy [331].

A meta-analysis of four RCTs including 671 men evaluated the use of rectal preparation by enema before transrectal biopsy. No significant advantage was found regarding infectious complications (RR: 0.96, 95% CI: 0.64–1.54) [318, 332-334].

A meta-analysis of 26 RCTs with 3,857 patients found no evidence that use of peri-prostatic injection of local anaesthesia resulted in more infectious complications than no injection (RR: 1.07, 95% CI: 0.77–1.48) [318]. A meta-analysis of 9 RCTs including 2,230 patients found that extended biopsy templates showed comparable infectious complications to standard templates (RR: 0.80, 95% CI: 0.53–1.22) [318]. Additional meta-analyses found no difference in infections complications regarding needle guide type (disposable vs. reusable), needle type (coaxial vs. non-coaxial), needle size (large vs. small), and number of injections for peri-prostatic nerve block (standard vs. extended) [318].

A meta-analysis of eleven studies including 1,753 patients showed significantly reduced infections after transrectal prostate biopsy when using antimicrobial prophylaxis as compared to placebo/control (RR: 0.56, 95% CI: 0.40–0.77) [335].

Fluoroquinolones have been traditionally used for antibiotic prophylaxis in this setting; however, overuse and misuse of fluoroquinolones has resulted in an increase in fluoroquinolone resistance. In addition, the European Commission has implemented stringent regulatory conditions regarding the use of fluoroquinolones resulting in the suspension of the indication for peri-operative antibiotic prophylaxis including prostate biopsy [336].

A systematic review and meta-analysis on antibiotic prophylaxis for the prevention of infectious complications following prostate biopsy concluded that in countries where fluoroquinolones are allowed as antibiotic prophylaxis, a minimum of a full one-day administration, as well as targeted therapy in case of fluoroquinolone resistance, or augmented prophylaxis (combination of two or more different classes of antibiotics) is recommended [335]. In countries where use of fluoroquinolones are suspended, cephalosporins or aminoglycosides can be used as individual agents with comparable infectious complications based on a meta-analysis of two RCTs [335]. A meta-analysis of three RCTs reported that fosfomycin trometamol was superior to fluoroquinolones (RR: 0.49, 95% CI: 0.27–0.87) [335], but routine general use should be critically
assessed due to the relevant infectious complications reported in non-randomised studies [337]. Another possibility is the use of augmented prophylaxis without fluoroquinolones, although no standard combination has been established to date. Finally, targeted prophylaxis based on rectal swap/stool culture is plausible, but no RCTs are available on non-fluoroquinolones. See figure 5.1 for prostate biopsy workflow to reduce infections complications.

Based on a meta-analysis, suggested antimicrobial prophylaxis before transrectal biopsy may consist of:

1. Targeted prophylaxis - based on rectal swab or stool culture.
2. Augmented prophylaxis - two or more different classes of antibiotics (of note: this option is against antibiotic stewardship programmes).
3. Alternative antibiotics:
   - fosfomycin trometamol (e.g., 3 g before and 3 g 24–48 hrs. after biopsy);
   - cephalosporin (e.g., ceftriaxone 1 g i.m; cefixime 400 mg p.o for 3 days starting 24 hrs. before biopsy) aminoglycoside (e.g., gentamicin 3 mg/kg i.v.; amikacin 15 mg/kg i.m).

*Note on strength ratings:
The above strength ratings are explained here due to the major clinical implications of these new recommendations. Although data showing the lower risk of infection via the transperineal approach is low in certainty, its statistical and clinical significance warrants its Strong rating. Strong ratings are also given for routine surgical disinfection of skin in transperineal biopsy and povidone-iodine rectal cleansing in transrectal biopsy as, although quality of data is low, the clinical benefit is high and practical application simple. A ‘Strong’ rating is given for avoiding fluoroquinolones in prostate biopsy due to its legal implications in Europe.

5.2.8.3 Local anaesthesia prior to biopsy

Ultrasound-guided peri-prostatic block is recommended [339]. It is not important whether the depot is apical or basal. Intra-rectal instillation of local anaesthesia is inferior to peri-prostatic infiltration [340]. Local anaesthesia can also be used effectively for MRI-targeted and systemic transperineal biopsy [341]. Patients are placed in the lithotomy position. Bupivacaine is injected into the perineal skin and subcutaneous tissues, followed two minutes later by a peri-prostatic block. A systematic review evaluating pain in 3 studies comparing transperineal vs. transrectal biopsies found that the transperineal approach significantly increased patient pain (RR: 1.83 [1.27–2.65]) [342]. In a randomised comparison a combination of peri-prostatic and pudendal block anaesthesia reduced pain during transperineal biopsies compared to peri-prostatic anaesthesia only [343]. Targeted biopsies can then be taken via a brachytherapy grid or a freehand needle-guiding device under local infiltration anaesthesia [341, 344, 345].

5.2.8.4 Complications

Complications of TRUS biopsy are listed in Table 5.6 [316]. Mortality after prostate biopsy is extremely rare and most are consequences of sepsis [126]. Low-dose aspirin is no longer an absolute contraindication [346].
A systematic review found favourable infection rates for transperineal compared to TRUS biopsies with similar rates of haematuria, haematospermia and urinary retention [347]. A meta-analysis of 4,280 men randomised between transperineal vs. TRUS biopsies in 13 studies found no significant differences in complication rates, however, data on sepsis compared only 497 men undergoing TRUS biopsy to 474 having transperineal biopsy. The transperineal approach required more (local) anaesthesia [348].

5.2.8.5 Seminal vesicle biopsy

Indications for SV (staging) biopsies are poorly defined. At a PSA of > 15 ng/mL, the odds of tumour involvement are 20–25% [349]. A SV staging biopsy is only useful if it has a decisive impact on treatment, such as ruling out radical tumour resection or for potential subsequent RT. Its added value compared with MRI is questionable.

5.2.8.6 Transition zone biopsy

Transition zone sampling during baseline biopsies has a low detection rate and should be limited to MRI-detected lesions or repeat biopsies [350].

5.2.9 Pathology of prostate needle biopsies

5.2.9.1 Processing

Prostate core biopsies from different sites are processed separately. Before processing, the number and length of the cores are recorded. The length of biopsy tissue significantly correlates with the PCa detection rate [351]. To achieve optimal flattening and alignment, a maximum of three cores should be embedded per tissue cassette, and sponges or paper used to keep the cores stretched and flat [352, 353]. To optimise detection of small lesions and improve accuracy of grading, paraffin blocks should be cut at three levels and intervening unstained sections may be kept for immunohistochemistry (IHC) [354].

5.2.9.2 Microscopy and reporting

Diagnosis of PCa is based on histology. The diagnostic criteria include features pathognomonic of cancer, major and minor features favouring cancer and features against cancer. Ancillary staining and additional (deeper) sections should be considered if a suspect lesion is identified [354-356]. Diagnostic uncertainty is resolved by intradepartamental or external consultation [354]. Section 5.2.8.3 lists the recommended terminology for reporting prostate biopsies [352]. Type and subtype of PCa should be reported such as for instance acinar adenocarcinoma (> 95% of PCa), ductal adenocarcinoma (< 5%) and poorly differentiated small or large cell neuroendocrine carcinoma (< 1%), even if representing a small proportion of the PCa. The distinct aggressive nature of ductal adenocarcinoma and small/large cell neuroendocrine carcinoma should be commented upon in the pathology report [352]. Considerable evidence has been accumulated in recent years supporting that among the Gleason grade 4 patterns, the expansile cribriform pattern carries an increased risk of biochemical recurrence, metastatic disease and death of disease [357, 358]. Reporting of this sub-pattern based on established criteria is recommended [89, 359]. Intraductal carcinoma, defined as an extension of cancer cells into pre-existing prostatic ducts and acini, distending them, with preservation of basal cells [89], should be distinguished from high-grade PIN [360] as it conveys unfavourable prognosis in terms of biochemical recurrence and cancer-specific survival (CSS) [361, 362]. Its presence should be reported, whether occurring in isolation or associated with adenocarcinoma [89].
5.2.9.2.1 Recommended terminology for reporting prostate biopsies [287]

Each biopsy site should be reported individually, including its location (in accordance with the sampling site) and histopathological findings, which include the histological type and the ISUP 2014 grade [88]. For MRI targeted biopsies consisting of multiple cores per target the aggregated (or composite) ISUP grade and percentage of high-grade carcinoma should be reported per targeted lesion [89]. If the targeted biopsies are negative, presence of specific benign pathology should be mentioned, such as dense inflammation, fibromuscular hyperplasia or granulomatous inflammation [89, 363]. A global ISUP grade comprising all systematic (non-targeted) and targeted biopsies is also reported (see Section 4.2). The global ISUP grade takes into account all biopsies positive for carcinoma, by estimating the total extent of each Gleason grade present. For instance, if three biopsy sites are entirely composed of Gleason grade 3 and one biopsy site of Gleason grade 4 only, the global ISUP grade would be 2 (i.e. GS 7[3+4]) or 3 (i.e. GS 7[4+3]), dependent on whether the extent of Gleason grade 3 exceeds that of Gleason grade 4, whereas the worse grade would be ISUP grade 4 (i.e. GS 8[4+4]). Recent publications demonstrated that global ISUP grade is somewhat superior in predicting prostatectomy ISUP grade [364] and BCR [365].

Lymphovascular invasion (LVI) and EPE must each be reported, if identified, since both carry unfavourable prognostic information [366-368].

The proportion of systematic (non-targeted) carcinoma-positive cores as well as the extent of tumour involvement per biopsy core correlate with the ISUP grade, tumour volume, surgical margins and pathologic stage in RP specimens and predict BCR, post-prostatectomy progression and RT failure. These parameters are included in nomograms created to predict pathologic stage and SV invasion after RP and RT failure [369-371]. A pathology report should therefore provide both the proportion of carcinoma-positive cores and the extent of cancer involvement for each core. The length in mm and percentage of carcinoma in the biopsy have equal prognostic impact [372]. An extent of > 50% of adenocarcinoma in a single core is used in some AS protocols as a cut off [373] triggering immediate treatment vs. AS in patients with ISUP grade 1 (see Section 6.1.1.2).

A prostate biopsy that does not contain glandular tissue should be reported as diagnostically inadequate. Mandatory elements to be reported for a carcinoma-positive prostate biopsy are:

- type of carcinoma;
- primary and secondary/worst Gleason grade (per biopsy site and global);
- International Society of Urological Pathology grade (global);
- percentage high-grade carcinoma (global);
- extent of carcinoma (in mm or percentage) (per biopsy site);
- if present: EPE, SV invasion, LVI, intraductal carcinoma/cribriform pattern, peri-neural invasion;
- For MRI-targeted biopsies with multiple cores report aggregate (or composite) ISUP grade and percentage high-grade carcinoma per targeted site;
- For carcinoma-negative MRI-targeted biopsy report specific benign pathology, e.g., fibromuscular hyperplasia or granulomatous inflammation, if present [89].

5.2.9.3 Tissue-based prognostic biomarker testing

After a comprehensive literature review and several panel discussions an ASCO-EAU-AUA multidisciplinary expert panel made recommendations regarding the use of tissue-based PCA biomarkers. The recommendations were limited to 5 commercially available tests (Oncotype Dx®, Prolaris®, Decipher®, Decipher PORTOS and ProMark®) with extensive validation in large retrospective studies and evidence that their test results might actually impact clinical decision-taking [374].
The selected commercially available tests significantly improved the prognostic accuracy of clinical multivariable models for identifying men who would benefit of AS and those with csPCa requiring curative treatment, as well as for guidance of patient management after RP. In addition, a few studies showed that tissue biomarker tests and MRI findings independently improved the detection of csPCa in an AS setting, but it remains unclear which men would benefit of both tests. Since the long-term impact of the use of these commercially available tests on oncological outcome remains unproven and prospective trials are largely lacking, the Panel concluded that these tests should not be offered routinely but only in subsets of patients where the test result provides clinically actionable information, such as for instance in men with favourable intermediate-risk PCa who might opt for AS or men with unfavourable intermediate-risk PCa scheduled for RT to decide on treatment intensification with hormonal therapy (HT).

5.2.9.4 Histopathology of radical prostatectomy specimens

5.2.9.4.1 Processing of radical prostatectomy specimens

Histopathological examination of RP specimens describes the pathological stage, histopathological type, grade and surgical margins of PCa. It is recommended that RP specimens are totally embedded to enable assessment of cancer location, multifocality and heterogeneity. For cost-effectiveness, partial embedding may also be considered, particularly for prostates > 60 g. The most widely accepted method includes complete embedding of the posterior prostate and a single mid-anterior left and right section. Compared with total embedding, partial embedding with this method missed 5% of positive margins and 7% of extraprostatic extension [375].

The entire RP specimen should be inked upon receipt in the laboratory to demonstrate the surgical margins. Specimens are fixed by immersion in buffered formalin for at least 24 hours, preferably before slicing. Fixation can be enhanced by injecting formalin which provides more homogeneous fixation and sectioning after 24 hours [376]. After fixation, the apex and the base (bladder neck) are removed and cut into (para)sagittal or radial sections; the shave method is not recommended [87]. The remainder of the specimen is cut in transverse, 3–4 mm sections, perpendicular to the long axis of the urethra. The resultant tissue slices can be embedded and processed as whole-mounts or after quadrant sectioning. Whole-mounts provide better topographic visualisation, faster histopathological examination and better correlation with pre-operative imaging, although they are more time-consuming and require specialist handling. For routine sectioning, the advantages of whole mounts do not outweigh their disadvantages.

5.2.9.4.2 Radical prostatectomy specimen report

The pathology report provides essential information on the prognostic characteristics relevant for clinical decision-making (Table 5.7). As a result of the complex information to be provided for each RP specimen, the use of synoptic(-like) or checklist reporting is recommended (Table 5.8). Synoptic reporting results in more transparent and complete pathology reporting [377].

5.2.9.4.3 ISUP grade in prostatectomy specimens

Grading of conventional prostatic adenocarcinoma using the (ISUP 2014 modified) Gleason system is the strongest prognostic factor for clinical behaviour and treatment response [88]. The ISUP grade is incorporated in nomograms that predict disease-specific survival (DSS) after prostatectomy [378].

The ISUP grade is based on the sum of the most and second-most dominant (in terms of volume) Gleason grade. ISUP grade 1 is GS 6. ISUP grades 2 and 3 represent carcinomas constituted of Gleason grade 3 and 4 components, with ISUP grade 2 when 50% of the carcinoma, or more, is Gleason grade 3 and ISUP grade 3 when the grade 4 component represents more than 50% of the carcinoma. In a carcinoma almost entirely composed of Gleason grade 3 the presence of a minor (< 5%) Gleason pattern 4 component is not included in the GS (ISUP grade 1), but its presence is commented upon.

ISUP grade 4 is largely composed of Gleason grade 4 and ISUP grade 5 of a combination of Gleason grade 4 and 5 or only Gleason grade 5. A global ISUP grade is given for multiple tumours, but a separate tumour focus with a higher ISUP grade should also be mentioned. Tertiary Gleason grade 5, if > 5% of the PCa volume, is an unfavourable prognostic indicator for BCR and should be incorporated in the ISUP grade. If less than 5% its presence should be mentioned in the report as minor grade component [89, 379].

5.2.9.4.4 Definition of extraprostatic extension

Extraprostatic extension is defined as carcinoma mixed with peri-prostatic adipose tissue, or tissue that extends beyond the prostate gland boundaries (e.g., neurovascular bundle, anterior prostate). Microscopic bladder neck invasion is considered EPE. It is useful to report the location and extent of EPE because the latter is related to recurrence risk [380].

There are no internationally accepted definitions of focal or microscopic, vs. non-focal or extensive EPE. Some describe focal as a few glands [381] or < 1 high-power field in one or at most two sections [382] whereas others measure the depth of extent in millimetres [383].
At the apex of the prostate, tumour mixed with skeletal muscle does not constitute EPE. In the bladder neck, microscopic invasion of smooth muscle fibres is not equated to bladder wall invasion, i.e. not as pT4, because it does not carry independent prognostic significance for PCa recurrence and should be recorded as EPE (pT3a) [384, 385]. Stage pT4 is only assigned when the tumour invades the bladder muscle wall as determined macroscopically [386].

5.2.9.4.5 PCa volume
The independent prognostic value of PCa volume in RP specimens has not been established [382, 387-390]. Nevertheless, a cut-off of 0.5 mL is traditionally used to distinguish insignificant from clinically relevant cancer [387]. Improvement in prostatic radio-imaging allows more accurate pre-operative measurement of cancer volume. It is recommended that at least the diameter/volume of the dominant tumour nodule should be assessed, or a rough estimate of the percentage of cancer tissue provided [391].

5.2.9.4.6 Surgical margin status
Surgical margin is an independent risk factor for BCR. Margin status is positive if tumour cells are in contact with the ink on the specimen surface. Margin status is negative if tumour cells are close to the inked surface [388] or at the surface of the tissue lacking ink. In tissues that have severe crush artefacts, it may not be possible to determine margin status [392].

Surgical margin is separate from pathological stage, and a positive margin is not evidence of EPE [393]. There is evidence for a relationship between margin extent and recurrence risk [394, 395]. However, some indication must be given of the multifocality and extent of margin positivity, such as the linear extent in mm of involvement: focal, ≤ 1 mm vs. extensive, > 1 mm [396], or number of blocks with positive margin involvement. Gleason score at the positive margin was found to correlate independently with outcome, and should be reported [394, 397].

5.3 Diagnosis - Clinical Staging
5.3.1 T-staging
The cT category used in the risk table only refers to the DRE finding. The imaging parameters and biopsy results for local staging are, so far, not part of the risk category stratification [398].

5.3.1.1 TRUS
Transrectal US is no more accurate at predicting organ-confined disease than DRE [399]. Some single-centre studies reported good results in local staging using 3D TRUS or colour Doppler but these good results were not confirmed by large-scale studies [400, 401].

5.3.1.2 MRI
T2-weighted imaging remains the most useful method for local staging on MRI. Pooled data from a meta-analysis showed a sensitivity and specificity of 0.57 (95% CI: 0.49–0.64) and 0.91 (95% CI: 0.88–0.93), 0.58 (95% CI: 0.47–0.68) and 0.96 (95% CI: 0.95–0.97), and 0.61 (95% CI: 0.54–0.67) and 0.88 (95% CI: 0.85–0.91), for EPE, SVI, and overall stage T3 assessment, respectively [402].

Detection of EPE and SVI seems more accurate at high field strength (3 Tesla) [402], while the added value of functional imaging remains debated [402, 403].

In 552 men treated by RP at seven different Dutch centres, MRI showed significantly higher sensitivity (51% vs. 12%; p < 0.001), and lower specificity (82% vs. 97%; p < 0.001) than DRE for non-organ confined disease. All risk groups redefined using MRI findings rather than DRE findings showed better BCR-free survival due to improved discrimination and the Will Roger’s phenomenon [404].

Traditionally, EPE/SVI is diagnosed on MRI using direct qualitative signs (e.g., irregular bulging of the prostate, capsular disruption, visible tumour within periprostatic fat, obliteration of the rectoprostatic angle, asymmetry of the neuromuscular bundles or focal low signal intensity in the SVs) [405]. With such subjective reading, experience of the reader remains of paramount importance [406] and the inter-reader agreement is moderate with kappa (κ) values ranging from 0.41 to 0.68 [407]. The length of tumour capsule contact (LCC) is also a significant predictor of EPE; it has the advantage of being quantitative, although the ideal cut-off value remains debated [408]. Several grading systems combining subjective qualitative signs and/or LCC into a score have shown good sensitivity for EPE (0.68–0.82) with substantial inter-reader agreement (κ = 0.63–0.74), but at the expense of decreased specificity (0.71–0.77); none of these scores has shown definitive superiority over the others [409].

Magnetic resonance imaging findings can improve the prediction of the pathological stage when combined with clinical and biopsy data. As a result, several groups developed multivariate risk calculators for predicting
EPE/SVI or positive surgical margins [410]. In external validation cohorts, these risk calculators showed significantly better discrimination than nomograms without MRI-based features [411-413]. However, they remain limited by substantial miscalibration and therefore their results must be interpreted with care.

Given its low sensitivity for focal (microscopic) EPE, MRI is not recommended for local staging in low-risk patients [414-416]. However, MRI can still be useful for treatment planning.

5.3.2 N-staging

5.3.2.1 Computed tomography and magnetic resonance imaging

Abdominal CT and T1-T2-weighted MRI indirectly assess nodal invasion by using LN diameter and morphology. However, the size of non-metastatic LNs varies widely and may overlap the size of LN metastases. Usually, LNs with a short axis > 8 mm in the pelvis and > 10 mm outside the pelvis are considered malignant. Decreasing these thresholds improves sensitivity but decreases specificity. As a result, the ideal size threshold remains unclear [417, 418]. Computed tomography and MRI sensitivity is less than 40% [419, 420]. Detection of microscopic LN invasion by CT is < 1% in patients with ISUP grade < 4 cancer, PSA < 20 ng/mL, or localised disease [421-423].

Diffusion-weighted MRI (DW-MRI) may detect metastases in normal-sized nodes, but a negative DW-MRI cannot rule out the presence of LN metastases, and DW-MRI provides only modest improvement for LN staging over conventional imaging [424].

5.3.2.2 Risk calculators incorporating MRI findings and clinical data

Because CT and MRI lack sensitivity for direct detection of positive LNs, nomograms combining clinical and biopsy findings have been used to estimate the risk of patients harbouring positive LNs [425-427]. Although these nomograms are associated with good performance, they have been developed using systematic biopsy findings and may therefore not be appropriate for patients diagnosed with combined MRI-targeted biopsy and systematic biopsy.

Two models incorporating MRI-targeted biopsy findings and MRI-derived findings recently underwent external validation [428, 429]. One model was tested on an external cohort of 187 patients with a prevalence of LN invasion of 13.9% (vs. 16.9% in the development cohort). The C-index was 0.73 (vs. 0.81 in the development cohort); at calibration analysis, the model tended to overpredict the actual risk [428]. The other model was validated in an external multi-centre cohort of 487 patients with a prevalence of 8% of LN invasion (vs. 12.5% in the development cohort). The AUC was 0.79 (vs. 0.81 in the development cohort). Using a risk cut-off of 7% would have avoided LN dissection in 273 (56% of the cohort), while missing LN invasion in 7 patients (2.6% of the patients below the 7% threshold; 18% of the 38 patients with LN invasion) [430]. Therefore, this nomogram and a 7% threshold should be used after MRI-targeted biopsy to identify candidates for extended lymph node dissection (eLND).

5.3.2.3 Choline PET/CT

In a meta-analysis of 609 patients, pooled sensitivity and specificity of choline PET/CT for pelvic LN metastases were 62% (95% CI: 51–66%) and 92% (95% CI: 89–94%), respectively [431]. In a prospective trial of 75 patients at intermediate risk of nodal involvement (10–35%), the sensitivity was only 8.2% at region-based analysis and 18.9% at patient-based analysis, which is too low to be of clinical value [432]. The sensitivity of choline PET/CT increases to 50% in patients at high risk and to 71% in patients at very high risk, in both cases out-performing contrast-enhanced CT [433]. Comparisons between choline PET/CT and DW-MRI yielded contradictory results [432, 434-436].

Due of its low sensitivity, choline PET/CT does not reach clinically acceptable diagnostic accuracy for detection of LN metastases, or to rule out a nodal dissection based on risk factors or nomograms (see Section 6.3.4.1.2).

5.3.2.4 Prostate-specific membrane antigen-based PET/CT

Prostate-specific membrane antigen (PSMA) positron-emission tomography (PET)/CT uses several different radiopharmaceuticals; most published studies used 68 Ga-labelling for PSMA PET imaging, but some used 18F-labelling. At present there are no conclusive data about comparison of such tracers, with additional new radiotracers being developed. Prostate-specific membrane antigen is also an attractive target because of its specificity for prostate tissue, even if the expression in other non-prostatic malignancies or benign conditions may cause incidental false-positive findings [437-441].

A prospective, multi-centre study addressed the use of 68Ga-PSMA PET/CT in patients with newly diagnosed PCa and negative bone scan findings. Positron-emission tomography was positive in 17 patients, resulting in a per-patient-based sensitivity and specificity of 41.5% (95% CI: 26.7–57.8) and 90.9% (95% CI: 79.3–96.6), respectively. A treatment change occurred in 12.6% of patients [442]. Another prospective multi-centre trial
investigated the diagnostic accuracy of $^{18}$F-DCFPyL PET/CT for LN staging in 117 patients with primary PCa, prior to RP with ePLND. $^{18}$F-DCFPyL PET/CT showed a high specificity (94.0%; CI: 86.9–97.5%), and a limited sensitivity (41.2%; CI: 19.4–66.5%) for the detection of pelvic LN metastases [443]. Comparable results were demonstrated in a phase II/III prospective, multi-centre study (OSPREY). In 252 evaluable patients with high risk of PCa who underwent RP with PLND, $^{18}$F-DCFPyL PET/CT showed a median specificity of 97.9% (95% CI: 94.5–99.4%) and median sensitivity of 40.3% (28.1–52.5%) for pelvic nodal involvement [444]. This suggests that current PSMA-based PET/CT imaging cannot yet replace diagnostic ePLND.

Prostate-specific antigen may be a predictor of a positive PSMA PET/CT. In the primary staging cohort from a meta-analysis, however, no robust estimates of positivity were found [445]. The tracer uptake is also influenced by the ISUP grade. Similarly, patients with PSA levels ≥ 10 ng/mL showed significantly higher uptake than those with PSA levels < 10 ng/mL [446].

Comparison between PSMA PET/CT and MRI was performed in a systematic review and meta-analysis including 13 studies (n = 1,597) [447]. $^{68}$Ga-PSMA was found to have a higher sensitivity and a comparable specificity for staging pre-operative LN metastases in intermediate- and high-risk PCa. Another prospective trial reported superior sensitivity of PSMA PET/CT as compared to MRI for nodal staging of 36 high-risk PCa patients [448].

PSMA PET/CT has a good sensitivity and specificity for LN involvement, possibly impacting clinical decision-making. In a review and meta-analysis including 37 articles, a subgroup analysis was performed in patients undergoing PSMA PET/CT for primary staging. On a per-patient-based analysis, the sensitivity and specificity of $^{68}$Ga-PSMA PET were 77% and 97%, respectively, after eLND at the time of RP. On a per-lesion-based analysis, sensitivity and specificity were 75% and 99%, respectively [445].

In summary, PSMA PET/CT is more appropriate in N-staging as compared to MRI, abdominal contrast-enhanced CT or choline PET/CT; however, small LN metastases, under the spatial resolution of PET (~5 mm), may still be missed.

5.3.2.5 Risk calculators incorporating MRI and PSMA findings

Recently, an international, multi-centre study incorporated PSMA PET into existing nomograms in order to predict pelvic LN metastatic disease in PCa patients. Performance of 3 nomograms was assessed in 757 patients undergoing RARP and ePLND. Addition of PSMA PET to the nomograms substantially improved the discriminative ability of the models yielding cross-validated AUCs of 0.76 (95% CI: 0.70–0.82), 0.77 (95% CI: 0.72–0.83), and 0.82 (95% CI: 0.76–0.87), respectively [449].

5.3.3 M-staging

5.3.3.1 Bone scan

$^{99m}$Tc-Bone scan is a highly sensitive conventional imaging technique, evaluating the distribution of active bone formation in the skeleton related to malignant and benign disease. A meta-analysis showed combined sensitivity and specificity of 79% (95% CI: 73–83%) and 82% (95% CI: 78–85%) at patient level [450]. Bone scan diagnostic yield is significantly influenced by the PSA level, the clinical stage and the tumour ISUP grade [417, 451]. A retrospective study investigated the association between age, PSA and GS in 703 newly diagnosed PCa patients who were referred for bone scintigraphy. The incidence of bone metastases increased substantially with rising PSA and upgrading GS [452]. In two studies, a dominant Gleason pattern of 4 was found to be a significant predictor of positive bone scan [453, 454]. Bone scanning should be performed in symptomatic patients, independent of PSA level, ISUP grade or clinical stage [417].

5.3.3.2 Fluoride PET and PET/CT, choline PET/CT and MRI

$^{18}$F-sodium fluoride ($^{18}$F-NaF) PET or PET/CT, similarly to bone scintigraphy, only assesses the presence of bone metastases. $^{18}$F-NaF PET or PET/CT was reported to have similar specificity and superior sensitivity to bone scintigraphy for detecting bone metastases in patients with newly diagnosed high-risk PCa [455, 456]. However, in a prospective study $^{18}$F-NaF PET showed no added value over bone scintigraphy in patients with newly diagnosed intermediate- or high-risk PCa and negative bone scintigraphy results [457]. Recently, the interobserver agreement for the detection of bone metastases and the accuracy of $^{18}$F-NaF PET/CT in the diagnosis of bone metastases were investigated. Bone metastases were identified in 211 out of 219 patients with an excellent interobserver agreement, demonstrating that $^{18}$F-NaF PET/CT is a robust tool for the detection of osteoblastic lesions in patients with PCa [458].

It remains unclear whether choline PET/CT is more sensitive than bone scan but it has higher specificity with fewer indeterminate bone lesions [446, 459, 460]. Choline PET/CT has also the advantage of detecting visceral and nodal metastases.

Diffusion-weighted whole-body and axial skeleton MRI are more sensitive than bone scan and targeted conventional radiography in detecting bone metastases in high-risk PCa. Whole-body MRI can also
detect visceral and nodal metastases; it was shown to be more sensitive and specific than combined bone scan, targeted radiography and abdominopelvic CT [461].

A meta-analysis found that whole-body MRI is more sensitive than choline PET/CT and bone scan for detecting bone metastases on a per-patient basis, although choline PET/CT had the highest specificity [450].

5.3.3.3 Prostate-specific membrane antigen-based PET/CT

A systematic review including 12 studies (n = 322) reported high variation in 68 Ga-PSMA PET/CT sensitivity for initial staging (range 33–99%; median sensitivity on per-lesion analysis 33–92%, and on per-patient analysis 66–91%), with good specificity (per-lesion 82–100%, and per-patient 67–99%), with most studies demonstrating increased detection rates with respect to conventional imaging modalities (bone scan and CT) [462]. Table 5.9 reports the data of the 5 studies including histopathologic correlation.

Table 5.9: PSMA PET/CT results in primary staging alone [462]

NPV = negative predictive value; PPV = positive predictive value.

One prospective multi-centre study evaluated changes in planned management before and after PSMA PET/CT in 108 intermediate- and high-risk patients referred for primary staging. As compared to conventional staging, additional LNs and bone/visceral metastases were detected in 25% and 6% of patients, respectively [463]; management changes occurred in 21% of patients. A retrospective review investigated the risk of metastases identified by 68 Ga-PSMA at initial staging in 1,253 patients (high-risk disease in 49.7%) [464]. Metastatic disease was identified by PSMA PET/CT in 12.1% of men, including 8.2% with a PSA level of < 10 ng/mL and 43% with a PSA level of > 20 ng/mL. Lymph node metastases were suspected in 107 men, with 47.7% outside the boundaries of an ePLND. Bone metastases were identified in 4.7%. In men with intermediate-risk PCa metastases were identified in 5.2%, compared to 19.9% with high-risk disease.

In the PSMA PET/CT prospective multi-centre study in patients with high-risk PCa before curative-intent surgery or RT (proPSMA), 302 patients were randomly assigned to conventional imaging with CT and bone scintigraphy or 68 Ga-PSMA-11 PET/CT. The primary outcome focused on the accuracy of first-line imaging for the identification of pelvic LN or distant metastases, using a predefined reference standard consisting of histopathology, imaging, and biochemistry at 6-month follow-up. Accuracy of 68 Ga-PSMA PET/CT was 27% (95% CI: 23–31) higher than that of CT and bone scintigraphy (92% [88–95] vs. 65% [60–69]; p < 0.0001). Conventional imaging had a lower sensitivity (38% [24–52] vs. 85% [74–96]) and specificity (91% [85–97] vs. 98% [95–100]) than PSMA PET/CT. Furthermore, 68 Ga-PSMA PET/CT scan prompted management change more frequently as compared to conventional imaging (41 [28%] men [21–36] vs. 23 [15%] men [10–22], p = 0.08), with less equivocal findings (7% [4–13] vs. 23% [17–31]) and lower radiation exposure (8.4 mSv vs. 19.2 mSv; p < 0.001) [465]. In a small study 18F-PSMA-1007 PET/CT proved superior to whole-body MRI with DWI and Single-photon Emission Computed Tomography (SPECT) CT [466].

5.3.4 Summary of evidence and practical considerations on initial N/M staging

The field of non-invasive N- and M-staging of PCa patients is evolving very rapidly. Evidence shows that choline PET/CT, PSMA PET/CT and whole-body MRI provide a more sensitive detection of LN- and bone metastases than the classical work-up with bone scan and abdominopelvic CT. In view of the evidence offered by the randomised, multi-centre proPSMA trial [465], replacing bone scan and abdominopelvic CT by more sensitive imaging modalities may be a consideration in patients with high-risk PCa undergoing initial staging. However, in absence of prospective studies demonstrating survival benefit, caution must be used when taking therapeutic decisions [467]. The prognosis and ideal management of patients diagnosed as metastatic by these more sensitive tests is unknown. In particular, it is unclear whether patients with metastases detectable only with PET/CT or whole-body MRI should be managed using systemic therapies, or whether they should be subjected to aggressive local and metastases-directed therapies [468].

Results from RCTs evaluating the management and outcome of patients with (and without) metastases detected by choline PET/CT, PSMA PET/CT and MRI are awaited before a decision can be made to treat patients based on the results of these tests [469].

5.4 Estimating life expectancy and health status

5.4.1 Introduction

Evaluation of life expectancy and health status is important in clinical decision-making for screening, diagnosis, and treatment of PCa. Prostate cancer is common in older men (median age 68) and diagnoses in men > 65 will result in a 70% increase in annual diagnosis by 2030 in Europe and the USA [470, 471]. Active treatment mostly benefits patients with intermediate- or high-risk PCa and longest expected survival. In localised disease, over 10 years life expectancy is considered mandatory for any benefit from local treatment and an improvement in CSS may take longer to become apparent. Older age and worse baseline health status have been associated with a smaller benefit in PCa-specific mortality (PCSM) and life expectancy of surgery vs. AS [472]. Although in a RCT the benefit of surgery with respect to death from PCa was largest in men < 65 years of age (RR: 0.45), RP was associated with a reduced risk of metastases and use of androgen deprivation therapy (ADT) among older men (RR: 0.68 and 0.60, respectively) [473]. External beam RT shows similar cancer control regardless of age, assuming a dose of > 72 Gy when using intensity-modulated or image-guided RT [474].

Older men have a higher incidence of PCa and may be under-treated despite the high overall mortality rates [475, 476]. Of all PCa-related deaths 71% occur in men aged > 75 years [477], probably due to the higher incidence of advanced disease and death from PCa despite higher death rates from competing causes [478-480]. In the USA, only 41% of patients aged > 75 years with intermediate- and high-risk disease received curative treatment compared to 88% aged 65–74 [481].

5.4.2 Life expectancy

Life expectancy tables for European men are available online: https://ec.europa.eu/eurostat/web/products-datasets/-/tps00205. Survival may be variable and therefore estimates of survival must be individualised. Gait speed is a good single predictive method of life expectancy (from a standing start, at usual pace, generally over 6 meters). For men at age 75, 10-year survival ranged from 19% < 0.4 m/s to 87%, for ≥ 1.4 m/s [482].
5.4.3 Health status screening

Heterogeneity increases with advancing age, so it is important to use measures other than just age or performance status (PS) when considering treatment options. The International SIOG PCa Working Group recommends that treatment for adults over 70 years of age should be based on a systematic evaluation of health status using the G8 (Geriatric 8) screening tool (see Table 5.10) [151]. This tool helps to discriminate between those who are fit and those with frailty, a syndrome of reduced ability to respond to stressors. Patients with frailty have a higher risk of mortality and negative side effects of cancer treatment [483]. Healthy patients with a G8 score > 14 or vulnerable patients with reversible impairment after resolution of their geriatric problems should receive the same treatment as younger patients. Frail patients with irreversible impairment should receive adapted treatment. Patients who are too ill should receive only palliative treatment (see Figure 5.3) [151]. Patients with a G8 score ≤ 14 should undergo a comprehensive geriatric assessment (CGA) as this score is associated with 3-year mortality. A CGA is a multi-domain assessment that includes co-morbidity, nutritional status, cognitive and physical function, and social supports to determine if impairments are reversible [484]. A systematic review of the effect of geriatric evaluation for older cancer patients showed improved treatment tolerance and completion [485].

The Clinical Frailty Scale (CFS) is another screening tool for frailty (see Figure 5.4) [486]. Although not frequently used in the cancer setting, it is considered to be a common language for expressing degree of frailty. The scale runs from 1 to 9, with higher scores indicating increasing frailty. Patients with a higher CFS score have a higher 30-day mortality after surgery and are less likely to be discharged home [487].

It is important to use a validated tool to identify frailty, such as the G8 or CFS, as clinical judgement has been shown to be poorly predictive of frailty in older patients with cancer [488].

5.4.3.1 Co-morbidity

Co-morbidity is a major predictor of non-cancer-specific death in localised PCa treated with RP and is more important than age [489, 490]. Ten years after not receiving active treatment for PCa, most men with a high co-morbidity score had died from competing causes, irrespective of age or tumour aggressiveness [489]. Measures for co-morbidity include: Cumulative Illness Score Rating-Geriatrics (CISR-G) [491, 492] (Table 5.11) and Charlson Co-morbidity Index (CCI) [493].

5.4.3.2 Nutritional status

Malnutrition can be estimated from body weight during the previous 3 months (good nutritional status < 5% weight loss; risk of malnutrition: 5–10% weight loss; severe malnutrition: > 10% weight loss) [494].
5.4.3.3 Cognitive function

Cognitive impairment can be screened for using the mini-COG (https://mini-cog.com/) which consists of three-word recall and a clock-drawing test and can be completed within 5 minutes. A score of ≤ 3/5 indicates the need to refer the patient for full cognitive assessment. Patients with any form of cognitive impairment (e.g., Alzheimer's or vascular dementia) may need a capacity assessment of their ability to make an informed decision, which is an increasingly important factor in health status assessment [495-497]. Cognitive impairment also predicts risk of delirium, which is important for patients undergoing surgery [498].

5.4.3.4 Physical function

Measures for overall physical functioning include: Karnofsky score and ECOG scores [499]. Measures for dependence in daily activities include: Activities of Daily Living (ADL; basic activities) and Instrumental Activities of Daily Living (IADL; activities requiring higher cognition and judgement) [500-502].

5.4.3.5 Shared decision-making

The patient's own values and preferences should be taken into account as well as the above factors. A shared decision-making process also involves anticipated changes to QoL, functional ability, and a patient’s hopes, worries and expectations about the future [503]. Particularly in older and frail patients, these aspects should be given equal importance to disease characteristics during the decision-making process [504]. Older patients may also wish to involve family members, and this is particularly important where cognitive impairment exists.

5.4.4 Conclusion

Individual life expectancy, health status, frailty, and co-morbidity, not only age, should be central in clinical decisions on screening, diagnostics, and treatment for PCa. A life expectancy of 10 years is most commonly used as a threshold for benefit of local treatment. Older men may be undertreated. Patients aged 70 years of age or older who have frailty should receive a comprehensive geriatric assessment. Resolution of impairments in vulnerable men allows a similar urological approach as in fit patients.

SCORING FRAILTY IN PEOPLE WITH DEMENTIA

The degree of frailty generally corresponds to the degree of dementia. Common symptoms in mild dementia include forgetting the details of a recent event, though still remembering the event itself, repeating the same question/story and social withdrawal.

In moderate dementia, recent memory is very impaired, even though they seemingly can remember their past life events well. They can do personal care with prompting. In severe dementia, they cannot do personal care without help. In very severe dementia they are often bedfast. Many are virtually mute.

6. TREATMENT

This chapter reviews the available treatment modalities, followed by separate sections addressing treatment for the various disease stages.

6.1 Treatment modalities

6.1.1 Deferred treatment (active surveillance/watchful waiting)

In localised disease a life expectancy of at least 10 years is considered mandatory for any benefit from active treatment. Data are available on patients who did not undergo local treatment with up to 25 years of follow-up, with endpoints of OS and CSS. Several series have shown a consistent CSS rate of 82–87% at 10 years [506-511], and 80–95% for T1/T2 and ISUP grade ≤ 2 PCas [512]. In three studies with data beyond 15 years, the DSS was 80%, 79% and 58% [508, 510, 511], and two reported 20-year CSS rates of 57% and 32%, respectively [508, 510]. The observed heterogeneity in outcomes is due to differences in inclusion criteria, with some older studies from the pre-PSA era showing worse outcomes [510]. In addition, many patients classified as ISUP grade 1 would now be classified as ISUP grade 2–3 based on the 2005 Gleason classification, suggesting that the above-mentioned results should be considered as minimal. Patients with well-, moderately- and poorly differentiated tumours had 10-year CSS rates of 91%, 90% and 74%, respectively, correlating with data from the pooled analysis [512]. Observation was most effective in men aged 65–75 years with low-risk PCa [513].
Co-morbidity is as important as age in predicting life expectancy in men with PCa. Increasing co-morbidity greatly increases the risk of dying from non-PCa-related causes and for those men with a short life expectancy. In an analysis of 19,639 patients aged > 65 years who were not given curative treatment, most men with a CCI score ≥ 2 had died from competing causes at 10 years follow-up regardless of their age at time of diagnosis. Tumour aggressiveness had little impact on OS suggesting that patients could have been spared biopsy and diagnosis of cancer. Men with a CCI score ≤ 1 had a low risk of death at 10 years, especially for well- or moderately-differentiated lesions [489]. This highlights the importance of assessing co-morbidity before considering a biopsy.

In screen-detected localised PCa the lead-time bias is likely to be greater. Mortality from untreated screen-detected PCa in patients with ISUP grade 1–2 might be as low as 7% at 15 years follow-up [514]. Consequently, approximately 45% of men with PSA-detected PCa are suitable for close follow-up through a robust surveillance programme. There are two distinct strategies for conservative management that aim to reduce over-treatment: AS and WW (Table 6.1.1).

### 6.1.1 Definitions

Active surveillance aims to avoid unnecessary treatment in men with clinically localised PCa who do not require immediate treatment, but at the same time achieve the correct timing for curative treatment in those who eventually do [515]. Patients remain under close surveillance through structured surveillance programmes with regular follow-up consisting of PSA testing, clinical examination, MRI imaging and repeat prostate biopsies, with curative treatment being prompted by pre-defined thresholds indicative of potentially life-threatening disease, which is still potentially curable, while considering individual life expectancy.

Watchful waiting refers to conservative management for patients deemed unsuitable for curative treatment from the outset, and patients are clinically “watched” for the development of local or systemic progression with (imminent) disease-related complaints, at which stage they are then treated palliatively according to their symptoms in order to maintain QoL.

### 6.1.1.2 Active surveillance

No formal RCT is available comparing this modality to standard treatment. The ProtecT trial is discussed later as it is not a formal AS strategy but rather active monitoring (AM), which is a significantly less stringent surveillance strategy in terms of clinical follow-up, imaging and repeat biopsies [516].

Several cohorts have investigated AS in organ-confined disease, the findings of which were summarised in a systematic review [517]. More recently, the largest prospective series of men with low-risk PCa managed by AS was published [518]. Table 6.1.2 summarises the results of selective AS cohorts. It is clear that the long-term OS and CSS of patients on AS are extremely good. However, more than one-third of patients are ‘reclassified’ during follow-up, most of whom undergo curative treatment due to disease upgrading, increase in disease extent, disease stage, progression or patient preference. There is considerable variation and heterogeneity between studies regarding patient selection and eligibility, follow-up policies (including frequency and type of imaging such as MRI imaging, type and frequency of repeat prostate biopsies, such as MRI-targeted biopsies or transperineal template biopsies, use of PSA kinetics and density, and frequency of clinical follow-up), when active treatment should be instigated (i.e. reclassification criteria) and which outcome measures should be prioritised [515]. These will be discussed further in section 6.2.1.

6.1.1.3 Watchful Waiting
6.1.1.3.1 Outcome of watchful waiting compared with active treatment
The SPCG-4 study was a RCT from the pre-PSA era, randomising patients to either WW or RP (Table 6.1.3) [526]. The study found RP to provide superior CSS, OS and PFS compared to WW at a median follow-up of 23.6 years (range 3 weeks–28 years). However, the benefit in favour of RP over WW was only apparent after 10 years. The PIVOT trial was a RCT conducted in the early PSA era and made a similar comparison between RP vs. WW in 731 men (50% with non-palpable disease) but in contrast to the SPCG-4, it found little, to no, benefit of RP (cumulative incidence of all-cause death, RP vs. observation: 68% vs. 73%; RR: 0.92, 95% CI: 0.84–1.01) within a median follow-up period of 18.6 years (interquartile range, 16.6 to 20 years) [527]. Exploratory subgroup analysis showed that the borderline benefit from RP was most marked for intermediate-risk disease (RR: 0.84, 95% CI: 0.73–0.98) but there was no benefit in patients with low- or high-risk disease. Overall, no adverse effects on health-related QoL (HRQoL) and psychological well-being was apparent in the first 5 years [528]. However, one of the criticisms of the PIVOT trial is the relatively high overall mortality rate in the WW group compared with more contemporary series. A Cochrane review performed a pooled analysis of RCTs comparing RP vs. WW [529]. Three studies were included (including the Veteran's Administration Cooperative Urological Research Group [VACURG] study which was conducted in the pre-PSA era [530], SPCG-4 and PIVOT). The authors found RP had lower overall mortality (HR: 0.79, 95% CI: 0.70–0.90) and lower cancer-specific mortality (HR: 0.57, 95% CI: 0.44–0.73) compared with WW at 29 years' follow-up. Radical prostatectomy also had lower risk of progression (HR: 0.43, 95% CI: 0.35–0.54) and lower risk of metastatic disease (HR: 0.56, 95% CI: 0.46–0.70). However, RP was associated with higher rates of urinary incontinence (RR: 3.97, 95% CI 2.34–6.74) and erectile dysfunction (ED) (RR: 2.67, 95% CI: 1.63–4.38).

The overall evidence indicates that for men with asymptomatic, clinically localised PCa and with a life expectancy of < 10 years based on co-morbidities and/or age, the oncological advantages of active treatment over WW are unlikely to be relevant to them. Consequently, WW should be adopted for such patients.

6.1.1.4 The ProtecT trial
The ProtecT trial randomised 1,643 patients into three arms: active treatment with either RP or EBRT, and active monitoring (AM) [525]. In this AM schedule patients with a PSA rise of more than 50% in 12 months underwent a repeat biopsy, but none had systematic repeat biopsies. Fifty-six percent of patients had low-risk disease, with 90% having a PSA < 10 ng/mL, 77% ISUP grade 1 (20% ISUP grade 2–3), and 76% T1c,
while the other patients had mainly intermediate-risk disease. After 10 years of follow-up, CSS was the same between those actively treated and those on AM (99% and 98.8%, respectively), as was the OS. Only metastatic progression differed (8% in the AM group as compared to 2.6% in the treated group). The key finding was that AM was as effective as active treatment at 10 years, at a cost of increased progression and double the metastatic risk. Metastases remained rare (6%), but more frequent than seen with AS protocols; probably driven by differences in intensity of monitoring and patient selection. It is important to note that the AM arm in ProtecT represented an intermediate approach between contemporary AS protocols and WW in terms of a monitoring strategy based almost entirely on PSA measurements alone; there was no use of MRI scan, either at recruitment or during the monitoring period, nor were there any protocol-mandated repeat prostate biopsies at regular intervals. In addition, approximately 40% of randomised patients had intermediate-risk disease. Nevertheless, the ProtecT study has reinforced the role of deferred active treatment (i.e., either AS or some form of initial AM) as a feasible alternative to active curative interventions in patients with low-grade and low-stage disease. Beyond 10 years, no data is available, as yet, although AS is likely to give more reassurance especially in younger men, based on more accurate risk stratification at recruitment and more stringent criteria regarding follow-up, imaging, repeat biopsy and reclassification. Individual life expectancy must be evaluated before considering any active treatment in low-risk patients and in those with up to 10 years’ individual life expectancy [531].

Recently, Bryant et al., performed a comprehensive characterisation of the ProtecT study cohort, stratifying patients at baseline according to risk of progression using clinical stage, grade at diagnosis and PSA level [531]. Additionally, detailed clinico-pathological information on participants who received RP were analysed. The authors aimed to test the hypothesis that the clinico-pathological features of participants with disease progression differed from those with stable disease in order to identify prognostic markers. The results showed that out of all patients who had been randomised (n = 1,643), 34% (n = 505) had intermediate- or high-risk disease, and 66% (n = 973) had low-risk disease. Out of all patients who had received AM, RP or RT within 12 months of randomisation (n = 1,607), at a median follow-up of 10 years, 12% of patients (n = 198) developed progression, of which 72% (n = 142) had undergone AM. Treatment received, age (65–69 vs. 50–64 years), PSA, GG at diagnosis, cT stage, risk group, number of PCa-involved biopsy cores, maximum length of tumour (median 5.0 vs. 3.0 mm), aggregate length of tumour (median 8.0 vs. 4.0 mm), and presence of perineural invasion were each associated with increased risk of disease progression (p < 0.001 for each). However, these factors could not reliably predict progression in individuals. Notably, 53% (n = 105) of patients who progressed had biopsy GG 1 disease, although, conversely, none of the participants who received RP and subsequently progressed had pathological GG 1 tumours. This discrepancy can be explained by inadequate sampling by PSA testing and 10-core TRUS-guided biopsies.

6.1.2 Radical prostatectomy
6.1.2.1 Introduction
The goal of RP by any approach is the eradication of cancer while, whenever possible, preserving pelvic organ function [532]. The procedure involves removing the entire prostate with its capsule intact and SVs, followed by vesico-urethral anastomosis. Surgical approaches have expanded from perineal and retropubic open approaches to laparoscopic and robotic-assisted techniques; anastomoses have evolved from Vest approximation sutures to continuous suture watertight anastomoses under direct vision and mapping of the anatomy of the dorsal venous complex (DVC) and cavernous nerves has led to excellent visualisation and potential for preservation of erectile function [533]. The main results from multi-centre RCTs involving RP are summarised in Table 6.1.4.

<th>Median FU (mo)</th>
<th>Risk category</th>
<th>CSS (%)</th>
</tr>
</thead>
</table>

CSS = cancer-specific survival; FU = follow-up; mo = months; PSA = prostate-specific antigen; yr. = year.
6.1.2.2 Pre-operative preparation

6.1.2.2.1 Pre-operative patient education

As before any surgery appropriate education and patient consent is mandatory prior to RP. Peri-operative education has been shown to improve long-term patient satisfaction following RP [535]. Augmentation of standard verbal and written educational materials such as use of interactive multimedia tools [536, 537] and pre-operative patient-specific 3D printed prostate models has been shown to improve patient understanding and satisfaction and should be considered to optimise patient-centred care [538].

6.1.2.2.2 Pre-operative pelvic floor exercises

Although many patients who have undergone RP will experience a return to urinary continence [539], temporary urinary incontinence is common early after surgery, reducing QoL. Pre-operative pelvic floor exercises (PFE) with, or without, biofeedback have been used with the aim of reducing this early post-operative incontinence. A systematic review and meta-analysis of the effect of pre-RP PFE on post-operative urinary incontinence showed a significant improvement in incontinence rates at 3 months post-operatively with an OR of 0.64 (p = 0.005), but not at 1 month or 6 months [540]. Pre-operative PFE may therefore provide some benefit, however the analysis was hampered by the variety of PFE regimens and a lack of consensus on the definition of incontinence.

6.1.2.2.3 Prophylactic antibiotics

Prophylactic antibiotics should be used; however, no high-level evidence is available to recommend specific prophylactic antibiotics prior to RP (see EAU Urological Infections Guidelines [541]). In addition, as the susceptibility of bacterial pathogens and antibiotic availability varies worldwide, any use of prophylactic antibiotics should adhere to local guidelines.

6.1.2.2.4 Neoadjuvant androgen deprivation therapy

Several RCTs have analysed the impact of neoadjuvant ADT before RP, most of these using a 3-month period. The main findings were summarised in a Cochrane review [542]. Neoadjuvant ADT is associated with a decreased rate of pT3 (downstaging), decreased positive margins, and a lower incidence of positive LNs. These benefits are greater with increased treatment duration (up to 8 months). However, since neither the PSA relapse-free survival nor CSS were shown to improve, neoadjuvant ADT should not be considered as standard clinical practice. One recent RCT compared neoadjuvant luteinising hormone-releasing hormone (LHRH) alone vs. LHRH plus abiraterone acetate plus prednisone (AAP) prior to RP in 65 localised high-risk PCA patients [543]. Patients in the combination arm were found to have both significantly lower tumour volume and significantly lower BCR at >4 years follow-up (p = 0.0014). A pooled analysis of 3 RCTs, including 117 patients and assessing the impact of intense neoadjuvant deprivation therapy has reported a complete pathological response rate of 9.4%, with improved BCR outcomes in complete responders [544]. Further supportive evidence is required before recommending combination neoadjuvant therapy including abiraterone prior to RP. Another RCT (CALGB 90203), comparing RP alone to RP with neoadjuvant chemo-hormonal therapy (CHT) including docetaxel for clinically high-risk localised PCa did not meet the study’s primary endpoint of biochemical PFS at 3 years post-operatively, due to contamination with early salvage RT. As a result, CHT is not currently recommended unless longer-term data show a survival benefit using clinical endpoints [545].

6.1.2.3 Surgical techniques

Prostatectomy can be performed by open-, laparoscopic- or robot-assisted (RARP) approaches. The initial open technique of RP described by Young in 1904 was via the perineum [533] but suffered from a lack of access to pelvic LNs. If lymphadenectomy is required during perineal RP it must be done via a separate open retropubic (RPP) or laparoscopic approach. The open retropubic approach was popularised by Walsh in 1982 following his anatomical description of the DVC, enabling its early control and of the cavernous nerves, permitting a bilateral nerve-sparing procedure [546]. This led to the demise in popularity of perineal RP and eventually to the first laparoscopic RP reported in 1997 using retropubic principles but performed transperitoneally [547]. The initial 9 cases averaged 9.4 hours, an indication of the significant technical and ergonomic difficulties of the technique. Most recently, RARP was introduced using the da Vinci Surgical System® by Binder in 2002 [548]. This technology combined the minimally-invasive advantages of laparoscopic RP with improved surgeon ergonomics and greater technical ease of suture reconstruction of the vesico-urethral anastomosis and has now become the preferred minimally-invasive approach, when available.

In a randomised phase III trial, RARP was shown to have reduced admission times and blood loss, but not earlier (12 weeks) functional or oncological outcomes compared to open RP [549]. An updated analysis with follow-up at 24 months did not reveal any significant differences in functional outcomes between the approaches [550]. Increased surgical experience has lowered the complication rates of RP and improved
cancer cure [510-513]. Lower rates of positive surgical margins for high-volume surgeons suggest that experience and careful attention to surgical details, can improve cancer control with RP [551-553]. There is a lack of studies comparing the different surgical modalities for these longer-term outcomes [509, 528, 534, 554]. A systematic review and meta-analysis of non-RCTs demonstrated that RARP had lower peri-operative morbidity and a reduced risk of positive surgical margins compared with laparoscopic prostatectomy (LRP), although there was considerable methodological uncertainty [555]. There was no evidence of differences in urinary incontinence at 12 months and there was insufficient evidence to draw conclusions based on differences in cancer-related, patient-driven or ED outcomes. Another systematic review and meta-analysis included two small RCTs comparing RARP vs. LRP [556]. The results suggested higher rates of return of erectile function (RR: 1.51, 95% CI: 1.19–1.92) and return to continence function (RR: 1.14, 95% CI: 1.04–1.24) in the RARP group. However, a Cochrane review comparing either RARP or LRP vs. open RP included two RCTs and found no significant differences between the comparisons for oncological-, urinary- and sexual function outcomes, although RARP and LRP both resulted in statistically significant improvements in duration of hospital stay and blood transfusion rates over open RP [557]. Therefore, no surgical approach can be recommended over another.

Outcome after prostatectomy has been shown to be dependent on both surgeon [558] as well as hospital volume [559]. Although various volume criteria have been set worldwide, the level of evidence is insufficient to pinpoint a specific lower volume limit.

6.1.2.3.1 Robotic anterior versus Retzius-sparing dissection
Robot-assisted RP has typically been performed via the anterior approach, first dropping the bladder to expose the space of Retzius. However, the posterior approach (Retzius-sparing [RS-RARP]) has been used to minimise injury to support structures surrounding the prostate.

Galfano et al., first described RS-RARP in 2010 [560]. This approach commences dissection posteriorly at the pouch of Douglas, first dissecting the SVs and progressing caudally behind the prostate. All of the anterior support structures are avoided, giving rise to the hypothetical mechanism for improved early post-operative continence. Retzius-sparing-RARP thus offers the same potential advantage as the open perineal approach, but without disturbance of the perineal musculature.

Retzius-sparing-RARP has been recently investigated in RCTs leading to four systematic reviews and meta-analyses [561-563] including a 2020 Cochrane systematic review [564] and a large propensity score matched analysis [565]. The Cochrane review used the most rigorous methodology and analysed 5 RCTs with 502 patients. It found with moderate certainty that RS-RARP improved continence at 1 week post catheter removal compared to standard RARP (RR: 1.74). Continence may also be improved at 3 months post-operatively (RR: 1.33), but this was based on low-certainty data. Continence outcomes appeared to equalise by 12 months (RR: 1.01). These findings matched those of the other systematic reviews. However, a significant concern was that RS-RARP appears to increase the risk of positive margins (RR: 1.95) but this was also low-certainty evidence. A single-surgeon propensity score matched analysis of 1,863 patients reached the same conclusion as the systematic reviews regarding earlier return to continence but did not show data on margin status [565].

Based on these data, recommendations cannot be made for one technique over another. However, the trade-offs between the risks of a positive margin vs. earlier continence recovery should be discussed with prospective patients. Furthermore, no high-level evidence is available on high-risk disease with some concerns that RS-RARP may confer an increased positive margin rate based on pT3 results. In addition, RS-RARP may be more technically challenging in various scenarios such as anterior tumours, post-TURP, a grossly enlarged gland, or a bulky median lobe [566].

6.1.2.3.2 Pelvic lymph node dissection
A systematic review demonstrated that performing PLND during RP failed to improve oncological outcomes, including survival [567]. Moreover, two RCTs have failed to show a benefit of an extended approach vs. a limited PLND on early oncologic outcomes [568, 569]. However, it is generally accepted that eLND provides important information for staging and prognosis which cannot be matched by any other currently available procedure [567].

Extended LND includes removal of the nodes overlying the external iliac artery and vein, the nodes within the obturator fossa located cranially and caudally to the obturator nerve, and the nodes medial and lateral to the internal iliac artery. With this template, 94% of patients are correctly staged [570].

The individual risk of patients harbouring positive LNs can be estimated based on validated nomograms. The Briganti nomogram [426, 427], the Roach formula [571] or the Partin and MSKCC nomograms [572] have
shown similar diagnostic accuracy in predicting LN invasion. These nomograms have all been developed in the pre-MRI setting based on systematic random biopsy. A risk of nodal metastases over 5% can be used to identify candidates for nodal sampling by eLND during RP [573-575].

An updated nomogram has been externally validated in men diagnosed based on MRI followed by MRI-targeted biopsy [427]. Based on this nomogram patients can be spared an ePLND if their risk of nodal involvement is less than 7%; which would result in missing only 1.5% of patients with nodal invasion [427, 430]. This 7% cut-off is comparable to the 5% cut-off of the Briganti nomogram in patients diagnosed by systematic random biopsy alone. Therefore, this novel nomogram and a 7% threshold should be used after MRI-targeted biopsy to identify candidates for eLND [429].

6.1.2.3.3 Sentinel node biopsy analysis
The rationale for a sentinel node biopsy (SNB) is based on the concept that a sentinel node is the first to be involved by migrating tumour cells. Therefore, when this node is negative it is possible to avoid an ePLND. There is heterogeneity and variation in techniques in relation to SNB (e.g. the optimal tracer) but a multidisciplinary collaborative endeavour attempted to standardise definitions, thresholds and strategies in relation to techniques of SNB using consensus methods [576].

Intraprostatic injections of indocyanine green (ICG) have been used to visualise prostate-related LNs during lymphadenectomy. In a randomised comparison, Harke et al., found more cancer containing LNs in men that underwent a LN dissection guided by ICG but no difference in BCR at 22.9-month follow-up [577]. A systematic review showed a sensitivity of 95.2% and NPV of 98.0% for SNB in detecting men with metastases at eLND [578]. However, there is still insufficient high-quality evidence supporting oncological effectiveness of SNB for nodal staging. Sentinel node biopsy is therefore still considered as an experimental nodal staging procedure.

6.1.2.3.4 Prostatic anterior fat pad dissection and histologic analysis
Several multi-centre and large single-centre series have shown the presence of lymphoid tissue within the fat pad anterior to the endopelvic fascia; the prostatic anterior fat pad (PAFP) [579-585]. This lymphoid tissue is present in 5.5–10.6% of cases and contains metastatic PCa in up to 1.3% of intermediate- and high-risk patients.

When positive, the PAFP is often the only site of LN metastasis. The PAFP is therefore a rare but recognised route of spread of disease. Unlike PLND, there is no morbidity associated with removal of the PAFP. The PAFP is always removed at RP for exposure of the endopelvic fascia and should be sent for histologic analysis as per all removed tissue.

6.1.2.3.5 Management of the dorsal venous complex
Since the description of the anatomical open RP by Walsh and Donker in the 1980s, various methods of controlling bleeding from the DVC have been proposed to optimise visualisation [546]. In the open setting, blood loss and transfusion rates have been found to be significantly reduced when ligating the DVC prior to transection [586]. However, concerns have been raised regarding the effect of prior DVC ligation on apical margin positivity and continence recovery due to the proximity of the DVC to both the prostatic apex and the urethral sphincter muscle fibres. In the robotic-assisted laparoscopic technique, due to the increased pressure of pneumoperitoneum, whether prior DVC ligation was used or not, blood loss was not found to be significantly different in one study [587]. In another study, mean blood loss was significantly less with prior DVC ligation (184 vs. 176 mL, p = 0.033), however it is debatable whether this was clinically significant [588]. The positive apical margin rate was not different, however, the latter study showed earlier return to full continence at 5 months post-operatively in the no prior DVC ligation group (61% vs. 40%, p < 0.01).

Ligation of the DVC can be performed with standard suture or using a vascular stapler. One study found significantly reduced blood loss (494 mL vs. 288 mL) and improved apical margin status (13% vs. 2%) when using the stapler [589].

Given the relatively small differences in outcomes, the surgeon’s choice to ligate prior to transection or not, or whether to use sutures or a stapler, will depend on their familiarity with the technique and the equipment available.

6.1.2.3.6 Nerve-sparing surgery
During prostatectomy, preservation of the neurovascular bundles with parasympathetic nerve branches of the pelvic plexus may spare erectile function [590, 591].

Although age and pre-operative function may remain the most important predictors for post-operative erectile function, nerve-sparing has also been associated with improved continence outcomes and
may therefore still be relevant for men with poor erectile function [592, 593]. The association with continence may be mainly due to the dissection technique used during nerve-sparing surgery, and not due to the preservation of the nerve bundles themselves [592].

Extra-, inter-, and intra-fascial dissection planes can be planned, with those closer to the prostate and performed bilaterally associated with superior (early) functional outcomes [594-597]. Furthermore, many different techniques are propagated such as retrograde approach after anterior release (vs. antegrade), and athermal and traction-free handling of bundles [598-600]. Nerve-sparing does not compromise cancer control if patients are carefully selected depending on tumour location, size and grade [601-603].

6.1.2.3.7 Lymph-node-positive patients during radical prostatectomy
Although no RCTs are available, data from prospective cohort studies comparing survival of pN+ patients (as defined following pathological examination after RP) support that RP may have a survival benefit over abandonment of RP in node-positive cases [604]. As a consequence there is no role for performing frozen section of suspicious LNs.

6.1.2.3.8 Removal of seminal vesicles
The more aggressive forms of PCa may spread directly into the SVs. For oncological clearance, the SVs have traditionally been removed intact with the prostate specimen [605]. However, in some patients the tips of the SVs can be challenging to dissect free. Furthermore, the cavernous nerves run past the SV tips such that indiscriminate dissection of the SV tips could potentially lead to ED [606]. However, a RCT comparing nerve-sparing RP with and without a SV-sparing approach found no difference in margin status, PSA recurrence, continence or erectile function outcomes. Another study of 71 consecutive RPs showed no cancer in any of the distal 1 cm of SVs, even in 12 patients with SV invasion [607]. Whilst complete SV removal should be the default, preservation of the SV tips may be considered in cases of low risk of involvement.

6.1.2.3.9 Techniques of vesico-urethral anastomosis
Following prostate removal, the bladder neck is anastomosed to the membranous urethra. The objective is to create a precisely aligned, watertight, tension-free, and stricture-free anastomosis that preserves the integrity of the intrinsic sphincter mechanism. Several methods have been described, based on the direct or indirect approach, the type of suture (i.e. barbed vs. non-barbed/monofilament), and variation in suturing technique (e.g., continuous vs. interrupted, or single-needle vs. double-needle running suture). The direct vesico-urethral anastomosis, which involves the construction of a primary end-to-end inter-mucosal anastomosis of the bladder neck to the membranous urethra by using 6 interrupted sutures placed circumferentially, has become the standard method of reconstruction for open RP [608].

The development of laparoscopic- and robotic-assisted techniques to perform RP have facilitated the introduction of new suturing techniques for the anastomosis. A systematic review and meta-analysis compared unidirectional barbed suture vs. conventional non-barbed suture for vesico-urethral anastomosis during robotic-assisted laparoscopic prostatectomy (RALP) [609]. The review included 3 RCTs and found significantly reduced anastomosis time, operative time and posterior reconstruction time in favour of the unidirectional barbed suture technique, but there were no differences in post-operative leak rate, length of catheterisation and continence rate. However, no definitive conclusions could be drawn due to the relatively low quality of the data. In regard to suturing technique, a systematic review and meta-analysis compared continuous vs. interrupted suturing for vesico-urethral anastomosis during RP [610]. The study included only one RCT with 60 patients [611]. Although the review found slight advantages for continuous suturing over interrupted suturing in terms of catheterisation time, anastomosis time and rate of extravasation, the overall quality of evidence was low and no clear recommendations were possible. A recent RCT [612] compared the technique of suturing using a single absorbable running suture vs. a double-needle single-knot running suture (i.e. Van Velthoven technique) in laparoscopic RP [613]. The study found slightly reduced anastomosis time with the single running suture technique, but anastomatic leak, stricture, and continence rates were similar.

Overall, although there are a variety of approaches, methods and techniques for performing the vesico-urethral anastomosis, no clear recommendations are possible due to the lack of high-certainty evidence. In practice, the chosen method should be based on surgeon experience and individual preference [608-619].

6.1.2.3.10 Bladder neck management
**Bladder neck mucosal eversion**

Some surgeons perform mucosal eversion of the bladder neck as its own step in open RP with the aim of securing a mucosa-to-mucosa vesico-urethral anastomosis and avoiding anastomotic stricture. Whilst bringing bladder and urethral mucosa together by the everted bladder mucosa covering the bladder muscle layer, this
step may actually delay healing of the muscle layers. An alternative is to simply ensure bladder mucosa is included in the full thickness anastomotic sutures. A non-randomised study of 211 patients with and without bladder neck mucosal eversion showed no significant difference in anastomotic stricture rate [620]. The strongest predictor of anastomotic stricture in RP is current cigarette smoking [621].

**Bladder neck preservation**

Whilst the majority of urinary continence is maintained by the external urethral sphincter at the membranous urethra (see below), a minor component is contributed by the internal lissosphincter at the bladder neck [622]. Preservation of the bladder neck has therefore been proposed to improve continence recovery post-RP. A RCT assessing continence recovery at 12 months and 4 years showed improved objective and subjective urinary continence in both the short- and long term without any adverse effect on oncological outcome [623]. These findings were confirmed by a systematic review [624]. However, concern remains regarding margin status for cancers located at the prostate base.

A systematic review addressing site-specific margin status found a mean base-specific positive margin rate of 4.9% with bladder neck preservation vs. only 1.9% without [622]. This study was inconclusive, but it would be sensible to exercise caution when considering bladder neck preservation if significant cancer is known to be at the prostate base. Bladder neck preservation should be performed routinely when the cancer is distant from the base. However, bladder neck preservation cannot be performed in the presence of a large median lobe or a previous TURP.

6.1.2.3.11 Urethral length preservation

The membranous urethra sits immediately distal to the prostatic apex and is chiefly responsible, along with its surrounding pelvic floor support structures, for urinary continence. It consists of the external rhabdosphincter which surrounds an inner layer of smooth muscle. Using pre-operative MRI, the length of membranous urethra has been shown to vary widely. A systematic review and meta-analysis has found that every extra millimetre of membranous urethral length seen on MRI pre-operatively improves early return to continence post-RP [625]. Therefore, it is likely that preservation of as much urethral length as possible during RP will maximise the chance of early return to continence. It may also be useful to measure urethral length pre-operatively to facilitate counselling of patients on their relative likelihood of early post-operative continence.

6.1.2.3.12 Cystography prior to catheter removal

Cystography may be used prior to catheter removal to check for a substantial anastomotic leak. If such a leak is found, catheter removal may then be deferred to allow further healing and sealing of the anastomosis. However, small comparative studies suggest that a cystogram to assess anastomotic leakage is not indicated as SOC before catheter removal 8 to 10 days after surgery [626]. If a cystogram is used, men with LUTS, large prostates, previous TURP or bladder neck reconstruction, may benefit as these factors have been associated with leakage [627, 628]. Contrast-enhanced transrectal US is an alternative [629].

6.1.2.3.13 Urinary catheter

A urinary catheter is routinely placed during RP to enable bladder rest and drainage of urine while the vesicourethral anastomosis heals. Compared to a traditional catheter duration of around 1 week, some centres remove the transurethral catheter early (post-operative day 2–3), usually after thorough anastomosis with posterior reconstruction or in patients selected peri-operatively on the basis of anastomosis quality [630-633]. No higher complication rates were found. Although shorter catheterisation has been associated with more favourable short-term functional outcomes, no differences in long-term function were found [634]. One RCT has shown no difference in rate of UTI following indwelling catheter (IDC) removal whether prophylactic ciprofloxacin was given prior to IDC removal or not, suggesting antibiotics should not be given at catheter removal [635].

As an alternative to transurethral catheterisation, suprapubic catheter insertion during RP has been suggested. Some reports suggest less bother regarding post-operative hygiene and pain [636-640], while others did not find any differences [641, 642]. No impact on long-term functional outcomes were seen.

6.1.2.3.14 Use of a pelvic drain

A pelvic drain has traditionally been used in RP for potential drainage of urine leaking from the vesico-urethral anastomosis, blood, or lymphatic fluid when a PLND has been performed. Two RCTs in the robotic-assisted laparoscopic setting have been performed [643, 644]. Patients with urine leak at intra-operative anastomosis watertight testing were excluded. Both trials showed non-inferiority in complication rates when no drain was used. When the anastomosis is found to be watertight intra-operatively, it is reasonable to avoid inserting a pelvic drain. There is no evidence to guide usage of a pelvic drain in PLND.
6.1.2.4 Acute and chronic complications of surgery

Post-operative incontinence and ED are common problems following surgery for PCa. A key consideration is whether these problems are reduced by using newer techniques such as RALP. Systematic reviews have documented complication rates after RALP [555, 645-648], and can be compared with contemporaneous reports after radical RRP [649]. A prospective controlled non-RCT of patients undergoing RP in 14 centres using RALP or RRP showed that 12 months after RALP 21.3% of patients were incontinent, as were 20.2% after RRP (adjusted OR: 1.08, 95% CI: 0.87–1.34) [650]. Erectile dysfunction was observed in 70.4% after RALP and 74.7% after RRP. The adjusted OR was 0.81 (95% CI: 0.66–0.98) [650].

A systematic review and meta-analysis of unplanned hospital visits and re-admissions post-RP analysed 60 studies with over 400,000 patients over a 20-year period up to 2020. It found an emergency room visit rate of 12% and a hospital re-admission rate of 4% at 30 days post-operatively [651].

A RCT comparing RALP and RRP reported outcomes at 12 weeks in 326 patients and functional outcomes at 2 years [549]. Urinary function scores did not differ significantly between RRP vs. RALP at 6 and 12 weeks post-surgery (74–50 vs. 71–10, p = 0.09; 83–80 vs. 82–50, p = 0.48), with comparable outcomes for sexual function scores (30–70 vs. 32–70, p = 0.45; 35–00 vs. 38–90, p = 0.18). In the RRP group 14 (9%) patients had post-operative complications vs. 6 (4%) in the RALP group. The intra-and peri-operative complications of retropubic RP and RALP are listed in Table 6.1.5. The early use of phosphodiesterase-5 (PDE5) inhibitors in penile rehabilitation remains controversial resulting in a lack of clear recommendations (see Section 8.3.2.1).

6.1.2.4.1 Effect of anterior and posterior reconstruction on continence

Preservation of integrity of the external urethral sphincter is critical for continence post-RP. Less clear is the effect of reconstruction of surrounding support structures to return to continence. Several small RCTs have been conducted, however, pooling analyses is hampered by variation in the definitions of incontinence and surgical approach, such as open vs. robotic and intraperitoneal vs. extraperitoneal. In addition, techniques used to perform both anterior suspension or reconstruction and posterior reconstruction are varied. For example, anterior suspension is performed either through periosteum of the pubis or the combination of ligated DVC and puboprostatic ligaments (PPL). Posterior reconstruction from rhabdosphincter is described to either Denonvilliers fascia posterior to bladder or to posterior bladder wall itself.

Two trials assessing posterior reconstruction in RALRP found no significant improvement in return to continence [652, 653]. A third trial using posterior bladder wall for reconstruction showed only an earlier return to 1 pad per day (median 18 vs. 30 days, p = 0.024) [654]. When combining both anterior and posterior reconstruction, where for anterior reconstruction the PPL were sutured to the anterior bladder neck, another RCT found no improvement compared to a standard anastomosis with no reconstruction [655].

Four RCTs including anterior suspension have also shown conflicting results. Anterior suspension alone through the pubic periosteum, in the setting of extraperitoneal RALRP, showed no advantage [656]. However, when combined with posterior reconstruction in RRP, one RCT showed significant improvement in return to continence at one month (7.1% vs. 26.5%, p = 0.047) and 3 months (15.4% vs. 45.2%, p = 0.016), but not at 6 months (57.9% vs. 65.4%, p = 0.609) [657]. Another posterior plus posterior reconstruction RCT using the Advanced Reconstruction of VesicoUrthral Support (ARVUS) technique and the strict definition of continence of ‘no pads’, showed statistically significant improvement in continence at 2 weeks (43.8% vs. 11.8%), 4 weeks (62.5% vs. 14.7%), 8 weeks (68.8% vs. 20.6%), 6 months (75% vs. 44.1%) and 12 months (86.7% vs. 61.3%), when compared to standard posterior Rocco reconstruction [658]. Anterior suspension alone through the DVC and PPL combined without posterior reconstruction in the setting of RRP has shown improvement in continence at one month (20% vs. 53%, p = 0.029), 3 months (47% vs. 73%, p = 0.034) and 6 months (83% vs. 100%, p = 0.02), but not at 12 months (97% vs. 100%, p = 0.313) [659]. Together, these results suggest a possible earlier return to continence, but no long-term difference.

As there is conflicting evidence on the effect of anterior and/or posterior reconstruction on return to continence post-RP, no recommendations can be made. However, no studies showed an increase in adverse oncologic outcome or complications with reconstruction.

6.1.2.4.2 Deep venous thrombosis prophylaxis

For EAU Guidelines recommendations on post-RP deep venous thrombosis prophylaxis, please see the Thromboprophylaxis Guidelines Section 3.1.6 [660]. However, these recommendations should be adapted based on national recommendations, when available.

RALP = robot-assisted laparoscopic prostatectomy; RP = radical prostatectomy; RRP = radical retropubic prostatectomy.

### 6.1.2.4.3 Early complications of extended lymph node dissection
Pelvic eLND increases morbidity in the treatment of PCa [567]. Overall complication rates of 19.8% vs. 8.2% were noted for eLND vs. limited LND, respectively, with lymphoceles (10.3% vs. 4.6%) being the most common adverse event. Other authors have reported more acceptable complication rates [661]. Similar rates of lymphoceles have been observed in RALP series; however, in one subgroup analysis lymphoceles were more common with the extraperitoneal approach (19%) vs. the transperitoneal approach (0%) [662, 663]. Briganti et al., [664] also showed more complications after extended compared to limited LND. Twenty percent of men suffer a complication of some sort after eLND. Thromboembolic events occur in less than 1% of cases.

### 6.1.3 Radiotherapy

#### 6.1.3.1 External beam radiation therapy

##### 6.1.3.1.1 Technical aspects
Intensity-modulated EBRT and volumetric arc external-beam RT (VMAT) employ dynamic multileaf collimators, which automatically and continuously adapt to the contours of the target volume seen by each beam. Viani et al., show significantly reduced acute and late grade ≥ 2 genito-urinary (GU) and gastro-intestinal (GI) toxicity in favour of IMRT, while BCR-free rates did not differ significantly when comparing IMRT with three-dimensional conformal radiation therapy (3D-CRT) in a RCT comprising 215 patients [665]. A meta-analysis by Yu et al., (23 studies, 9,556 patients) concluded that IMRT significantly decreases the occurrence of grade 2–4 acute GI toxicity, late GI toxicity and late rectal bleeding, and achieves better PSA relapse-free survival in comparison with 3D-CRT. Intensity-modulated EBRT and 3D-CRT show comparable acute rectal toxicity, late GU toxicity and OS, while IMRT slightly increases the morbidity of acute GU toxicity [666]. Wortel et al., concluded that, as compared to 3D-CRT, image-guided IMRT was associated with significantly reduced late GI toxicity whereas GU toxicities remained comparable [242 IMRT patients vs. 189 3D-CRT patients] [667]. Finally, Zapatero et al., found, based on 733 consecutive patients (295 IMRT vs. 438 3D-CRT), that compared with 3D-CRT, high-dose IMRT/IGRT is associated with a lower rate of late urinary complications despite a higher radiation dose [668]. In conclusion, IMRT plus IGRT remain the SOC for the treatment of PCa.

The advantage of VMAT over IMRT is shorter treatment times, generally two to three minutes. Both techniques allow for a more complex distribution of the dose to be delivered and provide concave isodose curves, which are particularly useful as a means of sparing the rectum. Radiotherapy treatment planning for IMRT and VMAT differs from that used in conventional EBRT, requiring a computer system capable of ‘inverse planning’ and the appropriate physics expertise. Treatment plans must conform to pre-specified dose constraints to critical organs at risk of normal tissue damage and a formal quality assurance process should be routine.

With dose escalation using IMRT/VMAT, organ movement becomes a critical issue in terms of both tumour control and treatment toxicity. Techniques will therefore combine IMRT/VMAT with some form of IGRT (usually gold marker or cone-beam CT), in which organ movement can be visualised and corrected for in real time, although the optimum means (number of applications per week) of achieving this is still unclear [669, 670].
Tomotherapy is another technique for the delivery of IMRT, using a linear accelerator mounted on a ring gantry that rotates as the patient is delivered through the centre of the ring, analogous to spiral CT scanning.

### 6.1.3.1.2 Dose escalation

Local control is a critical issue for the outcome of RT of PCa. It has been shown that local failure due to insufficient total dose is prognostic for death from PCa as a second wave of metastases is seen 5 to 10 years later on [671]. Several RCTs have shown that dose escalation (range 74–80 Gy) has a significant impact on 10-year biochemical relapse as well as metastases and disease-specific mortality [672-679]. These trials have generally included patients from several risk groups, and the use of neoadjuvant/adjuvant HT has varied (see Table 6.1.6). The best evidence of an OS benefit in patients with intermediate- or high-risk PCa, but not with low-risk PCa, derives from a non-randomised but well conducted propensity-matched retrospective analysis of the U.S. National Cancer Database including a total of 42,481 patients [680]. The concept of a focal boost to the dominant intraprostatic lesion in the MRI has been successfully validated in a RCT of 571 intermediate- and high-risk patients [681]. Patients were randomised between 77 Gy in 35 fractions of 2.2 Gy and the same dose plus a focal boost up to 18 Gy. Additional ADT was given to 65% of patients in both arms. However, the duration of the ADT was not reported. With a median follow-up of 72 months there was a moderate improvement of biochemical PFS (primary endpoint) only. No significant difference for late GU- or GI toxicity grade ≥ 2 (23% and 12% vs. 28% and 13%) was documented. For grade ≥ 3 GU-toxicity these numbers were 3.5% and 5.6% (p > 0.05). However, longer follow-up is needed to assess late GU-toxicity. Of note, there was a clear decrease in biochemical failure with increasing boost dose, individually given up to 18 Gy. In everyday practice, a minimum dose of > 74 Gy is recommended for EBRT plus HT, with no different recommendations according to the patient’s risk group. If IMRT/VMAT and IGRT are used for dose escalation, rates of severe late side effects (> grade 3) for the rectum are 2–3% and for the GU tract 2–5% [674, 677, 682-695].

Hypofractionation

Fractionated RT utilises differences in the DNA repair capacity of normal and tumour tissue and slowly proliferating cells are very sensitive to an increased dose per fraction [696]. A meta-analysis of 25 studies including > 14,000 patients concluded that since PCa has a slow proliferation rate, hypofractionated RT could be more effective than conventional fractions of 1.8–2 Gy [697]. Hypofractionation (HFX) has the added advantage of being more convenient for the patient at lower cost.

Moderate HFX is defined as RT with 2.5–3.4 Gy/fx. Several studies report on moderate HFX applied in various techniques also including HT in part [698–708]. A systematic review concluded that studies on moderate HFX (2.5–3.4 Gy/fx) delivered with conventional 3D-CRT/IMRT have sufficient follow-up to support the safety of this therapy but long-term efficacy data are still lacking [707]. These results were confirmed by a recent Cochrane review on moderate HFX for clinically localised PCa [709]. Eleven studies were included (n = 8,278) with a median follow-up of 72 months showing little or no difference in PCa-specific survival (HR: 1.00). Based on 4 studies (n = 3,848), hypofractionation probably makes little or no difference to late radiation GU toxicity (RR: 1.05) or GI toxicity (RR: 1.1), but this conclusion is based on relatively short follow-up, and 10 to 15-year data will be required to confirm these findings [709].

Moderate HFX should only be done by experienced teams using high-quality EBRT using IGRT and IMRT/VMAT and published phase III protocols should be adhered to (see Table 6.1.7 below).

Ultra-HFX has been defined as RT with > 3.4 Gy per fraction [708]. It requires IGRT and stereotactic body RT (SBRT). Table 6.1.8 provides an overview of selected studies. Short-term biochemical control is comparable to conventional fractionation. However, there are concerns about high-grade GU and rectal toxicity and full long-term side effects may not yet be known [707, 711, 712]. In the HYPO-RT-PC randomised trial by Widmark et al., (n = 1,200), no difference in failure-free survival was seen for conventional or ultra-HFX but acute grade ≥ 2 GU toxicity was 23% vs. 28% (p = 0.057), favouring conventional fractionation. There were no significant differences in long-term toxicity [713]. A systematic review by Jackson et al., included 38 studies with 6,116 patients who received RT with < 10 fractions and ≥ 5 Gy per fraction. Five and 7-year biochemical recurrence-free survival (BRFS) rates were 95.3% and 93.7%, respectively, and estimated late grade ≥ 3 GU and GI toxicity rates were 2.0% and 1.1%, respectively [714]. The authors conclude that there is sufficient evidence to support SBRT as a standard treatment option for localised PCa, even though the median follow-up in this review was only 39 months and it included at least one trial (HYPO-RT-PC) which used 3D-CRT in 80% and IMRT/VMAT in the remainder for ultra-HFX. In their review on SBRT, Cushman and co-workers evaluated 14 trials, including 2,038 patients and concluded that despite a lack of long-term follow-up and the heterogeneity of the available evidence, prostate SBRT affords appropriate biochemical control with few high-grade toxicities [715]. In the Intensity-modulated fractionated RT vs. stereotactic body RT for PCa (PACE-B) trial, acute grade ≥ 2 GU or GI toxicities did not differ significantly between conventional fractionation and ultra-HFX [716]. Adopting planning dose constraints to the penile bulb might minimise ED, especially in younger patients [717].

First results of a small (n = 30) randomised phase-II trial in intermediate-risk PCa of ‘ultra-high single dose RT’ (SDRT) with 24 Gy compared with an extreme hypofractionated stereotactic body RT regime with 5x9 Gy to the prostate, have been published recently (see Table 6.1.8) [718]. The primary endpoint was toxic effects. With a median follow-up of 48 months SDRT was relatively well tolerated even though there was a trend towards a higher rate of GU side effects after SDRT at all time points. Longer follow-up should be awaited before any conclusion from this approach can be drawn. In conclusion, it seems prudent to restrict extreme HFX to prospective clinical trials and to inform patients on the uncertainties of the long-term outcome.

6.1.3.1.4 Neoadjuvant or adjuvant hormone therapy plus radiotherapy

The combination of RT with LHRH ADT has definitively proven its superiority compared with RT alone followed by deferred ADT on relapse, as shown by phase III RCTs [719-723] (Table 6.1.9). The main message is that for all intermediate-risk disease a short duration of around 6 months is optimal while a longer one, around 3 years, is needed for high-risk patients, as per NCCN definition (see Section 4.2). The OS impact of adding short-term ADT for favourable intermediate-risk disease, however, remains a matter of debate [91].

A meta-analysis based on individual patient data from two RCTs (RTOG 9413 and Ottawa 0101) has compared neoadjuvant/concomitant vs. adjuvant ADT (without substratifying between favourable- and unfavourable intermediate-risk disease) in conjunction with prostate RT and reported superior PFS with adjuvant ADT [724]. This is an important observation, which should influence future clinical trial design and evaluation of outcomes. However, there are differences between the two trials in patient characteristics, exact scheduling of neoadjuvant +/- concomitant ADT, hormonal preparation, and RT schedule. At present, either neoadjuvant or adjuvant ADT remain acceptable options for patients requiring short-term ADT in conjunction with EBRT.

The question of the added value of EBRT combined with ADT has been clarified by 3 RCTs. All showed a clear benefit of adding EBRT to long-term ADT (see Table 6.1.10).

6.1.3.1.5 Combined dose-escalated radiotherapy and androgen-deprivation therapy

Zelefsky et al., reported a retrospective analysis comprising 571 patients with low-risk PCa; 1,074 with intermediate-risk PCa and 906 with high-risk PCa. Three-dimensional conformal RT or IMRT were administered [733]. The prostate dose ranged from 64.8 to 86.4 Gy; doses beyond 81 Gy were delivered during the last 10 years of the study using image-guided IMRT. Complete androgen blockade was administered at the discretion of the treating physician to 623 high-risk (69%), 456 intermediate-risk (42%) and 170 low-risk (30%) PCa patients. The duration of ADT was 3 months for low-risk patients and 6 months for intermediate-risk and high-risk patients, starting at 3 months before RT. The 10-year biochemical disease-free rate was significantly improved by dose escalation: above 75.6 Gy in low-risk, and above 81 Gy for the intermediate- and high-risk groups. It was also improved by adding 6 months of ADT in intermediate- and high-risk patients. In the multivariate analysis, neither the dose > 81 Gy, nor adding ADT, influenced OS. Four RCTs have shown that the benefits of ADT are independent of dose escalation, and that the use of ADT would not compensate for a lower RT dose:

1. The GICOR study shows a better biochemical DFS in high-risk patients for 3D-CRT radiation dose > 72 Gy when combined with long-term ADT [687].
2. DART01/05 GICOR shows improved biochemical control and OS in high-risk patients if 2 years of adjuvant ADT is combined with high-dose RT [734].
3. EORTC trial 22991 shows that 6 months ADT improves biochemical and clinical DFS irrespective of the dose (70, 74, 78 Gy) in intermediate-risk and low-volume high-risk localised PCa patients [735].
4. A Canadian trial of 600 intermediate-risk patients showed that the addition of ADT to EBRT reduced biochemical failure and PCa deaths, in patients treated with either 70 Gy or 76 Gy [730].

A post-hoc meta-analysis of two RCTs has suggested that concomitant/adjuvant ADT may be superior to neoadjuvant ADT, but their heterogeneity means that this observation is hypothesis-generating only [724]. However, a Canadian two-arm dose-escalated (76 Gy) RCT compared neoadjuvant and concomitant with adjuvant short-term ADT in 432 patients with intermediate-risk PCa. After 10 years no significant difference in OS or RT-related grade ≥ 3 GI or GU toxicity was seen [737]. Therefore both regimen in combination with dose escalation are reasonable standards [737].

6.1.3.2 Proton beam therapy

In theory, proton beams are an attractive alternative to photon-beam RT for PCa, as they deposit almost all their radiation dose at the end of the particle’s path in tissue (the Bragg peak), in contrast to photons which deposit radiation along their path. There is also a very sharp fall-off for proton beams beyond their deposition depth, meaning that critical normal tissues beyond this depth could be effectively spared. In contrast, photon beams continue to deposit energy until they leave the body, including an exit dose.

One RCT on dose escalation (70.2 vs. 79.2 Gy) has incorporated protons for the boost doses of either 19.8 or 28.8 Gy. This trial shows improved outcome with the higher dose but it cannot be used as evidence for the superiority of proton therapy [673]. Thus, unequivocal information showing an advantage of protons over IMRT photon therapy is still not available. Studies from the SEER database and from Harvard describing toxicity and patient-reported outcomes do not point to an inherent superiority of protons [738, 739]. In terms of longer-term GI toxicity, proton therapy might even be inferior to IMRT [739].

A RCT comparing equivalent doses of proton-beam therapy with IMRT is underway. Meanwhile, proton therapy must be regarded as an experimental alternative to photon-beam therapy.

6.1.3.3 Spacer during external beam radiation therapy

Biodegradable spacer insertion involves using a liquid gel or balloon to increase the distance between the prostate and rectum and consequently reduce the amount of radiation reaching the rectum. Various materials have been used with most evidence available for CE-marked hydrogel spacers [740]. A meta-analysis including one RCT and six cohort studies using the hydrogel spacer demonstrated a 5–8% reduction in the rectal volume receiving high-dose radiation, although heterogeneity between studies is found [741]. In the final analysis of the RCT with a median follow-up of 37 months and with approximately two-thirds of patients evaluable, those treated with spacer in situ had no deterioration from baseline bowel function whilst those treated without spacer had a lower mean bowel summary score of 5.8 points which met the threshold for a minimally important difference of 4–6 points [742].

This meta-analysis highlights inconsistent reporting of procedural complications. In addition, with more widespread clinical use safety reports describe uncommon, but severe and life changing, complications including prostatic abscess, fistulae and sepsis [743]. Implantation is associated with a learning curve and should only be undertaken by teams with experience of TRUS and transperineal procedures with robust audit reporting in place [744]. Its role in the context of moderate or extreme hypofractionation is as yet unclear.
6.1.3.4 Brachytherapy

6.1.3.4.1 Low-dose rate brachytherapy

Low-dose rate (LDR) brachytherapy uses radioactive seeds permanently implanted into the prostate. There is a consensus on the group of patients with the best outcomes after LDR monotherapy [745] for low- or favourable intermediate-risk and good urinary function defined as an International Prostatic Symptom Score (IPSS) < 12 and maximum flow rate > 15 mL/min on urinary flow tests, as per NCCN definition (see Section 4.2) [746]. In addition, with due attention to dose distribution, patients having had a previous TURP can undergo brachytherapy without an increase in risk of urinary toxicity. A minimal channel TURP is recommended, leaving at least 1 cm rim of prostate tissue around the post-TURP urethral defect at the postero-lateral sides of the prostate and there should be at least a 3-month interval between TURP and brachytherapy to allow for adequate healing [747-750].

The only available RCT comparing RP and LDR brachytherapy as monotherapy was closed due to poor accrual [751]. Outcome data are available from a number of large population cohorts with mature follow-up [752-759]. The biochemical DFS for ISUP grade 1 patients after 5 and 10 years has been reported to range from 71% to 93% and 65% to 85%, respectively [752-759]. A significant correlation has been shown between the implanted dose and biochemical control [760]. A D90 (dose covering 90% of the prostate volume) of > 140 Gy leads to a significantly higher biochemical control rate (PSA < 1.0 ng/mL) after 4 years (92 vs. 68%). There is no OS benefit in adding neoadjuvant or adjuvant ADT to LDR monotherapy [761].

Low-dose rate brachytherapy can be combined with EBRT in unfavourable intermediate-risk PCa (See Section 4.2) and high-risk patients. External beam RT (total dose of 78 Gy) has been compared with EBRT (total dose 46 Gy) followed by LDR brachytherapy boost (prescribed dose 115 Gy) in intermediate-risk and high-risk patients in the ASCENDE-RT randomised trial with 12 months of ADT in both arms [762]. The LDR boost resulted in 5- and 7-year PSA PFS increase (89% and 86%, respectively, compared to 84% and 75%). This improvement was achieved at a cost of increased late grade 3+ GU toxicity (18% compared to 8%) [763]. Toxicity resulted mainly in the development of urethral strictures and incontinence and great care should be taken during treatment planning.

6.1.3.4.2 High-dose rate brachytherapy

High-dose rate (HDR) brachytherapy uses a radioactive source temporarily introduced into the prostate to deliver radiation. The technical differences are outlined in Table 6.1.11. The use of the GEC (Groupe Europeen de Curietherapie)/ESTRO Guidelines is strongly recommended [764]. High-dose rate brachytherapy can be delivered in single or multiple fractions and is often combined with EBRT of at least 45 Gy [765]. A systematic review of non-RCTs and data from population studies suggest outcomes with EBRT plus HDR brachytherapy are superior to EBRT alone [766, 767].

A single centre RCT of EBRT (55 Gy in 20 fractions) vs. EBRT (35.75 Gy in 13 fractions), followed by HDR brachytherapy (17 Gy in two fractions over 24 hours) has been reported [768]. In 218 patients with T1–3 N0M0 PCa the combination of EBRT and HDR brachytherapy showed a significant improvement in the biochemical disease-free rate (p = 0.04) at 5 and 10 years (75% and 46% compared to 61% and 39%). However, an unexpectedly high rate of early recurrences was observed in the EBRT arm alone, even after 2 years, possibly due to a dose lower than the current standard used [768].

Supporting, but not definitive, evidence of the benefit of HDR boost is available from the TROG 03.04 RADAR trial. This multi-centre study had upfront radiation dose escalation (non-randomised) with dosing options of 66, 70, or 74 Gy EBRT, or 46 Gy EBRT plus HDR brachytherapy boost and randomised men with locally-advanced PCa to 6 or 18 months ADT. After a minimum follow-up of 10 years HDR boost significantly reduced distant progression, the study primary endpoint (sub HR: 0.68, 95% CI: 0.57–0.80; p < 0.0001), when compared to EBRT alone and, independent of duration of ADT, HDR boost was associated with increased IPSS of 3 points at 18 months post-treatment resolving by 3 years but decreased rectal symptoms when compared to EBRT [769].

Although radiation dose escalation using brachytherapy boost provides much higher biological doses, the TROG 03.04 RADAR RCT and systematic reviews show ADT use independently predicts better outcomes regardless of radiation dose intensification [761, 769, 770]. Omitting ADT may result in inferior OS and based on current evidence ADT use and duration should be in line with that used when delivering EBRT alone.

Fractionated HDR brachytherapy as monotherapy can be offered to patients with low- and intermediate-risk PCa, who should be informed that results are only available from limited series in very experienced centres. Five-year PSA control rates of 97.5% and 93.5% for low- and intermediate-risk PCa, respectively, are reported, with late grade 3+ GU toxicity rates < 5% and no, or very minimal, grade 3+ GI toxicity rates [771]. Single fraction HDR monotherapy should not be used as it has inferior biochemical control rates compared to fractionated HDR monotherapy [772].

6.1.3.5  Acute side effects of external beam radiotherapy and brachytherapy

Gastro-intestinal and urinary side effects are common during and after EBRT. In the EORTC 22991 trial, approximately 50% of patients reported acute GU toxicity of grade 1, 20% of grade 2, and 2% grade 3. In the same trial, approximately 30% of patients reported acute grade 1 GI toxicity, 10% grade 2, and less than 1% grade 3. Common toxicities included dysuria, urinary frequency, urinary retention, haematuria, diarrhoea, rectal bleeding and proctitis. In addition, general side effects such as fatigue are common. It should be noted that the incidence of acute side effects is greater than that of late effects (see Section 8.2.2.1), implying that most acute effects resolve. In a RCT of conventional dose EBRT vs. EBRT and LDR brachytherapy the incidence of acute proctitis was reduced in the brachytherapy arm, but other acute toxicities were equivalent [762]. Acute toxicity of HDR brachytherapy has not been documented in a RCT, but retrospective reports confirm lower rates of GI toxicity compared with EBRT alone and grade 3 GU toxicity in 10%, or fewer, patients, but a higher incidence of urinary retention [773]. Similar findings are reported using HFX; in a pooled analysis of 864 patients treated using extreme HFX and stereotactic RT, declines in urinary and bowel domains were noted at 3 months which returned to baseline, or better, by 6 months [774].

6.1.4  Hormonal therapy

6.1.4.1  Introduction

6.1.4.1.1  Different types of hormonal therapy

Androgen deprivation can be achieved by suppressing the secretion of testicular androgens in different ways. This can be combined with inhibiting the action of circulating androgens at the level of their receptor which has been known as complete (or maximal or total) androgen blockade (CAB) using the old-fashioned anti-androgens [775].

6.1.4.1.1.1  Testosterone-lowering therapy (castration)

6.1.4.1.1.1.1  Castration level

The castration level of testosterone is < 50 ng/dL (1.7 nmol/L), which was defined more than 40 years ago when testosterone testing was less sensitive. Current methods have shown that the mean value after surgical castration is 15 ng/dL [776]. Therefore, a more appropriate level should be defined as < 20 ng/dL (1 nmol/L). This definition is important as better results are repeatedly observed with lower testosterone levels compared to 50 ng/dL [777-779]. However, the castrate level considered by the regulatory authorities and in clinical trials addressing castration in PCa is still the historical < 50 ng/dL (1.7 nmol/L).

6.1.4.1.1.1.2  Bilateral orchiectomy

Bilateral orchiectomy or subcapsular pulpectomy is still considered the primary treatment modality for ADT. It is a simple, cheap and virtually complication-free surgical procedure. It is easily performed under local anaesthesia, and it is the quickest way to achieve a castration level which is usually reached within less than twelve hours. It is irreversible and therefore does not allow for intermittent treatment [780].

6.1.4.1.1.1.3  Oestrogens

Treatment with oestrogens results in testosterone suppression and is not associated with bone loss [781]. Early studies tested oral diethylstilboestrol (DES) at several doses. Due to severe side effects, especially thromboembolic complications, even at lower doses these drugs are not considered as standard first-line treatment [782-784].
6.1.4.1.1.4 Luteinising-hormone-releasing hormone agonists

Long-acting LHRH agonists are currently the main forms of ADT. These synthetic analogues of LHRH are delivered as depot injections on a 1-, 2-, 3-, 6-monthly, or yearly, basis. The first injection induces a transient rise in luteinising hormone (LH) and follicle-stimulating hormone (FSH) leading to the ‘testosterone surge’ or ‘flare-up’ phenomenon which starts two to three days after administration and lasts for about one week. This may lead to detrimental clinical effects (the clinical flare) such as increased bone pain, acute bladder outlet obstruction, obstructive renal failure, spinal cord compression, and cardiovascular death due to hypercoagulation status [785]. Patients at risk are usually those with high-volume symptomatic bony disease. Concomitant therapy with an anti-androgen decreases the incidence of clinical flare but does not completely remove the risk. Anti-androgen therapy is usually continued for 4 weeks but neither the timing nor the duration of anti-androgen therapy are based on strong evidence. In addition, the long-term impact of preventing ‘flare up’ is unknown [786, 787].

Chronic exposure to LHRH agonists results in the down-regulation of LHRH-receptors, suppressing LH and FSH secretion and therefore testosterone production. A castration level is usually obtained within 2 to 4 weeks [788]. Although there is no formal direct comparison between the various compounds, they are considered to be equally effective [789]. So far, no survival difference between LHRH agonists and orchiectomy has been reported due to the lack of high-quality trials [790].

The different products have practical differences that need to be considered in everyday practice, including the storage temperature, whether a drug is ready for immediate use or requires reconstitution, and whether a drug is given by subcutaneous or intramuscular injection.

6.1.4.1.1.5 Luteinising-hormone-releasing hormone antagonists

Luteinising-hormone-releasing hormone antagonists immediately bind to LHRH receptors, leading to a rapid decrease in LH, FSH and testosterone levels without any flare. The practical shortcoming of these compounds is the lack of a long-acting depot formulation with, so far, only monthly formulations being available. Degarelix is a LHRH antagonist. The standard dosage is 240 mg in the first month followed by monthly injections of 80 mg. Most patients achieve a castrate level at day three [788]. A phase III RCT compared degarelix to monthly leuprolrelin following up patients for 12 months, suggesting a better PSA PFS for degarelix 240/80 mg compared to monthly leuprolrelin [791]. A systematic review did not show a major difference between agonists and degarelix and highlighted the paucity of on-treatment data beyond 12 months as well as the lack of survival data [792]. Its definitive superiority over the LHRH analogues remains to be proven. Short-term follow-up data from a meta-analysis indicate that the use of GnRH antagonist is associated with significantly lower overall mortality and cardiovascular events as compared with agonists. On the other hand, other adverse effects such as decreased libido, hot flushes, ED, weight gain, and injection site reactions are seen less often with the agonists [793, 794].

Relugolix is an oral gonadotropin-releasing hormone antagonist. It was compared to the LHRH agonist leuprolide in a randomised phase III trial [795]. The primary endpoint was sustained testosterone suppression to castrate levels through 48 weeks. There was a significant difference of 7.9 percentage points (95% CI: 4.1–11.8) showing non-inferiority and superiority of relugolix. The incidence of major adverse cardiovascular events was significantly lower with relugolix (prespecified safety analysis). Relugolix has been approved by the FDA [796].

6.1.4.1.1.6 Anti-androgens

These oral compounds are classified according to their chemical structure as:

- steroidal, e.g., cyproterone acetate (CPA), megestrol acetate and medroxyprogesterone acetate;
- non-steroidal or pure, e.g., nilutamide, flutamide and bicalutamide.

Both classes compete with androgens at the receptor level. This leads to an unchanged or slightly elevated testosterone level. Conversely, steroidal anti-androgens have progesterational properties leading to central inhibition by crossing the blood-brain barrier.

6.1.4.1.1.6.1 Steroidal anti-androgens

These compounds are synthetic derivatives of hydroxyprogesterone. Their main pharmacological side effects are secondary to castration (gynaecomastia is quite rare) whilst the non-pharmacological side effects are cardiovascular toxicity (4–40% for CPA) and hepatotoxicity.

Cyproterone acetate was the first licensed anti-androgen but the least studied. Its most effective dose as monotherapy is still unknown. Although CPA has a relatively long half-life (31–41 hours), it is usually administered in two or three fractionated doses of 100 mg each. In one RCT CPA showed a poorer OS when compared with LHRH analogues [797]. An underpowered RCT comparing CPA monotherapy with flutamide...
in M1b PCa did not show any difference in DSS and OS at a median follow-up of 8.6 years [798]. Other CPA monotherapy studies suffer from methodological limitations preventing firm conclusions.

6.1.4.1.1.6.2 Non-steroidal anti-androgens
Non-steroidal anti-androgen monotherapy with e.g., nilutamide, flutamide or bicalutamide does not suppress testosterone secretion and it is claimed that libido, overall physical performance and bone mineral density (BMD) are frequently preserved [799]. Non-androgen-related pharmacological side effects differ between agents. Bicalutamide shows a more favourable safety and tolerability profile than flutamide and nilutamide [800]. The dosage licensed for use in CAB is 50 mg/day, and 150 mg for monotherapy. The androgen pharmacological side effects are mainly gynaecomastia (70%) and breast pain (68%). However, non-steroidal anti-androgen monotherapy offers clear bone protection compared with LHRH analogues and probably LHRH antagonists [799, 801]. All three agents share the potential for liver toxicity (occasionally fatal), requiring regular monitoring of patients’ liver enzymes.

6.1.4.1.1.2 New androgen pathway targeting agents (ARTA)
Once on ADT the development of castration-resistance (CRPC) is only a matter of time. It is considered to be mediated through two main overlapping mechanisms: androgen-receptor (AR)-independent and AR-dependent mechanisms (see Section 6.5 - Castrate-resistant PCa). In CRPC, the intracellular androgen level is increased compared to androgen sensitive cells and an over-expression of the AR has been observed, suggesting an adaptive mechanism [802]. This has led to the development of several new compounds targeting the androgen axis. In mCRPC, AAP and enzalutamide have been approved. In addition to ADT (sustained castration), AAP, apalutamide and enzalutamide have been approved for the treatment of metastatic hormone sensitive PCa (mHSPC) by the FDA and the EMA. For the updated approval status see EMA and FDA websites [803-807]. Finally, apalutamide, darolutamide and enzalutamide have been approved for non-metastatic CRPC (nmCRPC) at high risk of further metastases [808-812].

6.1.4.1.1.2.1 Abiraterone acetate
Abiraterone acetate is a CYP17 inhibitor (a combination of 17α-hydrolase and 17,20-lyase inhibition). By blocking CYP17, abiraterone acetate significantly decreases the intracellular testosterone level by suppressing its synthesis at the adrenal level and inside the cancer cells (intracrine mechanism). This compound must be used together with prednisone/prednisolone to prevent drug-induced hyperaldosteronism [803, 806].

6.1.4.1.1.2.2 Apalutamide, darolutamide, enzalutamide (alphabetical order)
These agents are novel non-steroidal anti-androgens with a higher affinity for the AR receptor than bicalutamide. While previous non-steroidal anti-androgens still allow transfer of ARs to the nucleus and would act as partial agonists, all three agents also block AR transfer and therefore suppress any possible agonist-like activity [807-809]. Darolutamide has structurally unique properties [808]. In particular, in preclinical studies, it showed not to cross the blood-brain barrier [813, 814].

6.1.4.1.1.3 New compounds
6.1.4.1.1.3.1 PARP inhibitors
Poly (ADP-ribose) polymerase inhibitors (PARPi) block the enzyme poly ADP ribose polymerase (PARP) and were developed aiming to selectively target cancer cells harbouring BRCA mutations and other mutations inducing homologous recombination deficiency and high level of replication pressure with a sensitivity to PARPi treatment. Due to the oncogenic loss of some DNA repair effectors and incomplete DNA repair repertoire, some cancer cells are addicted to certain DNA repair pathways such as Poly (ADP-ribose) polymerase (PARP)-related single-strand break repair pathway. The interaction between BRCA and PARP is a form of synthetic lethal effect which means the simultaneously functional loss of two genes lead to cell death, while a defect in any single gene only has a limited effect on cell viability [815]. The therapeutic indication for PCa is discussed in Section 6.5.8.1.

6.1.4.1.1.3.2 Immune checkpoint inhibitors
Immune checkpoints are key regulators of the immune system. Checkpoint proteins, such as B7-1/B7-2 on antigen-presenting cells (APC) and CTLA-4 on T cells, help keep the immune responses in an equilibrium. The binding of B7-1/B7-2 to CTLA-4 keeps the T cells in the inactive state whilst an immune checkpoint inhibitor (anti-CTLA-4 antibody) allows the T cells to be active and to kill tumour cells. Approved checkpoint inhibitors target the molecules CTLA4, programmed cell death protein 1 (PD-1), and programmed death-ligand 1 (PD-L1). Programmed death-ligand 1 is the transmembrane programmed cell death 1 protein which interacts with PD-L1 (PD-1 ligand 1). Cancer-mediated upregulation of PD-L1 on the cell surface may inhibit T cells. Antibodies that bind to either PD-1 or PD-L1 and therefore block the interaction may allow the T cells to induce cell killing. Examples of PD-1 inhibitors are pembrolizumab and nivolumab; of
6.1.4.1.3.3 Protein kinase B (AKT) inhibitors
Aberrant activation of the PI3K (phosphatidylinositol-4,5-bisphosphate 3-kinase)/AKT pathway, predominately due to PTEN loss (phosphatase and tensin homologue deleted from chromosome 10), is common in PCa (40–60% of mCRPC) and is associated with worse prognosis. The androgen receptor signalling and AKT pathway are reciprocally cross-regulated, so that inhibition of one leads to upregulation of the other. AKT inhibitors are small molecules which are designed to target and bind to all three isoforms of AKT, which is a key component of the PI3K/AKT pathway and a key driver of cancer cell growth. Ipatasertib is an oral, highly specific, AKT inhibitor which shows clinically significant activity when combined with abiraterone acetate in patients with loss of the tumour suppressor protein PTEN (on IHC) within the tumour [818, 819]. The therapeutic indication for PCa is discussed in Section 6.5.6.5.

6.1.4.1.3.4 Radiopharmaceutical therapy
Radiopharmaceutical therapy (RPT) is based on the delivery of radioactive atoms to tumour-associated targets. The mechanism of action for RPT is radiation-induced killing of cells. Radionuclides with different emission properties are used to deliver radiation. The most commonly used radionuclides are represented by β-particles (e.g., 177Lu) or α-particles (e.g. 223Ra, 225Ac). 177Lu is increasingly used because of its optimal imaging range (100–200 keV), favourable half time (6.6 days) and appropriate β-particle energy for therapy.

The short path of the β-particles (0.05–0.08 mm) results in minimal toxic effects in adjacent healthy tissue. These properties enable such radionuclides to be used as theranostics (i.e., the same radionuclide may be used for both diagnostic and therapeutic purposes). However, an essential requirement prior to any RPT is to assess the targeting of the agent, mainly using PET techniques which show the tumour expression and the extent of cancer [820].

6.1.5 Investigational therapies
6.1.5.1 Background
Besides RP, EBRT and brachytherapy, other modalities have emerged as potential therapeutic options in patients with clinically localised PCa [821-824]. In this section, both whole gland- and focal treatment will be considered, looking particularly at high-intensity focused US (HIFU), cryoablation of the prostate (cryotherapy) and focal photodynamic therapy, as sufficient data are available to form the basis of some initial judgements. Other options such as radiofrequency ablation (RFA) and electroporation, among others, are considered to be in the early phases of evaluation [825]. In addition, a relatively newer development is focal ablative therapy [825, 826] whereby lesion-targeted ablation is undertaken in a precise organ-sparing manner. All these modalities have been developed as minimally-invasive procedures with the aim of providing equivalent oncological safety, reduced toxicity, and improved functional outcomes.

6.1.5.2 Cryotherapy
Cryotherapy uses freezing techniques to induce cell death by dehydration resulting in protein denaturation, direct rupture of cellular membranes by ice crystals and vascular stasis and microthrombi, resulting in stagnation of the microcirculation with consequent ischaemic apoptosis [821-824]. Freezing of the prostate is ensured by the placement of 17 gauge cryo-needles under TRUS guidance, placement of thermosensors at the level of the external sphincter and rectal wall, and insertion of a urethral warmer. Two freeze-thaw cycles are used under TRUS guidance resulting in a temperature of -40°C in the mid-gland and at the neurovascular bundle. Currently, third and fourth generation cryotherapy devices are mainly used. Since its inception, cryotherapy has been used for whole-gland treatment in PCa either as a primary or salvage treatment option.

The main adverse effects of cryosurgery are ED (18%), urinary incontinence (2–20%), urethral sloughing (0–38%), rectal pain and bleeding (3%) and recto-urethral fistula formation (0–6%) [827]. There is a lack of comparative prospective data regarding oncological outcomes of whole-gland cryosurgery as a curative treatment option for men with localised PCa, with most studies being non-comparative single-arm case series with short follow-up [827].

6.1.5.3 High-intensity focused ultrasound
High-intensity focused US consists of focused US waves emitted from a transducer that cause tissue damage by mechanical and thermal effects as well as by cavitation [828]. The goal of HIFU is to heat malignant tissue above 65°C so that it is destroyed by coagulative necrosis. High-intensity focused US is performed under general or spinal anaesthesia, with the patient lying in the lateral or supine position. High-intensity focused US has previously been widely used for whole-gland therapy. The major adverse effects of HIFU include acute urinary retention (10%), ED (23%), urethral stricture (8%), rectal pain or bleeding (11%), recto-urethral fistula
(0–5%) and urinary incontinence (10%) [827]. Disadvantages of HIFU include difficulty in achieving complete ablation of the prostate, especially in glands larger than 40 mL, and in targeting cancers in the anterior zone of the prostate. Similar to cryosurgery, the lack of any long-term prospective comparative data on oncological outcomes prevents whole-gland HIFU from being considered as a reasonable alternative to the established curative treatment options [827].

6.1.5.4 Focal therapy
During the past two decades, there has been a trend towards earlier diagnosis of PCa as a result of greater public and professional awareness leading to the adoption of both formal and informal screening strategies. The effect of this has been that men are identified at an earlier stage with smaller tumours that occupy only 5–10% of the prostate volume, with a greater propensity for unifocal or unilateral disease [829-831]. Most focal therapies to date have been achieved with ablative technologies: cryotherapy, HIFU, photodynamic therapy, electroporation, and focal RT by brachytherapy or CyberKnife® Robotic Radiosurgery System technology (Accuray Inc., Sunnyvale, CA, USA). The main purpose of focal therapy is to ablate tumours selectively whilst limiting toxicity by sparing the neurovascular bundles, sphincter and urethra [832-834].

A systematic review and network meta-analysis on ablative therapy in men with localised PCa performed a sub-group analysis of focal therapy vs. RP and EBRT [827]. Nine case series reporting on focal therapy were identified (5 studies reporting on focal cryosurgical ablation of the prostate [CSAP], three studies on focal HIFU, and one study reported on both). For focal CSAP vs. RP or EBRT, no statistically significant differences were found for BCR at 3 years. For focal HIFU vs. RP or EBRT there were neither comparable data on oncological-, continent- nor potency outcomes at one year or more. More recently, Valerio et al., performed a systematic review to summarise the evidence regarding the effectiveness of focal therapy in localised PCa [826]. Data from 3,230 patients across 37 studies were included, covering different energy sources including HIFU, CSAP, photodynamic therapy, laser interstitial thermotherapy, focal brachytherapy, irreversible electroporation and radiofrequency ablation. The overall quality of the evidence was low, due to the majority of studies being single-centre, non-comparative and retrospective in design, heterogeneity of definitions and approaches, follow-up strategies, outcomes, and duration of follow-up. Although the review suggests that focal therapy has a favourable toxicity profile in the short-to-medium term, its oncological effectiveness remains unproven due to lack of reliable comparative data against standard interventions such as RP and EBRT.

In order to update the evidence base, a systematic review incorporating a narrative synthesis was performed by the Panel, including comparative studies assessing focal ablative therapy vs. radical treatment, AS or alternative focal ablative therapy, published between 1st January 2000 and 12th June 2020 [835]. In brief, out of 1,119 articles identified, 4 primary studies (1 RCT and 3 retrospective cohort studies) [836-840] recruiting 3,961 patients, and 10 systematic reviews were included [827]. Only qualitative synthesis was possible due to clinical heterogeneity. Overall risk of bias (RoB) and confounding were moderate to high. Comparative effectiveness data regarding focal therapy were inconclusive. Data quality and applicability were poor due to clinical heterogeneity, RoB and confounding, lack of long-term data, inappropriate outcome measures and poor external validity. The majority of systematic reviews had a low or critically low confidence rating.

The only identified RCT, Azzouzi et al., deserves discussion [836]. The authors compared focal therapy using padeliporfin-based vascular-targeted photodynamic therapy (PDT) vs. AS in men with very low-risk PCa. The study found, at a median follow-up of 24 months, that less patients progressed in the PDT arm compared with the AS arm (adjusted HR: 0.34, 95% CI: 0.24–0.46), and needed less radical therapy (6% vs. 29%, p < 0.0001). In addition, more men in the PDT arm had a negative prostate biopsy at two years than men in the AS arm (adjusted RR: 3.67, 95% CI: 2.53–5.33). Updated results were published in 2018 showing that these benefits were maintained after four years [837]. Nevertheless, limitations of the study include inappropriately comparing an intervention designed to destroy cancer tissue in men with low-risk PCa against an intervention primarily aimed at avoiding unnecessary treatment in men with low-risk PCa, and an unusually high observed rate of disease progression in the AS arm (58% in two years). Furthermore, more patients in the AS arm chose to undergo radical therapy without a clinical indication which may have introduced confounding bias. Finally, the AS arm did not undergo any confirmatory biopsy or any MRI scanning, which is not representative of contemporary practice. Given the lack of robust comparative data on medium- to long-term oncological outcomes for focal therapy against curative interventions (i.e. RP or EBRT), significant uncertainties remain in regard to focal therapy as a proven alternative to either AS or radical therapy. Consequently, robust prospective trials reporting standardised outcomes [841] are needed before unrestricted recommendations in support of focal therapy for routine clinical practice can be made [825, 841, 842]. For now, the available evidence indicates that focal therapy should be performed within the context of a clinical trial setting or well-designed prospective cohort study. It is hoped that more mature and robust data demonstrating long-term efficacy in the next few years will provide the necessary evidence which will facilitate its wider implementation and acceptance.
6.1.6 **General guidelines for the treatment of prostate cancer**

<table>
<thead>
<tr>
<th>Recommendations</th>

**Surgical treatment**

Inform patients that no surgical approach (open-, laparoscopic- or robotic radical prostatectomy) has clearly shown superiority in terms of functional or oncological results. Weak

When a lymph node dissection (LND) is deemed necessary, perform an extended LND template for optimal staging. Strong

Do not perform nerve-sparing surgery when there is a risk of ipsilateral extracapsular extension (based on cT stage, ISUP grade, magnetic resonance imaging, or with this information combined into a nomogram). Weak

Do not offer neoadjuvant androgen deprivation therapy before surgery. Strong

**Radiotherapeutic treatment**

Offer intensity-modulated radiation therapy (IMRT) or volumetric arc radiation therapy (VMAT) plus image-guided radiation therapy (IGRT) for definitive treatment of PCa by external-beam radiation therapy. Strong

Offer moderate hypofractionation (HFX) with IMRT/VMAT plus IGRT to the prostate to patients with localised disease. Strong

Ensure that moderate HFX adheres to radiotherapy protocols from trials with equivalent outcome and toxicity, i.e. 60 Gy/20 fractions in 4 weeks or 70 Gy/28 fractions in 6 weeks. Strong

Offer low-dose rate (LDR) brachytherapy monotherapy to patients with good urinary function and low- or intermediate-risk disease with ISUP grade 2 and < 33% of biopsy cores involved. Strong

Offer LDR or high-dose rate (HDR) brachytherapy boost combined with IMRT/VMAT plus IGRT to patients with good urinary function intermediate-risk disease with ISUP G3 and/or PSA 10–20 ng/mL. Weak

Offer LDR or HDR brachytherapy boost combined with IMRT/VMAT plus IGRT to patients with good urinary function and high-risk and/or locally advanced disease. Weak

**Active therapeutic options outside surgery or radiotherapy**

Offer whole-gland cryotherapy and high-intensity focused ultrasound within a clinical trial setting or well-designed prospective cohort study. Strong

Offer focal therapy within a clinical trial setting or well-designed prospective cohort study. Strong

6.2 **Treatment by disease stages**

6.2.1 **Treatment of low-risk disease**

6.2.1.1 **Active surveillance**

The main risk for men with low-risk disease is over treatment (see Sections 6.1.1.2 and 6.1.1.4); therefore, AS should be considered for all such patients.

Guidance regarding selection criteria for AS is limited by the lack of data from prospective RCTs. As a consequence, the Panel undertook an international collaborative study involving healthcare practitioners and patients to develop consensus statements for deferred treatment with curative intent for localised PCa, covering all domains of AS (DETECTIVE Study) [284], as well as a formal systematic review on the various AS protocols [843]. The criteria most often published include: ISUP grade 1, clinical stage cT1c or cT2a, PSA < 10 ng/mL and PSA-D < 0.15 ng/mL/cc [517, 844]. The latter threshold remains controversial [844, 845]. These criteria were supported by the DETECTIVE consensus. There was no agreement on the maximum number of cores that can be involved with cancer or the maximum percentage core involvement (CI), although there was recognition that extensive disease on MRI should exclude men from AS [284]. A systematic review and meta-analysis found three clinico-pathological variables which were significantly associated with reclassification, which included PSA-D, > 2 positive cores, and African-American race [846]. In addition, a previous pathology consensus group suggested excluding men from AS when any of the following features were...
present: predominant ductal carcinoma (including pure intraductal carcinoma), cribriform histology, sarcomatoid carcinoma, small cell carcinoma, EPE or LVI in needle biopsy [382] and perineural invasion [847].

Recently, a multidisciplinary consensus conference on germline testing attempted to develop a genetic implementation framework for the management of PCa [165]. Based on consensus, BRCA2-gene testing was recommended for AS discussions. However, the nature of such discussions and how a positive result influences management were beyond the scope of the project. Currently, if included in AS programmes, patients with a BRCA2 mutation should be cautiously monitored until such time that more robust data are available.

6.2.1.1.2 Tissue-based prognostic biomarker testing

Biomarkers, including Oncotype Dx®, Prolaris®, Decipher®, PORTOS and ProMark® are promising (see Section 5.2.8.3). However, further data will be needed before such markers can be used in standard clinical practice [236].

6.2.1.1.3 Magnetic resonance imaging for selection for active surveillance

In men eligible for AS based upon systematic biopsy findings alone who did not have a pre-biopsy MRI, a re-biopsy within 6–12 months (usually referred to as ‘confirmatory biopsy’) seems mandatory to exclude sampling error [844, 848]. Magnetic resonance imaging can also improve the detection of aggressive cancers [849, 850]. A systematic review showed that men with positive baseline MRI have an, approximately, 3-fold higher chance (RR: 2.77, 95% CI: 1.76–4.38) of upgrading to an ISUP grade ≥ 2 cancer than men with negative MRI [851]. More recent studies of patients on AS for ISUP 1 cancer confirmed that a positive baseline MRI was a significant predictor of upgrading to ISUP grade ≥ 2 cancer and of unfavourable disease at RP [852, 853]. This is also true when upgrading is defined as progression to ISUP grade ≥ 3 cancer [854, 855]. Of note, MRI keeps its significant predictive power for upgrading when other strong predictors such as age or PSA-D are accounted for [853, 855, 856].

At confirmatory biopsy, adding MRI-targeted biopsy to systematic biopsy improves upgrade detection rates by increments of 3.3 to 7.9 per 100 men depending on the series [857]. However, systematic biopsy retains substantial added value [851].

A meta-analysis evaluated the proportion of men eligible for AS based on systematic TRUS-guided biopsy in whom the cancer was upgraded by MRI-targeted biopsy (17%) and systematic biopsy (20%) at confirmatory biopsy [851]. Ten percent of patients were upgraded by both biopsy methods, meaning MRI-targeted biopsy upgraded an additional 7% (95% CI: 5–10%) of men, whilst systematic biopsy upgraded an additional 10% of men (95% CI: 8–14%). Even if the analysed series used different definitions for cancer upgrading, combining the two biopsy techniques appears to be the best way to select patients for AS at confirmatory biopsy.

The Active Surveillance Magnetic Resonance Imaging Study (ASIST) randomised men on AS scheduled for confirmatory biopsy to either 12-core systematic biopsy or to MRI with targeted biopsy (when indicated) combined with systematic biopsy (up to 12 cores in total). After 2 years of follow-up, use of MRI before confirmatory biopsy resulted in fewer failures of surveillance (19% vs. 35%, p = 0.017) and in fewer patients progressing to ISUP grade ≥ 2 cancer (9.9% vs. 23%, p = 0.048) [858].

At the DETECTIVE consensus meeting it was agreed that men eligible for AS after combined systematic- and MRI-targeted biopsy do not require a confirmatory biopsy [284].

6.2.1.1.4 Follow-up during active surveillance

Based on the DETECTIVE consensus study, the follow-up strategy should be based on serial DRE (at least once yearly), PSA (at least once, every 6 months) and repeated biopsy. It was also agreed that PSA progression or change in PSA kinetics alone should lead to reclassification only if accompanied by changes in histology on repeat biopsy [284].

In 2016, the Prostate Cancer Radiological Estimation of Change in Sequential Evaluation (PRECISE) criteria were established to standardise the assessment of tumour progression on serial MRI [859]. Progression on MRI, defined using the PRECISE criteria, or not, is a strong predictor of histological upgrading [860]. Two independent meta-analyses assessed the value of MRI progression criteria for predicting histological progression (mostly defined as progression to ISUP grade ≥ 2). The pooled histological progression rate was 27% in both reviews. If biopsies were triggered only by MRI progression findings, approximately two thirds of the biopsies would be avoided, at the cost of missing 40% of men with histological progression. In addition, at least half of biopsied men would have had negative findings for histological progression and thus would have undergone unnecessary biopsies. If histological progression was restricted to progression to ISUP grade ≥ 3, approximately 30% of histological progression would be missed and approximately 80% of the biopsies performed would be unnecessary. The use of the PRECISE criteria did not seem to change these results [861, 862].

Combining MRI finding with PSA-D [855, 863, 864] or PSA kinetics [850, 865] may improve the prediction of histological progression, prompting, for example, the biopsy of all patients with elevated PSA-D...
regardless of MRI findings, or avoiding biopsy only when MRI does not show progression and the PSA level is stable. Combining MRI with other biomarkers may also help selecting patients for follow-up biopsy [866, 867]. Nonetheless, the level of evidence of these studies remains low and therefore, protocol-mandated, untriggered follow-up biopsies seem necessary [284].

A Panel systematic review incorporating 263 surveillance protocols showed that 78.7% of protocols mandated per-protocol confirmatory biopsies within the first 2 years and that 57.7% of the protocols performed repeat-biopsy at least every 3 years for 10 years after the start of AS [843]. In a single centre AS cohort of 514 patients who underwent at least three protocol-mandated biopsies after diagnosis (the confirmatory biopsy and at least two additional surveillance biopsies), men with one negative biopsy (i.e., no cancer at all) at confirmatory or second biopsy, or men with two consecutive negative biopsies had a lower likelihood of positive third biopsy and significantly better 10-year treatment-free survival [868]. This suggests that men with repetitive negative biopsies may pursue AS with at least less frequent untriggered biopsies.

6.2.1.1.5 Active Surveillance - change in treatment

Men may remain on AS whilst they continue to consent, have a life expectancy of > 10 years and the disease remains indolent. Patient anxiety about continued surveillance occurs in around 10% of patients on AS [869] and was recognised as a valid reason for active treatment [284]. More common is the development of other co-morbidities which may result in a decision to transfer to a WW strategy.

A PSA change alone (including PSA-DT < 3 years) should not change management based on its weak link with grade progression [870, 871] but rather trigger further investigation. There was clear agreement in the DETECTIVE consensus meeting that a change in PSA should lead to repeat-MRI and repeat-biopsy. It was also agreed that changes on follow-up MRI needed a confirmatory biopsy before considering active treatment [284].

However, the histopathology criteria required to trigger a change in management in the targeted biopsy era remain debated. Magnetic resonance imaging-targeted biopsy induces a grade shift and ISUP 2-3 cancers detected by MRI-targeted biopsy have, on average, better prognosis than those detected by systematic sampling (see Section 5.2.4.2.6.4). As an increasing number of men with favourable intermediate-risk disease are managed with AS, it seems illogical to use progression to ISUP grade 2 based on targeted biopsies as the sole criterion for reclassification. In addition, as acknowledged in the DETECTIVE consensus meeting, the number of positive cores is not an indicator of tumour volume anymore if targeted biopsies are performed [284, 866]. No agreement could be reached on the pathological criteria required to trigger a change in management during the DETECTIVE consensus meeting [284]. However, based on the findings of a systematic review incorporating 271 reclassification protocols, patients with low-volume ISUP 2 disease at recruitment, and with increased core positivity (> 3 cores) and/or core involvement (> 50% per core) on repeat systematic biopsies not using MRI, should be reclassified [843].

6.2.1.2 Alternatives to active surveillance

In terms of alternatives to AS in the management of patients with low-risk disease there is some data from randomised studies. In the PIVOT trial (Section 6.1.1.3.1) which compared surgery vs. observation, only 42% of patients had low-risk disease [527]. Sub-group analysis revealed that for low-risk disease there was no statistically significant difference in all-cause mortality between surgery vs. observation (RR: 0.93, 95% CI: 0.78–1.11). In the ProtecT study (Section 6.1.1.4) which compared AM vs. surgery vs. EBRT, 56% of patients had low-risk disease [516]. However, no sub-group analysis on disease risk was performed on this population. The study found no difference between the three arms in terms of OS and CSS, but AM had higher metastatic progression compared with surgery or EBRT (6.0% vs. 2.6%). There are no robust data comparing contemporary AS protocols with either surgery or EBRT in patients with low-risk disease. On balance, although AS should be the default management strategy in patients with low-risk disease and a life expectancy > 10 years, it would be reasonable to consider surgery and EBRT as alternatives to AS in patients suitable for such treatments and who accept a trade-off between toxicity and prevention of disease progression.

6.2.1.2.1 ADT monotherapy

Data regarding the use of ADT monotherapy in men with low-risk localised disease may be inferred indirectly from the Early Prostate Cancer (EPC) Trial Programme which published its findings in 2006 [872]. The EPC programme comprises three large RCTs including 8,113 men with localised (cT1–2, N0/NxM0) or locally advanced (cT3–4, any N; or any T, N+, M0) PCa. The intervention was oral bicalutamide 150 mg monotherapy vs. placebo following standard care (defined as RP, radical EBRT or WW). The primary endpoints were PFS and OS. Patients were stratified according to clinical stage only; data regarding PSA and Gleason score were not assessed. The authors found in patients with localised disease, ADT monotherapy did not improve PFS nor OS in any of the subgroups, compared with placebo. Instead, there was a statistically insignificant numerical
trend towards worse OS with ADT in the WW sub-group (HR: 1.16, 95% CI: 0.99–1.37; p = 0.07). Although the trial did not directly address men with low-risk disease, it offered some evidence suggesting that otherwise asymptomatic men with localised disease should not receive ADT monotherapy. Currently, there is no evidence supporting the use of ADT monotherapy in asymptomatic men with low-risk disease who are not eligible for any local/radical treatment; these men should simply be offered WW alone.

Other treatments such as whole-gland ablative therapy (f.i. cryotherapy or HIFU) or focal ablative therapy remain unproven in the setting of localised low-risk disease compared with AS or radical treatment options; these have been discussed in detail in Section 6.1.5.

6.2.2 Treatment of intermediate-risk disease

When managed with non-curative intent, intermediate-risk PCa is associated with 10-year and 15-year PCSM rates of 13.0% and 19.6%, respectively [873]. These estimates are based on systematic biopsies and may be overestimated in the era of MRI-targeted biopsies.

6.2.2.1 Active Surveillance

In the ProtecT trial, up to 22% of the randomised patients in the AM arm had ISUP grade > 1 and 10% a PSA > 10 ng/mL [516]. A Canadian consensus group proposes that low volume ISUP grade 2 (< 10% Gleason pattern 4 on systematic biopsies) may also be considered for AS. These recommendations have been endorsed by the American Society of Clinical Oncology (ASCO) [874] and the recent DETECTIVE consensus
3.6.2.2.2 Radical prostatectomy

Patients with intermediate-risk PCa should be informed about the results of two RCTs (SPCG-4 and PIVOT) comparing RRP vs. WW in localised PCa. In the SPCG-4 study, death from any cause (RR: 0.71, 95% CI: 0.53–0.95), death from PCa (RR: 0.38, 95% CI: 0.23–0.62) and distant metastases (RR: 0.49, 95% CI: 0.32–0.74) were significantly reduced in intermediate-risk PCa at 18 years. In the PIVOT trial, according to a pre-planned subgroup analysis among men with intermediate-risk tumours, RP significantly reduced all-cause mortality (HR: 0.69, 95% CI: 0.49–0.98), but not death from PCa (0.50, 95% CI: 0.21–1.21) at 10 years. A meta-analysis based on the findings of SPCG-4, PIVOT and ProtecT demonstrated a benefit from RP over observation with a significantly decreased risk of death of 9% and of disease progression of 43% [879]. However, no stratification by disease stages was performed. The risk of having positive LNs in intermediate-risk PCa is between 3.7–20.1% [880]. An eLND should be performed in intermediate-risk PCa if the estimated risk for pN+ exceeds 5% [426] or 7% if using the nomogram by Gandaglia et al., which incorporates MRI-guided biopsies [429]. In all other cases eLND can be omitted, which means accepting a low risk of missing positive nodes. Nerve sparing surgery is discussed in Section 6.1.2.3.6.

6.2.2.3 Radiation therapy

6.2.2.3.1 Recommended IMRT/VMAT for intermediate-risk PCa

Patients suitable for ADT can be given combined IMRT/VMAT with short-term ADT (4–6 months) [881-883]. For patients unsuitable (e.g., due to co-morbidities) or unwilling to accept ADT (e.g. to preserve their sexual health)
the recommended treatment is IMRT/VMAT (76–78 Gy) or a combination of IMRT/VMAT and brachytherapy as described below (see Section 6.2.3.2.3).

6.2.2.3.2 Brachytherapy for intermediate-risk PCa
The authors of a systematic review of LDR brachytherapy recommend that LDR brachytherapy monotherapy can be offered to patients with NCCN favourable intermediate-risk disease and good urinary function (see Section 4.2) [884]. Fractionated HDR brachytherapy as monotherapy can be offered to selected patients with intermediate-risk PCa although they should be informed that results are only available from small series in very experienced centres. Five-year PSA control rates over 90% are reported, with late grade 3+ GU toxicity rates < 5% and no, or very minimal, grade 3+ GI toxicity rates [771]. There are no direct data to inform on the use of ADT in this setting. Trimodality therapy with IMRT plus brachytherapy boost and short-term ADT can be considered for NCCN unfavourable intermediate-risk PCa (see Section 4.2) but patients should be made aware that the potential improvements in biochemical control are accompanied with an increased risk of long-term urinary problems [762, 763, 767].

6.2.2.4 Other options for the primary treatment of intermediate-risk PCa (experimental therapies)

6.2.2.4.1 Focal therapy
A prospective study on focal therapy using HIFU in patients with localised intermediate-risk disease was published but the data was derived from an uncontrolled single-arm case series [842]. There is a paucity of high-certainty data for either whole-gland or focal ablative therapy in the setting of intermediate-risk disease. Consequently, neither whole-gland treatment nor focal treatment can be considered as standard therapy for intermediate-risk patients and, if offered, it should only be in the setting of clinical trials [825].

6.2.2.4.2 Androgen deprivation therapy monotherapy
Data regarding the use of ADT monotherapy for intermediate-risk disease have been inferred indirectly from the EORTC 30891 trial, which was a RCT comparing deferred ADT vs. immediate ADT in 985 patients with T0–4 N0–2 M0 disease [880]. The trial showed a small, but statistically significant, difference in OS in favour of immediate ADT monotherapy but there was no significant difference in CSS, predominantly because the risk of cancer-specific mortality was low in patients with PSA < 8 ng/mL. Consequently, the use of ADT monotherapy for this group of patients is not considered as standard, even if they are not eligible for radical treatment.

### 6.2.3 Treatment of high-risk localised disease

Patients with high-risk PCa are at an increased risk of PSA failure, need for secondary therapy, metastatic progression and death from PCa. Nevertheless, not all high-risk PCa patients have a uniformly poor prognosis after RP [885]. When managed with non-curative intent, high-risk PCa is associated with 10-year and 15-year PCSM rates of 28.8 and 35.5%, respectively [886]. There is no consensus regarding the optimal treatment of men with high-risk PCa.

#### 6.2.3.1 Radical prostatectomy

Provided that the tumour is not fixed to the pelvic wall or there is no invasion of the urethral sphincter, RP is a reasonable option in selected patients with a low tumour volume. Extended PLND should be performed in all high-risk PCa cases [426, 427]. Patients should be aware pre-operatively that surgery may be part of multi-modal treatment, with adjuvant or salvage radiotherapy (SRT) or ADT. Neoadjuvant therapy using ADT with or without new generation hormone therapy or docetaxel is not indicated. (See Section 6.1.2.2.4) [542, 543]. Nerve sparing management is discussed in Section 6.1.2.3.6.

#### 6.2.3.1.1 ISUP grade 4–5

The incidence of organ-confined disease is 26–31% in men with an ISUP grade > 4 on systematic biopsy. A high rate of downgrading exists between the biopsy ISUP grade and the ISUP grade of the resected specimen [886]. Several retrospective case series have demonstrated CSS rates over 60% at 15 years after RP in the context of a multi-modal approach (adjuvant or salvage ADT and/or RT) in patients with a biopsy ISUP grade 5 [473, 549, 887, 888].

#### 6.2.3.1.2 Prostate-specific antigen > 20 ng/mL

Reports in patients with a PSA > 20 ng/mL who underwent surgery as initial therapy within a multi-modal approach demonstrated a CSS at 15 years of over 70% [473, 549, 556, 889-891].

#### 6.2.3.1.3 Radical prostatectomy in cN0 patients who are found to have pathologically confirmed LN invasion (pN1)

At 15 years follow-up cN0 patients who underwent RP but who were found to have pN1 were reported to have an overall CSS and OS of 45% and 42%, respectively [892-898]. A systematic review has reported 10-year BCR-free, CSS, and OS rates ranging from 28% to 56%, 72% to 98%, and 60% to 87.6%, respectively, in pN1 patients [899]. These findings highlight that pN1 patients represent a very heterogeneous patient group and further treatment must be individualised based on risk factors (see Sections 6.2.5.2 and 6.2.5.6).

#### 6.2.3.2 External beam radiation therapy

For high-risk localised PCa, a combined modality approach should be used consisting of IMRT/VMAT plus long-term ADT. The duration of ADT has to take into account PS, co-morbidities and the number of poor prognostic factors. It is important to recognise that in several studies EBRT plus short-term ADT did not improve OS in high-risk localised PCa and long-term ADT (at least 2 to 3 years) is currently recommended for these patients [721, 722, 725].

#### 6.2.3.2.1 Lymph node irradiation in cN0

There is low level evidence for prophylactic whole-pelvic irradiation as RCTs so far failed to show that patients benefit from prophylactic irradiation (46–50 Gy) of the pelvic LNs in intermediate- and high-risk disease [900-902].
The long-term results of the NRG/RTOG 9413-trial which randomised intermediate-risk and high-risk localised PCa patients (1,322 cN0 patients were enrolled), showed that neoadjuvant hormonal treatment plus whole pelvic RT improved PFS only compared with neoadjuvant ADT plus prostate RT and whole pelvic RT plus adjuvant ADT [903]. However, at the increased risk of ≥ grade 3 GI-toxicity. There was a suggestion of interaction between ADT and RT and therefore whole pelvic RT should be avoided without neoadjuvant ADT.

A well-conducted RCT compared prostate-only RT (PORT) vs. whole pelvic RT (WPRT) in localised high-risk- and locally advanced tumours (cN0) with a risk of > 20% of positive nodes (Roach formula). With a median follow-up of 68 months there was a significant improvement of distant metastasis-free survival (95.9% vs. 89.2%, HR: 0.35, p = 0.01) and DFS (89.5% vs. 77.2%, p = 0.02). However, there was a significant higher rate of late GU ≥ 2 effects (17.7% vs. 7.5%, p = 0.02), the trial was relatively small in size with additional limitations and these findings are therefore insufficient to define a change in practice [904, 905]. The benefits of pelvic nodal irradiation using IMRT/VMAT merit further investigation in large scale RCTs as conducted by the RTOG or the UK National Cancer Research Institute (NCRI). Performing an ePLND in order to decide whether or not pelvic RT is required (in addition to combined prostate EBRT plus long-term ADT) remains experimental in the absence of high-level evidence.

6.2.3.2.2 Brachytherapy boost
In men with intermediate- or high-risk PCa, brachytherapy boost with supplemental EBRT and hormonal treatment may be considered. See Sections 6.1.3.4.1 and 6.1.3.4.2 for details on RCTs comparing EBRT alone and EBRT with LDR or HDR boost, respectively.

6.2.3.3 Options other than surgery or radiotherapy for the primary treatment of localised PCa
Currently there is a lack of evidence supporting any other treatment option apart from RP and radical RT in localised high-risk PCa. The use of ADT monotherapy was addressed by the EORTC 30891 trial [880] (see Section 6.2.4.4.2). Immediate ADT may only benefit patients with a PSA-DT < 12 months, and either a PSA > 50 ng/mL or a poorly-differentiated tumour [880, 931].

6.2.4 Treatment of locally advanced PCa
In the absence of high-level evidence, a recent systematic review could not define the most optimal treatment option [906]. Randomised controlled trials are only available for EBRT. A local treatment combined with a systemic treatment provides the best outcome, provided the patient is ready and fit enough to receive both.

6.2.4.1 Radical prostatectomy
Surgery for locally advanced disease as part of a multi-modal therapy has been reported [886, 907, 908]. However, the comparative oncological effectiveness of RP as part of a multi-modal treatment strategy vs. upfront EBRT with ADT for locally advanced PCa remains unknown, although a prospective phase III RCT (SPCG-15)
comparing RP (with or without adjuvant or salvage EBRT) against primary EBRT and ADT among patients with locally advanced (T3) disease is currently recruiting [909]. Data from retrospective case series demonstrated over 60% CSS at 15 years and over 75% OS at 10 years [886, 907, 908, 910-914]. For cT3b–T4 disease, PCa cohort studies showed 10-year CSS of over 87% and OS of 65% [915-917]. The indication for RP in all previously described stages assumes the absence of clinically detectable nodal involvement (cN0). In case of suspected positive LNs during RP (initially considered cN0) the procedure should not be abandoned since RP may have a survival benefit in these patients. Intra-operative frozen section analysis is not justified in this case [604]. An ePLND is considered standard if a RP is planned.

6.2.4.2 Radiotherapy for locally advanced PCa

In locally advanced disease RCTs have clearly established that the additional use of long-term ADT combined with RT produces better OS than ADT or RT alone (see Section 6.1.3.1.4 and Tables 6.1.9 and 6.1.10) [906]. See Sections 6.1.3.4.1 and 6.1.3.4.2 for LDR and HDR brachytherapy boost in T3N0M0 PCa.

6.2.4.3 Treatment of cN1 M0 PCa

Lymph node metastasised PCa is where options for local therapy and systemic therapies overlap. Approximately 5% to 10% of newly diagnosed PCa patients have synchronous suspected pelvic nodal metastases on conventional imaging (CT/bone scan) without bone or visceral metastases (cN1 M0 stage). Meta-analyses have shown that PSMA-PET/CT prior to primary treatment in advanced PCa detected disease outside the prostate in 32% of cases despite prior negative conventional imaging using bone scan and pelvic CT/MRI [445]. A RCT assessing PSMA-PET/CT as staging tool in high-risk PCa confirmed these findings and showed a 32% increase in accuracy compared with conventional imaging for the detection of pelvic nodal metastases [465]. Notably, more sensitive imaging also causes a stage shift with more cases classified as cN1, but with, on average, lower nodal disease burden.

The management of cN1M0 PCa is mainly based on long-term ADT combined with a local treatment. The benefit of adding local treatment has been assessed in various retrospective studies, summarised in one systematic review [918] including 5 studies only [919-923]. The findings suggested an advantage in both OS and CSS after local treatment (RT or RP) combined with ADT as compared to ADT alone. The main limitations of this analysis were the lack of randomisation, of comparisons between RP and RT, as well as the value of the extent of PLND and of RT fields. Only limited evidence exists supporting RP for cN+ patients. Moschini et al., compared the outcomes of 50 patients with cN+ with those of 252 patients with pN1, but cN0 at pre-operative staging. cN+ was not a significant predictor of CSS [924].

Based on the consistent benefit seen in retrospective studies including cN1 patients, local therapy is recommended in patients with cN1 disease at diagnosis in addition to long-term ADT (see Table 6.2.4.1). The addition of a brachytherapy boost to ADT plus EBRT was not associated with improved OS in a retrospective study of 1,650 cN1 patients after multivariable adjustment and propensity score matching [925].

The intensification of systemic treatment (abiraterone acetate, docetaxel, zoledronic acid) has been assessed in unplanned sub-group analyses from the STAMPEDE multi-arm RCT by stratifying for cN+ and M+ status [40, 922]. The analyses were balanced for nodal involvement and for planned RT use in STAMPEDE at randomisation and at analysis. Abiraterone acetate was associated with a non-significant OS improvement (HR: 0.75, 95% CI: 0.48–1.18) in non-metastatic patients (N0/N+M0), but OS data were still immature with a low number of events. Furthermore, this was an underpowered subgroup analysis and hypothesis generating at best. Moreover, subgroup analyses were performed according to the metastatic/non-metastatic status and to the nodal status (any M) without specific data for the N+M0 population (n = 369; 20% of the overall cohort). The same would apply for the docetaxel arm in the STAMPEDE trial for which no specific subgroup analysis of newly diagnosed N+M0 PCa (n = 171, 14% of the overall cohort) was performed. However, the addition of docetaxel, zoledronic acid, or their combination, did not provide any OS benefit when stratifying by M0 and N+ status.

In the AFU-GETUG 12 trial comparing the impact of docetaxel plus estramustine in addition to ADT, 29% of included high-risk non-metastatic PCa patients had a nodal involvement at randomisation [926]. A non-significant trend towards better relapse survival rates was reported in the treatment arm (HR 0.66; 0.43–1.01) without OS benefit. A meta-analysis of docetaxel trials in N0M0-M1 patients concluded to an 8% 4-year survival advantage for docetaxel compared with ADT alone in terms of failure-free survival without OS benefit [927].

The STAMPEDE trial reported on 1,974 men with de novo high-risk/locally-advanced M0 disease, or relapse after primary curative therapy with high-risk features [928]. Eligibility criteria for de novo disease were: at least two of T-category clinical T3 or T4, Gleason sum score 8–10, PSA > 40 ng/mL, or node positive. Eligibility
criteria for relapsed patients were any of: node positive; PSA > 4 ng/mL and rising with a doubling time < 6 months; or PSA > 20 ng/mL. Patients were randomised to ADT alone, or ADT plus abiraterone, with or without enzalutamide. Radiotherapy was mandated for N0 disease and recommended for N1 disease. Androgen deprivation therapy was administered for 3 years, and abiraterone/enzalutamide for 2 years.

Four hundred and fifty-nine patients were treated with ADT plus abiraterone, and 527 with ADT plus abiraterone plus enzalutamide. Ninety-seven percent of patients randomised were treated for de novo disease. Thirty-three percent of patients were N+. Radiotherapy was administered in 99% of N0 and 71% of cN1 patients, respectively. The primary outcome measure was metastasis-free survival. With a median follow-up of 72 months, the combination therapy significantly improved metastasis-free survival (HR 0.53, \( p = 2.9 \times 10^{-11} \)) and OS (HR: 0.60, \( p = 9.3 \times 10^{-7} \)). Adding enzalutamide did not improve efficacy. Combined ADT (for 3 years) and additional abiraterone (for 2 years), plus prostate and whole pelvic RT in the case of primary therapy, should be a SOC in this group of patients.

ADT = androgen deprivation therapy; CSS = cancer-specific survival; EBRT = external beam radiotherapy; FFS = failure-free survival; HR = hazard ratio; mo = months; n = number of patients; OS = overall survival; RP = radical prostatectomy; RT = radiotherapy; yr = year.
6.2.4.4 Options other than surgery or radiotherapy for primary treatment

6.2.4.4.1 Investigational therapies
Currently cryotherapy, HIFU or focal therapies have no place in the management of locally-advanced PCa.

6.2.4.4.2 Androgen deprivation therapy monotherapy
The deferred use of ADT as single treatment modality has been answered by the EORTC 30891 trial [880]. Nine hundred and eighty-five patients with T0–4 N0–2 M0 PCa received ADT alone, either immediately or after symptomatic progression or occurrence of serious complications. After a median follow-up of 12.8 years, the OS favoured immediate treatment (HR: 1.21, 95% CI: 1.05–1.39). Surprisingly, no different disease-free or symptom-free survival was observed, raising the question of survival benefit. In locally-advanced T3–T4 M0 disease unsuitable for surgery or RT, immediate ADT may only benefit patients with a PSA > 50 ng/mL and a PSA-DT < 12 months or those that are symptomatic [880, 931]. The median time to start deferred treatment was 7 years. In the deferred treatment arm 25.6% of patients died without needing treatment.

**Therapeutic options outside surgery or radiotherapy**

Do not offer whole gland treatment or focal treatment to patients with locally-advanced PCa. Strong

Only offer ADT monotherapy to those patients unwilling or unable to receive any form of local treatment if they have a prostate-specific antigen (PSA)-doubling time < 12 months, and either a PSA > 50 ng/mL, a poorly-differentiated tumour or troublesome local disease-related symptoms. Strong

Offer patients with cN1 disease a local treatment (either RP or IMRT/VMAT plus IGRT) plus long-term ADT. Weak

6.2.5 Adjuvant treatment after radical prostatectomy

6.2.5.1 Introduction
Adjuvant treatment is by definition additional to the primary or initial therapy with the aim of decreasing the risk of relapse. A post-operative detectable PSA is an indication of persistent prostate cells (see Section 6.2.6). All information listed below refers to patients with a post-operative undetectable PSA.

6.2.5.2 Risk factors for relapse
Patients with ISUP grade > 2 in combination with EPE (pT3a) and particularly those with SV invasion (pT3b) and/or positive surgical margins are at high risk of progression, which can be as high as 50% after 5 years [932]. Irrespective of the pT stage, the number of removed nodes [933-940], tumour volume within the LNs and capsular perforation of the nodal metastases are predictors of early recurrence after RP for pN1 disease [941]. A LN density (defined as “the percentage of positive LNs in relation to the total number of analysed/removed LNs”) of over 20% was found to be associated with poor prognosis [942]. The number of involved nodes seems to be a major factor for predicting relapse [935, 936, 943]; the threshold considered is less than 3 positive nodes from an ePLND [567, 935, 943]. However, prospective data are needed before defining a definitive threshold value.
6.2.5.2.1 Biomarker-based risk stratification after radical prostatectomy

The Decipher® gene signature consists of a 22-gene panel representing multiple biological pathways and was developed to predict systemic progression after definitive treatment. A meta-analysis of five studies analysed the performance of the Decipher® Genomic Classifier (GC) test on men post-RP. The authors showed in multivariable analysis that Decipher® GC remained a statistically significant predictor of metastasis (HR: 1.30, 95% CI: 1.14–1.47, p < 0.001) per 0.1 unit increase in score and concluded that it can independently improve prognostication of patients post-RP within nearly all clinicopathologic, demographic, and treatment subgroups [944]. A systematic review of the evidence for the Decipher® GC has confirmed the clinical utility of this test in post-RP decision-making [945]. Further studies are needed to establish how to best incorporate Decipher® GC in clinical decision-making.

6.2.5.3 Immediate (adjuvant) post-operative external irradiation after RP (cN0 or pN0)

Four prospective RCTs have assessed the role of immediate post-operative RT (adjuvant RT [ART]), demonstrating an advantage (endpoint, development of BCR) in high-risk patients (e.g., pT2/pT3 with positive surgical margins and GS 8–10) post-RP (Table 6.2.5.1). In the ARO 96-02 trial, 80% of the pT3/R1/GS 8–10 patients randomised to observation developed BCR within 10 years. It must be emphasised that PSA was undetectable at inclusion only in the ARO 96-02 trial which presents a major limitation interpreting these findings as patients with a detectable PSA would now be considered for salvage therapy rather than ART [946].

*See Section 6.3.5.1 for delayed (salvage) post-radical prostatectomy external irradiation.

BCR = biochemical recurrence; FU = follow-up; mo = months; n = number of patients; n.s. = not significant; OS = overall survival; PSA = prostate-specific antigen; RP = radical prostatectomy; SM = surgical margin; SRT = salvage radiotherapy.

6.2.5.4 Comparison of adjuvant- and salvage radiotherapy

Two retrospective matched studies (510 and 149 patients receiving ART) failed to show an advantage for metastasis-free survival [950, 951]. However, both studies were underpowered for high-risk patients (pT3b/R1/ISUP grade 4–5 PCa).

In contrast to these studies, a propensity score-matched retrospective analysis of two cohorts of 366 pT3 and/or R1 patients found that compared to SRT at a PSA between 0.1 and 0.5 ng/mL, ART given at an undetectable PSA (< 0.1 ng/mL) improved all three endpoints; BCR, metastasis-free survival, and OS [952].
Both approaches (ART and early SRT) together with the efficacy of adjuvant ADT are compared in three prospective RCTs: the Medical Research Council (MRC) Radiotherapy and Androgen Deprivation In Combination After Local Surgery (RADICALS) trial [953], the Trans-Tasman Oncology Group (TROG) Radiotherapy Adjuvant Versus Early Salvage (RAVES) trial [954], and the Groupe d’Etude des Tumeurs Uro-Genitales (GETUG-AFU 17) trial [955]. In addition, a pre-planned meta-analysis of all three trials has been published (Table 6.2.5.2) [956].

Two trials closed early after randomising 333/470 patients (RAVES) and 424/718 (GETUG-AFU-17) patients. RADICALS-RT included 1,396 patients with the option of subsequent inclusion in RADICALS-HT; 154/649 (24%) of patients starting in the adjuvant RT group also received neoadjuvant or adjuvant HT; 90 patients for 6 months/45 for 2 years/19 patients outside RADICALS-HT. From the SRT group, 61/228 (27%) received neoadjuvant or adjuvant HT for 6 months (n = 33) and 2 years (n = 13). Fifteen of these patients were treated outside the trial [953]. All men in the GETUG-AFU-17 trial (n = 424) received 6 months of HT. All together, 684 out of 2,153 patients received additional ADT for at least 6 months across both trials [956]. Radiotherapy to the pelvic lymphatics was allowed in the GETUG-AFU and in the RADICALS-RT trials.

The primary endpoint for RAVES and GETUG-AFU 17 was biochemical PFS, and for RADICALS-RT metastasis-free survival. So far only PFS data has been reported, and not metastasis-free survival- or OS data. With a median follow-up between 4.9 years and 6.25 years there was no statistically significant difference for biochemical PFS for both treatments in all three trials (see Table 6.2.5.2) indicating that in the majority of patients adjuvant irradiation should be avoided. Additionally, there was a significant lower rate of grade ≥ 2 GU late side effects and grade 3–4 urethral strictures in favour of early SRT; which may also be caused by the low number of patients with PSA-progression and subsequent need for early SRT at the time of analysis (40% of patients).

It is important to note that the indication for ART changed over the last ten years with the introduction of ultra-sensitive PSA-tests, favouring early SRT. Therefore many patients, randomised in these 3 trials (accruing 2006–2008) are not likely to benefit from ART as there is a low risk of biochemical progression (~20-30%) in, for example, pT3R0 or pT2R1-tumours. The median pre-SRT PSA in all 3 trials was 0.24 ng/mL which is much lower than the conventional cut-off level of PSA < 0.5 ng/mL used to base ‘early’ SRT on. Therefore, patients with ‘low-risk factors’ of biochemical progression after RP should be closely followed up with ultra-sensitive assays and SRT should be discussed as soon as PSA starts to rise, which has to be confirmed by a second PSA measurement (see Section 6.3). The proportion of patients with adverse pathology at RP (ISUP grade group 4–5 and pT3 with or without positive margins) in all 3 trials was low (between 10–20%) and therefore even the meta-analysis may be underpowered to show an outcome in favour of SRT [956]. In addition, the side-effect profile may have been impacted with a larger proportion of ART patients receiving treatment with older 3D-treatment planning techniques as compared to SRT patients (GETUG-AFU 17: ART, 69% 3D vs. 46% SRT) and patients treated more recently were more likely to undergo IMRT techniques with a proven lower rate of late side effects [665].

For these reasons, 10-year OS and metastasis-free survival endpoints results should be awaited before drawing final conclusions. Due to the small number of patients with adverse pathology (ISUP grade group 4–5 and pT3) included in these 3 trials (between 10–20%), ART remains a recommended treatment option in highly selected patients with adverse pathology (‘high-risk patients’) i.e. ISUP grade group 4–5 and pT3 with or without positive margins [936, 957, 958]. This recommendation was supported by a published retrospective multi-centre study comparing ART and SRT in patients with high-risk features (pN1 or ISUP 4–5 and pT3/4-tumours) after RP [959]. After a median follow-up of 8.2 years of the 26,118 men included in the study, 2,104 patients died, 25.62% from PCa (n = 539) and 2,424 patients had adverse pathology compared with 23,694 who did not. After excluding men with persistent PSA after RP, ART when compared with early SRT showed a significantly lower acute mortality risk (p = 0.02, HR: 0.33).

6.2.5.5 Adjuvant androgen ablation in men with N0 disease

Adjuvant androgen ablation with bicalutamide 150 mg daily did not improve PFS in localised disease while it did for locally-advanced disease after RT. However, this never translated to an OS benefit [960]. A systematic review showed a possible benefit for PFS but not OS for adjuvant androgen ablation [542].

The TAX3501 trial comparing the role of leuprolide (18 months) with and without docetaxel (6 cycles) ended prematurely due to poor accrual. A phase III RCT comparing adjuvant docetaxel against surveillance after RP for locally-advanced PCa showed that adjuvant docetaxel did not confer any oncological benefit [961]. Consequently, adjuvant chemotherapy after RP should only be considered in a clinical trial [962].

6.2.5.6 Adjuvant treatment in pN1 disease

6.2.5.6.1 Adjuvant androgen ablation alone

The combination of RP and early adjuvant HT in pN+ PCa has been shown to achieve a 10-year CSS rate of 80% and has been shown to significantly improve CSS and OS in prospective RCTs [963, 964]. However, these trials included mostly patients with high-volume nodal disease and multiple adverse tumour characteristics and these findings may not apply to men with less extensive nodal metastases.

6.2.5.6.2 Adjuvant radiotherapy combined with ADT in pN1 disease

In a retrospective multi-centre cohort study, maximal local control with RT to the prostatic fossa appeared to be beneficial in PCa patients with pN1 after RP, treated “adjuvantly” with continuous ADT (within 6 months after
surgery irrespective of PSA). The beneficial impact of adjuvant RT on survival in patients with pN1 PCa was highly influenced by tumour characteristics. Men with low-volume nodal disease (< 3 LNs), ISUP grade 2–5 and pT3–4 or R1, as well as men with 3 to 4 positive nodes were more likely to benefit from RT after surgery, while the other subgroups did not [965]. Comparable results were obtained from another retrospective single centre study [966]. These results were confirmed by a US National Cancer Database analysis based on 5,498 patients [967]. Another US National Cancer Database study including 8,074 pN1 patients reports improved OS after ADT plus EBRT (including pelvic LNs) vs. observation and vs. ADT alone in all men with single or multiple adverse pathological features. Men without any adverse pathological features did not benefit from immediate adjuvant therapy [968].

In a series of 2,596 pN1 patients receiving ADT (n = 1,663) or ADT plus RT (n = 906), combined treatment was associated with improved OS, with a HR of 1.5 for ADT alone [969]. In a SEER retrospective population-based analysis, adding RT to RP showed a non-significant trend for improved OS but not PCA-specific survival, but data on the extent of additional RT is lacking in this study [923]. Radiotherapy should be given to the pelvic lymphatics and the prostatic fossa [965, 966, 970, 971]. In a systematic review of the literature, RT with or without ADT was associated with improved survival in men with locally-advanced disease and a higher number of positive nodes [899].

Retrospective data from a multi-centre cohort (1,491 pN1-patients after RP) with a median follow-up of 8.2 years, after excluding patients with persisting PSA, show a significantly lower all-cause mortality risk for adjuvant RT compared with early SRT (p = 0.04, HR: 0.66). No data are available in pN1 patients addressing adjuvant EBRT without ADT [972].

6.2.5.6.3 Observation of pN1 patients after radical prostatectomy and extended lymph node dissection

Several retrospective studies and a systematic review addressed the management of patients with pN1 PCa at RP [899, 943, 965, 966, 973]. A subset of patients with limited nodal disease (1–2 positive LNs) showed favourable oncological outcomes and did not require additional treatment.

An analysis of 209 pN1 patients with one or two positive LNs at RP showed that 37% remained metastasis-free without need of salvage treatment at a median follow-up of 60.2 months [973]. Touijer et al., reported their results of 369 LN-positive patients (40 with and 329 without adjuvant treatment) and showed that higher pathologic grade group and > 3 positive LNs were significantly associated with an increased risk of BCR on multivariable analysis [943]. Biochemical-free survival rates in pN1 patients without adjuvant treatment ranged from 43% at 4 years to 28% at 10 years [899]. Reported CSS rates were 78% at 5 years and 72% at 10 years. The majority of these patients were managed with initial observation after surgery, had favourable disease characteristics, and 63% had only one positive node [899]. Initial observation followed by early salvage treatment at the time of recurrence may represent a safe option in selected patients with a low disease burden [899].

### Persistent PSA after radical prostatectomy

Between 5 and 20% of men continue to have detectable or persistent PSA after RP (when defined in the majority of studies as detectable post-RP PSA of ≥ 0.1 ng/mL within 4 to 8 weeks of surgery) [974, 975]. It may result from persistent local disease, pre-existing metastases or residual benign prostate tissue.

#### Natural history of persistently elevated PSA after RP

Several studies have shown that persistent PSA after RP is associated with more advanced disease (such as positive surgical margins, pathologic stage ≥ T3a, positive nodal status and/or pathologic ISUP grade > 3) and poor prognosis. Initially defined as ≥ 0.1 ng/mL, improvements in the sensitivity of PSA assays now allow for the detection of PSA at much lower levels.

Moréira et al., demonstrated that failure to achieve a PSA of less than 0.03 ng/mL within 6 months of surgery was associated with an increased risk of BCR and overall mortality [976, 977]. However, since the majority of the published literature is based on the 0.1 ng/mL PSA cut-off, there is significantly more long-term data for this definition. Predictors of PSA persistence were higher BMI, higher pre-operative PSA and ISUP grade ≥ 3 [977]. In patients with PSA persistence, one and 5-year BCR-free survival were 68% and 36%, compared to 95% and 72%, respectively, in men without PSA persistence [976]. Ten-year OS in patients with and without PSA persistence was 63% and 80%, respectively.

Spratt et al., confirmed that a persistently detectable PSA after RP represents one of the worst prognostic factors associated with oncological outcome [978]. Of 150 patients with a persistent PSA, 95% received RT before detectable metastasis. In a multivariable analysis the presence of a persistently detectable PSA post-RP was associated with a 4-fold increase in the risk of developing metastasis. This was confirmed by data from Preisser et al., who showed that persistent PSA is prognostic of an increased risk of metastasis and death [979]. At 15 years after RP, metastasis-free survival rates, OS and CSS rates were 53.0 vs. 93.2% (p < 0.001), 64.7 vs. 81.2% (p < 0.001) and 75.5 vs. 96.2% (p < 0.001) for persistent vs. undetectable PSA, respectively. The median follow-up was 61.8 months for patients with undetectable PSA vs. 46.4 months for patients with persistent PSA. In multivariable Cox regression models, persistent PSA represented an independent predictor for metastasis (HR: 3.59, p < 0.001), death (HR: 1.86, p < 0.001) and cancer-specific death (HR: 3.15, p < 0.001).

However, not all patients with persistent PSA after RP experience disease recurrence. Xiang et al., showed a 50% 5-year BCR-free survival in men who had a persistent PSA level > 0.1 but ≤ 0.2 ng/mL at 6–8 weeks after RP [980].

Rogers et al., assessed the clinical outcome of 160 men with a persistently detectable PSA level after RP [981]. No patient received adjuvant therapy before documented metastasis. In their study, 38% of patients had no evidence of metastases for ≥ 7 years while 32% of the patients were reported to develop metastases within 3 years. Noteworthy is that a significant proportion of patients had low-risk disease. In multivariable analysis the PSA slope after RP (as calculated using PSA levels 3 to 12 months after surgery) and pathological ISUP grade were significantly associated with the development of distant metastases.

#### Imaging in patients with persistently elevated PSA after RP

Standard imaging with bone scan and MRI has a low pick-up rate in men with a PSA below 2 ng/mL. However, PSMA PET/CT has been shown to identify residual cancer with positivity rates of 33%, 46%, 57%, 82%, and 97%, in men with post-RP PSA ranges of 0–0.19, 0.2–0.49, 0.5–0.99, 1–1.99, and ≥ 2 ng/mL, respectively [982-987] which can guide SRT planning [988]. Based on these post-RP PSA ranges, Schmidt-Hegemann et al., studied 129 patients who had either persistent PSA (52%) or BCR (48%) after RP, showing that men with a persistent PSA had significantly more pelvic nodal involvement on PSMA PET/CT than those developing a detectable PSA [989]. In a multi-centre retrospective study including 191 patients, 68Ga-PSMA localised biochemical persistence after RP in more than two-thirds of patients with high-risk PCa features. The obturator and presacral/mesorectal nodes were identified as high risk for residual disease [990]. Another retrospective study included 150 patients with persistent PSA after RARP who were re-staged with both 68Ga-PSMA and 18F-DCFPyL PSMA. The authors found that in the presence of persistent PSA the majority of patients already had metastatic pelvic LNs or distant metastases which would support a role of PSMA PET/CT imaging in guiding (salvage) treatment strategies [991]. At present there is uncertainty regarding the best treatment if PSMA PET/CT shows metastatic disease.
6.2.6.3 Impact of post-operative RT and/or ADT in patients with persistent PSA

The benefit of SRT in patients with persistent PSA remains unclear due to a lack of RCTs, however, it would appear that men with a persistent PSA do less well than men with BCR undergoing RT.

Preisser et al., compared oncological outcomes of patients with persistent PSA who received SRT vs. those who did not [979]. In the subgroup of patients with persistent PSA, after 1:1 propensity score matching between patients with SRT vs. no RT, OS rates at 10 years after RP were 86.6 vs. 72.6% in the entire cohort (p < 0.01), 86.3 vs. 60.0% in patients with positive surgical margin (p = 0.02), 77.8 vs. 49.0% in pT3b disease (p < 0.001), 79.3 vs. 55.8% in ISUP grade 1 disease (p < 0.01) and 87.4 vs. 50.5% in pN1 disease (p < 0.01), respectively. Moreover, CSS rates at 10 years after RP were 93.7 vs. 81.6% in the entire cohort (p < 0.01), 90.8 vs. 69.7% in patients with positive surgical margin (p = 0.04), 82.7 vs. 55.3% in pT3b disease (p < 0.01), 85.4 vs. 69.7% in ISUP grade 1 disease (p < 0.01) and 96.2 vs. 55.8% in pN1 disease (p < 0.01), for SRT vs. no RT, respectively. In multivariable models, after 1:1 propensity score matching, SRT was associated with lower risk for death (HR: 0.42, p = 0.02) and lower cancer-specific death (HR: 0.29, p = 0.03). These survival outcomes in patients with persistent PSA who underwent SRT suggest they benefit but outcomes are worse than for men experiencing BCR [992].

It is clear from a number of studies that poor outcomes are driven by the level of pre-RT PSA, the presence of ISUP grade > 4 in the RP histology and pT3b disease [993-998]. Fossati et al., suggested that only men with a persistent PSA after RP and ISUP grade < 3 benefit significantly [999], although this is not supported by Preisser et al. [979]. The current data do not allow making any clear treatment decisions.

Addition of ADT may improve PFS [994]. Choo et al., studied the addition of 2-year ADT to immediate RT to the prostate bed in patients with pathologic T3 disease (pT3) and/or positive surgical margins after RP [994]. Twenty-nine of the 78 included patients had persistently detectable post-operative PSA. The relapse-free rate was 85% at 5 years and 68% at 7 years, which was superior to the 5-year progression-free estimates of 74% and 61% in the post-operative RT arms of the EORTC and the SWOG studies, respectively, which included patients with undetectable PSA after RP [946, 947]. Patients with persistently detectable post-operative PSA comprised approximately 50% and 12%, respectively, of the study cohorts in the EORTC and the SWOG studies.

In the ARO 96-02, a prospective RCT, 74 patients with PSA persistence (20%) received immediate SRT only (66 Gy per protocol [arm C]). The 10-year clinical relapse-free survival was 63% [993]. The GETUG-22 trial comparing RT with RT plus short-term ADT for post-RP PSA persistence (0.2–2.0 ng/mL) reported good tolerability of the combined treatment. The oncological endpoints are yet to be published [1000].

Two systematic reviews addressing persistent PSA confirmed a strong correlation of PSA persistence with poor oncologic outcomes [974, 975]. Ploussard et al., also reported that SRT was associated with improved survival outcomes, although the available evidence is of low quality [975].

6.2.6.4 Conclusion

The available data suggest that patients with PSA persistence after RP may benefit from early aggressive multimodality treatment, however, the lack of prospective RCTs makes firm recommendations difficult.

6.3 Management of PSA-only recurrence after treatment with curative intent

Follow-up will be addressed in Chapter 7 and is not discussed in this section.

6.3.1 Background

Between 27% and 53% of all patients undergoing RP or RT develop a rising PSA (PSA recurrence). Whilst a rising PSA level universally precedes metastatic progression, physicians must inform the patient that the natural history of PSA-only recurrence may be prolonged and that a measurable PSA may not necessarily
lead to clinically apparent metastatic disease. Physicians treating patients with PSA-only recurrence face a
difficult set of decisions in attempting to delay the onset of metastatic disease and death while avoiding over-
treating patients whose disease may never affect their OS or QoL. It should be emphasised that the treatment
recommendations for these patients should be given after discussion in a multidisciplinary team.

6.3.2 **Controversies in the definitions of clinically relevant PSA relapse**

The PSA level that defines treatment failure depends on the primary treatment. Patients with rising PSA
after RP or primary RT have different risks of subsequent symptomatic metastatic disease based on various
parameters, including the PSA level. Therefore, physicians should carefully interpret BCR endpoints when
comparing treatments.

After RP, the threshold that best predicts further metastases is a PSA > 0.4 ng/mL and rising [1001-
1003]. However, with access to ultra-sensitive PSA testing, a rising PSA much below this level will be a cause for
concern for patients.

After primary RT, with or without short-term hormonal manipulation, the RTOG-ASTRO Phoenix Consensus
Conference definition of PSA failure (with an accuracy of > 80% for clinical failure) is ‘any PSA increase > 2 ng/mL
higher than the PSA nadir value, regardless of the serum concentration of the nadir’ [1004]. Clinicians should
interpret a PSA rise in light of the EAU BCR risk groups (see Section 6.3.3).

After HIFU or cryotherapy no endpoints have been validated against clinical progression or
survival; therefore, it is not possible to give a firm recommendation of an acceptable PSA threshold after these
alternative local treatments [1005].

6.3.3 **Natural history of biochemical recurrence**

Once a PSA recurrence has been diagnosed, it is important to determine whether the recurrence has
developed at local or distant sites. A systematic review and meta-analysis investigated the impact of BCR on
hard endpoints and concluded that patients experiencing BCR are at an increased risk of developing distant
metastases, PCa-specific and overall mortality [1005]. However, the effect size of BCR as a risk factor for
mortality is highly variable. After primary RP its impact ranges from HR 1.03 (95% CI: 1.004–1.06) to HR 2.32
(95% CI: 1.45–3.71) [1006, 1007]. After primary RT, OS rates are approximately 20% lower at 8 to 10 years
follow-up even in men with minimal co-morbidity [1008, 1009]. Still, the variability in reported effect sizes of
BCR remains high and suggests that only certain patient subgroups with BCR might be at an increased risk of
mortality.

The risk of subsequent metastases, PCa-specific- and overall mortality may be predicted by the
initial clinical and pathologic factors (e.g., T-category, PSA, ISUP grade) and PSA kinetics (PSA-DT and interval
to PSA failure), which was further investigated by the systematic review [1005].

For patients with BCR after RP, the following outcomes were found to be associated with significant prognostic
factors:
- distant metastatic recurrence: positive surgical margins, high RP specimen pathological ISUP grade, high
  pT category, short PSA-DT, high pre-SRT PSA;
- prostate-cancer-specific mortality: high RP specimen pathological ISUP grade, short interval to
  biochemical failure as defined by investigators, short PSA-DT;
- overall mortality: high RP specimen pathological ISUP grade, short interval to biochemical failure, high
  PSA-DT.

For patients with BCR after RT, the corresponding outcomes are:
- distant metastatic recurrence: high biopsy ISUP grade, high cT category, short interval to biochemical
  failure;
- prostate-cancer-specific mortality: short interval to biochemical failure;
- overall mortality: high age, high biopsy ISUP grade, short interval to biochemical failure, high initial (pre-
treatment) PSA.

Based on this meta-analysis, proposal is to stratify patients into ‘EAU Low-Risk BCR’ (PSA-DT > 1 year AND
pathological ISUP grade < 4 for RP; interval to biochemical failure > 18 months AND biopsy ISUP grade < 4 for
RT) or ‘EAU High-Risk BCR’ (PSA-DT < 1 year OR pathological ISUP grade 4–5 for RP; interval to biochemical
failure < 18 months OR biopsy ISUP grade 4–5 for RT), since not all patients with BCR will have similar
outcomes. The stratification into ‘EAU Low-Risk’ or ‘EAU High-Risk’ BCR has recently been validated in a
European cohort [1010].
The role of imaging in PSA-only recurrence

Imaging is only of value if it leads to a treatment change which results in an improved outcome. In practice, however, there are very limited data available regarding the outcomes consequent on imaging at recurrence.

Assessment of metastases

Bone scan and abdominopelvic CT

Because BCR after RP or RT precedes clinical metastases by 7 to 8 years on average [937, 1011], the diagnostic yield of common imaging techniques (bone scan and abdominopelvic CT) is low in asymptomatic patients [1012]. In men with PSA-only recurrence after RP the probability of a positive bone scan is < 5%, when the PSA level is < 7 ng/mL [1013, 1014]. Only 11–14% of patients with BCR after RP have a positive CT [1013]. In a series of 132 men with BCR after RP the mean PSA level and PSA velocity associated with a positive CT were 27.4 ng/mL and 1.8 ng/mL/month, respectively [1015].

Choline PET/CT

In two different meta-analyses the combined sensitivities and specificities of choline PET/CT for all sites of recurrence in patients with BCR were 86–89% and 89–93%, respectively [1016, 1017]. Choline PET/CT may detect multiple bone metastases in patients showing a single metastasis on bone scan [1018] and may be positive for bone metastases in up to 15% of patients with BCR after RP and negative bone scan [1019]. The specificity of choline PET/CT is also higher than bone scan with fewer false-positive and indeterminate findings [450]. Detection of LN metastases using choline PET/CT remains limited by the relatively poor sensitivity of the technique (see Section 5.3.2.3). Choline PET/CT sensitivity is strongly dependent on the PSA level and kinetics [459, 1020, 1021]. In patients with BCR after RP, PET/CT detection rates are only 5–24% when the PSA level is < 1 ng/mL but rises to 67–100% when the PSA level is > 5 ng/mL. Despite its limitations, choline PET/CT may change medical management in 18–48% of patients with BCR after primary treatment [1022-1024]. Choline PET/CT should only be recommended in patients fit enough for curative loco-regional salvage treatment.

Fluoride PET and PET/CT

18 F-NaF PET/CT has a higher sensitivity than bone scan in detecting bone metastases [1025]. However, 18 F-NaF PET/CT is limited by a relative lack of specificity and by the fact that it does not assess soft-tissue metastases [1026].

Fluciclovine PET/CT

18F-Fluciclovine PET/CT has been approved in the U.S. and Europe and it is therefore one of the PCa-specific radiotracers widely commercially available [1027-1029]. 18F-Fluciclovine PET/CT has a slightly higher sensitivity than choline PET/CT in detecting the site of relapse in BCR [1030]. In a multi-centre trial evaluating 596 patients with BCR in a mixed population (33.3% after RP, 59.5% after RT ± RP, 7.1% other) fluciclovine PET/CT showed an overall detection rate of 67.7%; lesions could be visualised either at local level (38.7%) or in LNs and bones (9%) [1031]. As for choline PET/CT, fluciclovine PET/CT sensitivity is dependent on the PSA level, with a sensitivity likely inferior to 50% at PSA < 1 ng/mL. In a prospective RCT evaluating the impact of 18F-fluciclovine PET/CT on SRT management decisions in patients with recurrence post-prostatectomy, in 28 of 79 (35.4%) patients overall radiotherapeutic management changed following 18F-fluciclovine PET/CT [1032]. 18F-Fluciclovine PET/CT had a significantly higher positivity rate than conventional imaging (abdominopelvic CT or MRI plus bone scan) for whole body (79.7% vs. 13.9%, p < 0.001), prostate bed (69.6% vs. 5.1%, p < 0.001), and pelvic LNs (38.0% vs. 10.1%, p < 0.001) [1032]. However, as yet, no data demonstrating that these changes translate into a survival benefit are available.

Prostate-specific membrane antigen based PET/CT

Prostate-specific membrane antigen PET/CT has shown good potential in patients with BCR, although most studies are limited by their retrospective design. Reported predictors of 68Ga-PSMA PET in the recurrence setting were recently updated based on a high-volume series (see Table 6.3.1) [982]. High sensitivity (75%) and specificity (99%) were observed on per-lesion analysis.

PSA = prostate-specific antigen; ⁶⁸Ga-PMSA PET = Gallium-68 prostate-specific membrane antigen positron emission tomography.

Prostate-specific membrane antigen PET/CT seems substantially more sensitive than choline PET/CT, especially for PSA levels < 1 ng/mL [1033, 1034]. In a study of 314 patients with BCR after treatment and a median PSA level of 0.83 ng/mL, ⁶⁸Ga-PSMA PET/CT was positive in 197 patients (67%) [1035]. In another prospective multi-centre trial including 635 patients with BCR after RP (41%), RT (27%), or both (32%), PPV for ⁶⁸Ga-PSMA PET/CT was 0.84 (95% CI: 0.75–0.90) by histopathologic validation (primary endpoint, n = 87) and 0.92 (95% CI: 0.75–0.90) by a composite reference standard. Detection rates significantly increased with PSA value [1036].

A prospective multi-centre, multi-reader, open-label, phase II/III trial (OSPREY) evaluated the diagnostic performance of ¹⁸F-DCFPyL in patients with presumptive radiologic evidence of recurrent or metastatic PCa on conventional imaging [444]. Median sensitivity and median PPV 95.8% (95% CI: 87.8%–99.0%) and 81.9% (95% CI: 73.7%–90.2%), respectively.

Another prospective study evaluated the diagnostic performance of ¹⁸F-DCFPyL in 208 men with BCR after RP or RT. The primary endpoint, the correct localisation rate was achieved, demonstrating positive findings on DCFPyL PET/CT in the setting of negative standard imaging [1037]. At present there are no conclusive data about comparison of such tracers [1038].

6.3.4.1.6 Whole-body and axial MRI

Whole body MRI has not been widely evaluated in BCR because of its limited value in the detection of early metastatic involvement in normal-sized LNs [461, 1039]. In a prospective series of 68 patients with BCR, the diagnostic performance of DW-MRI was significantly lower than that of ⁶⁸Ga-PSMA PET/CT and ¹⁸NaF PET/CT for diagnosing bone metastases [1040].

6.3.4.2 Assessment of local recurrences

6.3.4.2.1 Local recurrence after radical prostatectomy

Because the sensitivity of anastomotic biopsies is low, especially for PSA levels < 1 ng/mL [1012], salvage RT is usually decided on the basis of BCR without histological proof of local recurrence. The dose delivered to the prostatic fossa tends to be uniform since it has not demonstrated that a focal dose escalation at the site of recurrence improves the outcome. Therefore, most patients undergo salvage RT without local imaging.

Magnetic resonance imaging can detect local recurrences in the prostatic bed but its sensitivity in patients with a PSA level < 0.5 ng/mL remains controversial [1041, 1042]. Choline PET/CT is less sensitive than MRI when the PSA level is < 1 ng/mL [1043]. In a retrospective study of 53 patients with BCR after RP (median PSA level 1.5 ng/mL) who underwent ¹⁸F-choline whole body hybrid PET/MRI, MRI identified more local relapses while PET detected more regional and distant metastases [1044].

The detection rates of ⁶⁸Ga-PSMA PET/CT in patients with BCR after RP increase with the PSA level [1045]. Prostate-specific membrane antigen PET/CT studies showed that a substantial part of recurrences after RP were located outside the prostatic fossa even at low PSA levels [983, 1046]. Combining ⁶⁸Ga-PSMA PET and MRI may improve the detection of local recurrences, as compared to ⁶⁸Ga-PSMA PET/CT [1047-1049].

The EMPIRE-1, a single-centre, open-label, phase II/III RCT evaluated the role of ¹⁸F-fluciclovine-PET/CT compared with conventional imaging for salvage RT. Three hundred and sixty five patients with detectable PSA after RP, but negative results on conventional imaging were randomised to RT directed by conventional imaging alone or to conventional imaging plus PET/CT; patients with M1 disease in the PET/CT group (n = 4) were excluded. Patients with cN1 were irradiated to the pelvic lymphatics but without a boost to the metastasis. Median follow-up was 3.5 years. In adjusted analyses, the study group was significantly associated with event-free survival (HR: 2.04, 95% CI: 1.06–3.93, p = 0.0327) [1050].
6.3.4.2 Local recurrence after radiation therapy
In patients with BCR after RT, biopsy status is a major predictor of outcome, provided the biopsies are obtained 18–24 months after initial treatment. Given the morbidity of local salvage options it is necessary to obtain histological proof of the local recurrence before treating the patient [1012].

Transrectal US is not reliable in identifying local recurrence after RT. In contrast, MRI has yielded excellent results and can be used for biopsy targeting and guiding local salvage treatment [1012, 1051-1054], even if it slightly underestimates the volume of the local recurrence [1055]. Detection of recurrent cancer is also feasible with choline PET/CT [1056], but choline PET/CT has not yet been compared to MRI. Prostate-specific membrane antigen PET/CT can also play a role in the detection of local recurrences after RT [982].

6.3.4.3 Summary of evidence on imaging in case of biochemical recurrence
In patients with BCR imaging can detect both local recurrences and distant metastases, however, the sensitivity of detection depends on the PSA level. After RP, PSMA PET/CT seems to be the imaging modality with the highest sensitivity at low PSA levels (< 0.5 ng/mL) and may help distinguishing patients with recurrences confined to the prostatic fossa from those with distant metastases which may impact the design and use of post-RP salvage RT. After RT, MRI has shown excellent results at detecting local recurrences and guiding prostate biopsy. Given the substantial morbidity of post-RT local salvage treatments, distant metastases must be ruled out in patients with local recurrences and who are fit for these salvage therapies. Choline-, fluciclovine- or PSMA-PET/CT can be used to detect metastases in these patients but for this indication PSMA PET/CT seems the most sensitive technique.

6.3.5 Treatment of PSA-only recurrences
The timing and treatment modality for PSA-only recurrences after RP or RT remain a matter of controversy based on the limited evidence.

6.3.5.1 Treatment of PSA-only recurrences after radical prostatectomy
6.3.5.1.1 Salvage radiotherapy for PSA-only recurrence after radical prostatectomy (cTxN0M0, without PET/CT)
Early SRT provides the possibility of cure for patients with an increasing PSA after RP. Boorjian et al., reported a 75% reduced risk of systemic progression with SRT when comparing 856 SRT patients with 1,801 non-SRT patients [1057]. The RAVES and RADICAL trials assessing SRT in post-RP patients with PSA levels exceeding 0.1–0.2 ng/mL showed 5-year freedom from BCR and BCR-free survival rates of 88% [953, 1058].

The PSA level at BCR was shown to be prognostic [1057]. More than 60% of patients who are treated before the PSA level rises to > 0.5 ng/mL will achieve an undetectable PSA level [1059-1062], corresponding to a ~80% chance of being progression-free 5 years later [1063]. A retrospective analysis of 635 patients who were followed after RP and experienced BCR and/or local recurrence and either received no salvage treatment (n = 397) or salvage RT alone (n = 160) within 2 years of BCR showed that salvage RT was associated with a 3-fold increase in PCa-specific survival relative to those who received no salvage treatment (p < 0.001). Salvage RT has been shown to be effective mainly in patients with a short PSA-DT [1064].

The EAU BCR definitions have been externally validated and may be helpful for individualised treatment decisions [1010]. Despite the indication for salvage RT, a ‘wait and see’ strategy remains an option for the EAU BCR ‘Low-Risk’ group [1005, 1065]. For an overview see Table 6.3.2.
Although biochemical progression is now widely accepted as a surrogate marker of PCa recurrence; metastatic disease, disease-specific and OS are more meaningful endpoints to support clinical decision-making. A systematic review and meta-analysis on the impact of BCR after RP reports SRT to be favourable for OS and PCa-specific mortality. In particular SRT should be initiated in patients with rapid PSA kinetics after RP and with a PSA cut-off of 0.4 ng/mL [1005]. An international multi-institutional analysis of pooled data from RCTs has suggested that metastasis-free survival is the most valid surrogate endpoint with respect to impact on OS [1066, 1067]. Table 6.3.3 summarises results of recent studies on clinical endpoints after SRT.

6.3.5.1.2 Salvage radiotherapy combined with androgen deprivation therapy (cTxcN0, without PET/CT)

Data from RTOG 9601 suggest both CSS and OS benefit when adding 2 years of bicalutamide (150 mg o.d.) to SRT [1072]. According to GETUG-AFU 16 also 6-months treatment with a LHRH-analogue can significantly improve 10-year BCR, biochemical PFS and, modestly, metastasis-free survival. However, SRT combined with either goserelin or placebo showed similar DSS and OS rates [1073]. Table 6.3.4 provides an overview of these two RCTs.

These RCTs support adding ADT to SRT. However, when interpreting these data it has to be kept in mind that RTOG 9601 used outdated radiation dosages (< 66 Gy) and technique. The question with respect to the patient risk profile, whether to offer combination treatment or not and the optimal combination (LHRH or bicalutamide) remains, as yet, unsolved. The EAU BCR risk classification may offer guidance in this respect [1005, 1010].

One of these RCTs reports improved OS (RTOG 96-01) and the other improved metastasis-free survival but due to methodological discrepancies also related to follow-up and risk patterns, it is, as yet, not evident which patients should receive ADT, which type of ADT, and for how long. Men at high risk of further progression (e.g., with a PSA > 0.7 ng/mL and GS > 8) may benefit from SRT combined with two years of ADT; for those at lower risk (e.g., PSA < 0.7 ng/mL and GS = 8) SRT combined with 6 months of ADT may be sufficient. Men with a low-risk profile (PSA < 0.5 ng/mL and GS < 8) may receive SRT alone. In a sub-analysis of men with a PSA of 0.61 to 1.5 (n = 253) there was an OS benefit associated with anti-androgen assignment (HR: 0.61, 95% CI: 0.39–0.94). In those receiving early SRT (PSA < 0.6 ng/mL, n = 389), there was no improvement in OS (HR: 1.16, 95% CI: 0.79–1.70), with increased other-cause mortality (sub-distribution HR: 1.94, 95% CI: 1.17–3.20, p = 0.01) and increased odds of late grades 3–5 cardiac and neurologic toxic side-effects (OR: 3.57, 95% CI: 1.09–11.97, p = 0.05). These results suggest that pre-SRT PSA level may be a prognostic biomarker for outcomes of anti-androgen treatment with SRT. In patients receiving late SRT (PSA > 0.6 ng/mL), hormone therapy was associated with improved outcomes. In men receiving early SRT (PSA < 0.6 ng/mL), long-term anti-androgen treatment was not associated with improved OS [1074].

A review addressing the benefit from combining HT with SRT suggested risk stratification of patients based on the pre-SRT PSA (< 0.5, 0.6–1, > 1 ng/mL), margin status and ISUP grade as a framework to individualise treatment [1075]. In a retrospective multi-centre-study including 525 patients, only in patients with more aggressive disease characteristics (pT3b/4 and ISUP grade > 4 or pT3b/4 and PSA at early SRT > 0.4 ng/mL) the administration of concomitant ADT was associated with a reduction in distant metastasis [1076]. Similarly, in a retrospective analysis of 1,125 patients, stage ≥ pT3b, GS ≥ 8 and a PSA level at SRT > 5 ng/mL were identified as risk factors for clinical recurrence. A significant effect of long-term ADT was observed in patients with ≥ 2 adverse features. For patients with a single risk factor, short-term HT was sufficient whilst patients without risk factors showed no significant benefit from concomitant ADT [1077].

6.3.5.1.2.1 Target volume, dose, toxicity
There have been various attempts to define common outlines for ‘clinical target volumes’ of PCa [1078-1081] and for organs at risk of normal tissue complications [1082]. However, given the variations of techniques and dose-constraints, a satisfactory consensus has not yet been achieved. A benefit in biochemical PFS but not metastasis-free survival has been reported in patients receiving whole pelvis SRT (± ADT) but the advantages must be weighed against possible side effects [1083].

The optimal SRT dose has not been well defined. It should be at least 64 Gy to the prostatic fossa (± the base of the SVs, depending on the pathological stage after RP) [958, 1060, 1084]. In a systematic review, the pre-SRT PSA level and SRT dose both correlated with BCR, showing that relapse-free survival decreased by 2.4% per 0.1 ng/mL PSA and improved by 2.6% per Gy, suggesting that the treatment dose above 70 Gy should be administered at the lowest possible PSA level [1085]. The combination of pT stage, margin status and ISUP grade and the PSA at SRT seems to define the risk of biochemical progression, metastasis and overall mortality [950, 1086, 1087]. In a study on 894 node-negative PCa patients, doses ranging from 64 to > 74 Gy were assigned to twelve risk groups defined by their pre-SRT PSA classes < 0.1, 0.1–0.2, 0.2–0.4, and > 0.4 ng/mL and ISUP grade, < 1 vs. 2/3 vs. > 4 [1088]. The updated Stephenson nomograms incorporate the SRT and ADT doses as predictive factors for biochemical failure and distant metastasis [1070].

Two RCT’s were recently published (Table 6.3.5). Intensity-modulated radiation therapy plus IGRT was used in 57% of the patients in the SAKK-trial [958] and in all patients of the Chinese trial [1089]. No patient had a PSMA PET/CT before randomisation. The primary endpoint in both trials was ‘freedom from biochemical progression’, which was not significantly improved with higher doses. However, in the Chinese trial a subgroup analysis showed a significant improvement of this endpoint for patients with Gleason 8-10 tumours (79.7% vs. 55%, p = 0.049). In this trial, patients were treated with ART or SRT and the number of patients was relatively small (n = 144). At this time it seems difficult to draw final conclusions about the optimal total RT-dose and longer follow-up should be awaited.

ADT = androgen deprivation therapy; ART = adjuvant radiotherapy; FFBP = freedom from biochemical failure; GI = gastro-intestinal; GU = genito-urinary; Gy = Gray; IGRT = image guided radiotherapy; mo = month; n = number of patients; PSA = prostate-specific antigen; RT = radiotherapy; SRT = y = year; vs. = versus; VMAT = volumetric arc radiation therapy.

Salvage RT is associated with toxicity. In one report on 464 SRT patients receiving median 66.6 (max. 72) Gy, acute grade 2 toxicity was recorded in 4.7% for both the GI and GU tract. Two men had late grade 3 reactions of the GI tract, but overall, severe GU tract toxicity was not observed. Late grade 2 complications occurred in 4.7% (GI tract) and 4.1% (GU tract), respectively, and 4.5% of the patients developed moderate urethral stricture [1068].

In a RCT on dose escalation for SRT (n = 350), acute grade 2 and 3 GU toxicity was observed in 13.0% and 0.6%, respectively, with 64 Gy and in 16.6% and 1.7%, respectively, with 70 Gy. Gastro-intestinal tract grades 2 and 3 toxicity occurred in 16.0% and 0.6%, respectively, with 64 Gy, and in 15.4% and 2.3%, respectively, with 70 Gy. Late effects have yet to be reported [1090, 1091]. Late grade 2 and 3 GI toxicity was significantly increased with higher doses but without significant differences in QoL. In this study, however, the rectal wall dose constraints were rather permissive and in 44% of the patients outdated 3-D-techniques were used [958].

With dose escalation over 72 Gy and/or up to a median of 76 Gy, the rate of severe side effects, especially GU symptoms, clearly increases, even with newer planning and treatment techniques [1092, 1093]. In particular, when compared with 3D-CRT, IMRT was associated with a reduction in grade 2 GI toxicity from 10.2 to 1.9% (p = 0.02) but no effect on the relatively high level of GU toxicity was shown (5-year, 3D-CRT 15.8% vs. IMRT 16.8%) [1092]. However, in a RCT comparing 66 Gy and 72 Gy with all patients having IMRT plus IGRT (n = 144), no significant differences for GI and GU-toxicity was demonstrated [1089]. After a median salvage IMRT dose of 76 Gy however, the 5-year risk of grade 2–3 toxicity rose to 22% for GU and 8% for GI symptoms, respectively [1093]. Doses of at least 64 Gy and up to 72 Gy in patients without PET/CT can be recommended [1068, 1090].

6.3.5.1.2.2 Salvage RT with or without ADT (cTx CN0/1) with PET/CT

In a prospective multi-centre study of 323 patients with BCR, PSMA PET/CT changed the management intent in 62% of patients as compared to conventional staging. This was due to a significant reduction in the number of men in whom the site of disease recurrence was unknown (77% vs. 19%, p < 0.001) and a significant increase in the number of men with metastatic disease (11% vs. 57%) [463]. A prospective study
in a subgroup of 119 BCR patients with low PSA (< 0.5 ng/mL) reported a change in the intended treatment in 30.2% of patients [983]; however, no data exist on the impact on final outcome. Another prospective study in 272 patients with early biochemical recurrent PCas after RP showed that 68Ga-PSMA-ligand PET/CT may tailor further therapy decisions (e.g., local vs. systemic treatment) at low PSA values (0.2–1 ng/mL) [985].

A single-centre study retrospectively assessed 164 men from a prospective database who underwent imaging with PSMA PET/CT for a rising PSA after RP with PSA levels < 0.5 ng/mL. In men with a negative PSMA PET/CT who received salvage RT, 85% (23 out of 27) demonstrated a treatment response compared to a further PSA increase in 65% of those not treated (22 out of 34). In the 36/99 men with disease confined to the prostate fossa on PSMA, 83% (29 out of 36) responded to salvage RT [1094]. Thus, PSMA PET/CT might stratify men into a group with high response (negative findings or recurrence confined to the prostate) and poor response (positive nodes or distant disease) to salvage RT. As there are no prospective phase III data (in particular not for PCa-specific survival or OS) these results have to be confirmed before any recommendation can be provided.

A single-centre open-label, phase II/III RCT (EMPIRE-1) evaluated the role of 18F-fluciclovine-PET/CT compared with conventional imaging for salvage RT. Three hundred and sixty five patients with detectable PSA after RP but negative results on conventional imaging, were randomised to RT directed by conventional imaging alone or to conventional imaging plus PET/CT; patients with M1 disease in the PET/CT group (n = 4) were excluded. Patients with cN1 were irradiated to the pelvic lymphatics but without a boost to the metastasis. Median follow-up was 3.5 years. In adjusted analyses, the study group was significantly associated with event-free survival (HR: 2.04, 95% CI: 1.06–3.93, p = 0.0327) [1050].

6.3.5.1.2.3 Metastasis-directed therapy for rcN+ (with PET/CT)
Radiolabelled PSMA PET/CT is increasingly used as a diagnostic tool to assess metastatic disease burden in patients with BCR following prior definitive therapy. A review including 30 studies and 4,476 patients showed overall estimates of positivity in a restaging setting of 38% in pelvic LNs and 13% in extra-pelvic LN metastases [982]. The percentage positivity of PSMA PET/CT was proven to increase with higher PSA values, from 33% (95% CI: 16–51) for a PSA of < 0.2 ng/mL, to 45% (39–52), 59% (50–68), 75% (66–84), and 95% (92–97) for PSA subgroup values of 0.2–0.49, 0.5–0.99, 1.00–1.99, and > 2.00 ng/mL, respectively [982]. Results of this review demonstrated high sensitivity and specificity of 68Ga-PSMA PET in advanced PCa with a per-lesion-analysed sensitivity and specificity of 75% and 99%, respectively.

In patients relapsing after a local treatment (including cN+ and highly selected M1 patients), a metastases-targeting therapy has been proposed, with the aim to delay systemic treatment. Metastasis-directed (MDT) therapy in PET/CT detected nodal oligo-recurrent PCa after RP was assessed in a large retrospective multi-institutional study (263 patients received MDT and 1,816 patients SOC as control group [matched 3:1]). Metastasis-targeting therapy consisted of salvage LN resection (n = 166) and stereotactic ablation RT (SABR) (n = 97). After a median follow-up of 70 months, the MDT-group showed significantly better CSS (5-year survival 98.6% vs. 95.7%, p < 0.01, respectively), however, these results should be viewed with caution as this was a retrospective study, the findings of which require further validation in prospective trials [1095].

Another retrospective study compared SABR with elective nodal irradiation (ENRT) in PET/CT-detected nodal oligo-recurrent PCa (n = 506 patients, 365 of which with N1 pelvic recurrence). With a median follow-up of 36 months, ENRT (n = 197) was associated with a significant reduction of nodal recurrences compared with SABR (n = 309) of 2% vs. 18%, respectively, but at the cost of higher side effects of ENRT [1096]. These results have to be confirmed in prospective trials before any recommendations can be made. In these situations SABR should be used in highly selected patients in prospective cohorts or clinical trials only. For MDT in M1-patients see Section 6.4.7.

A phase II trial assessed the biochemical response after 18F-DCFPyL PET/MRI and subsequent MDT. Overall biochemical response rate, defined as ≥ 50% PSA decline, was 60%, including 22% of patients with complete biochemical response [1097].

Phillips and colleagues reported outcomes of the phase II ORIOLE (Observation vs. Stereotactic Ablative Radiation for Oligometastatic Prostate Cancer) clinical trial in patients with hormone-sensitive oligometastatic PCa randomised to receive SABR or observation alone [1098]. The primary outcome was the proportion of patients with disease progression at 6 months. Fifty-four patients were randomised and progression at 6 months occurred in 19% of patients receiving SABR and in 61% undergoing observation. In a post-hoc analysis, total consolidation of PSMA-positive disease decreased the risk of new lesions at 6 months (16% vs. 63%; p = 0.0.006).
A review on new generation imaging modalities (whole-body MRI and PET with choline or fluciclovine or sodium fluoride or PSMA) for the detection of recurrent oligometastatic hormone-sensitive PCa showed that PSMA and choline PET can contribute to guiding MDT [1099]. However, such studies should still be considered as experimental as no data demonstrating the clinical significance of any outcomes are available. For MDT in M1-patients see Section 6.4.7.

6.3.5.1.3 Salvage lymph node dissection
The surgical management of (recurrent) nodal metastases in the pelvis has been the topic of several retrospective analyses [1100-1102] and a systematic review [1103]. The reported 5-year BCR-free survival rates ranged from 6% to 31%. Five-year OS was approximately 84% [1103]. Biochemical recurrence rates were found to be dependent on PSA at surgery and location and number of positive nodes [1104]. Addition of RT to the lymphatic template after salvage LN dissection may improve the BCR rate [1105]. In a multi-centre retrospective study long-term outcomes of salvage LN dissection were reported to be worse than previously described in studies with shorter follow-up [1106]. Biochemical recurrence-free survival at 10 years was 11%. Patients with a PSA response after salvage LN dissection and patients receiving ADT within 6 months from salvage LN dissection had a lower risk of death from PCa [1106]. High-level evidence for the oncological value of salvage LN dissection is still lacking [1103].

6.3.5.1.4 Comparison of adjuvant- and salvage radiotherapy
Section 6.2.5.4 is referred to for more details. Main findings are that after RP the vast majority of patients do not need ART which is supported by the results of 3 phase III RCTs comparing adjuvant RT and early salvage RT with a median follow-up of 5 years [953-957].

However, longer term (10-year) results and results of metastasis-free survival endpoints are needed before final conclusions can be drawn. Due to the small number of patients with adverse pathology (ISUP grade group 4–5 and pT3) included in these 3 trails (only approximately 20%) ART remains a recommended treatment option in highly selected patients with adverse pathology ('high-risk patients') i.e. ISUP grade group 4–5 and pT3 with or without positive margins. This is supported by retrospective studies [957, 959].

6.3.5.2 Management of PSA failures after radiation therapy
Therapeutic options in these patients are ADT or salvage local procedures. A systematic review and meta-analysis included studies comparing the efficacy and toxicity of salvage RP, salvage HIFU, salvage cryotherapy, SBRT, salvage LDR brachytherapy, and salvage HDR brachytherapy in the management of locally recurrent PCa after primary radical EBRT [1107]. The outcomes were BCR-free survival at 2 and 5 years. No significant differences with regards to recurrence-free survival (RFS) between these modalities was found. Five-year RFS ranged from 50% after cryotherapy to 60% after HDR brachytherapy and SBRT. The authors reported that severe GU toxicity exceeded 21% for HIFU and RP, whereas it ranged from 4.2% to 8.1% with re-irradiation. Differences in severe GI toxicity also appeared to favour re-irradiation, particularly HDR brachytherapy [1107].

Due to the methodological limitations of this review (the majority of the included studies were uncontrolled single-arm case series and there was considerable heterogeneity in the definitions of core outcomes) the available evidence for these treatment options is of low quality and strong recommendations regarding the choice of any of these techniques cannot be made. The following is an overview of the most important findings for each of these techniques.

6.3.5.2.1 Salvage radical prostatectomy
Salvage RP after RT is associated with a higher likelihood of adverse events (AEs) compared to primary surgery because of the risk of fibrosis and poor wound healing due to radiation [1108].

6.3.5.2.1.1 Oncological outcomes
In a systematic review of the literature, Chade, et al., showed that SRP provided 5- and 10-year BCR-free survival estimates ranging from 47–82% and from 28–53%, respectively. The 10-year CSS and OS rates ranged from 70–83% and from 54–89%, respectively. The pre-SRP PSA value and prostate biopsy ISUP grade were the strongest predictors of the presence of organ-confined disease, progression, and CSS [1109]. In a multi-centre analysis including 414 patients, 5-year BCR-free survival, CSS and OS were 56.7%, 97.7% and 92.1%, respectively [1110]. Pathological T stage ≥ T3b (OR: 2.348) and GS (up to OR 7.183 for GS > 8) were independent predictors for BCR (see Table 6.3.6).

BCR = biochemical recurrence; CSS = cancer-specific survival; FU = follow-up; mo = months; n = number of patients; PSM = positive surgical margin.

6.3.5.2.1.2 Morbidity
Compared to primary open RP, SRP is associated with a higher risk of later anastomotic stricture (47 vs. 5.8%), urinary retention (25.3% vs. 3.5%), urinary fistula (4.1% vs. 0.06%), abscess (3.2% vs. 0.7%) and rectal injury (9.2 vs. 0.6%) [1114]. In more recent series, these complications appear to be less common [1108, 1109, 1112].

Functional outcomes are also worse compared to primary surgery, with urinary incontinence ranging from 21% to 90% and ED in nearly all patients (see Table 6.3.7) [1109, 1112].

6.3.5.2.1.3 Summary of salvage radical prostatectomy
In general, SRP should be considered only in patients with low co-morbidity, a life expectancy of at least 10 years, a pre-SRP PSA < 10 ng/mL and initial biopsy ISUP grade ≤ 2/3, no LN involvement or evidence of distant metastatic disease pre-SRP, and those whose initial clinical staging was T1 or T2 [1109].

A meta-analysis and systematic review of local salvage therapies after RT for PCa has suggested that re-irradiation with SBRT, HDR brachytherapy or LDR brachytherapy appears to result in less severe GU toxicity than RP; and re-irradiation with HDR brachytherapy in less severe GI toxicity than RP [1107].

6.3.5.2.2 Salvage cryoablation of the prostate
6.3.5.2.2.1 Oncological outcomes
Salvage cryoablation of the prostate (SCAP) has been proposed as an alternative to salvage RP, as it has a potentially lower risk of morbidity and equal efficacy.

In a systematic review a total of 32 studies assessed SCAP, recruiting a total of 5,513 patients. The overwhelming majority of patients (93%) received whole-gland SCAP. The adjusted pooled analysis for 2-year BCR-free survival for SCAP was 67.49% (95% CI: 61.68–72.81%), and for 5-year BCR-free survival was 50.25% (95% CI: 44.10–56.40%). However, the certainty of the evidence was low. Table 6.3.8 summarises the results of a selection of the largest series on SCAP to date in relation to oncological outcomes (BCR only) [1107].

ED = erectile dysfunction; mo = months; n = number of patients.

### 6.3.5.2.2.2 Morbidity

The main adverse effects and complications relating to SCAP include urinary incontinence, urinary retention due to bladder outflow obstruction, recto-urethral fistula, and ED. A systematic review and meta-analysis showed an adjusted pooled analysis for severe SCAP-related GU toxicity of 15.44% (95% CI: 10.15–21.54%) [1107]. As before, the certainty of the evidence was low. Table 6.3.9 summarises the results of a selection of the largest series on SCAP to date in relation to GU outcomes.

### 6.3.5.2.2.3 Summary of salvage cryoablation of the prostate

In general, the evidence base relating to the use of SCAP is poor, with significant uncertainties relating to long-term oncological outcomes, and SCAP appears to be associated with significant morbidity. Consequently, SCAP should only be performed in selected patients in experienced centres as part of a clinical trial or well-designed prospective cohort study.

### 6.3.5.2.3 Salvage re-irradiation

6.3.5.2.3.1 Salvage brachytherapy for radiotherapy failure

Carefully selected patients with a good PS, primary localised PCa, good urinary function and histologically proven local recurrence are candidates for salvage brachytherapy using either HDR- or LDR.

In a systematic review a total of 16 studies (4 prospective) and 32 studies (2 prospective) assessed salvage HDR and LDR brachytherapy, respectively, with the majority (> 85%) receiving whole-gland brachytherapy rather than focal treatment [1107]. The adjusted pooled analysis for 2-year BCR-free survival for HDR was 77% (95% CI: 70–83%) and for LDR was 81% (95% CI:74–86%). The 5-year BCR-free survival for
HDR was 60% (95% CI: 52–67%) and for LDR was 56% (95% CI: 48–63%). As noted above, brachytherapy techniques are associated with lower rates of severe GU toxicity when compared to RP or HIFU, at 8% for HDR (95% CI: 5.1–11%) and 8.1% for LDR (95% CI: 4.3–13%). Rates of severe GI toxicity are reported to be very low at 0% for HDR (95% CI: 0–0.2%) and 1.5% for LDR (95% CI: 0.2–3.4%). High-dose-rate or LDR brachytherapy are effective treatment options with an acceptable toxicity profile. However, the published series are small and likely under-report toxicity. Consequently, this treatment should be offered in experienced centres ideally within randomised clinical trials or prospective registry studies (see Table 6.3.10).

6.3.5.2.3.2 Salvage stereotactic ablative body radiotherapy for radiotherapy failure

6.3.5.2.3.2.1 Oncological outcomes and morbidity

Stereotactic ablative body radiotherapy (CyberKnife® or linac-based treatment) is a potentially viable new option to treat local recurrence after RT. Carefully selected patients with good IPSS-score, without obstruction, good PS and histologically proven localised local recurrence are potential candidates for SABR. In a meta-analysis and systematic review five mostly retrospective studies including 206 patients were treated with CyberKnife® or linac-based treatment showing 2-year RFS estimates (61.6%, 95% CI: 52.6–69.9%) [1107]. In a retrospective multi-centre study (n = 100) the median pre-salvage PSA was 4.3 ng/mL with 34% of patients having received ADT for twelve months (median). All recurrences were biopsy proven. Patients were treated with the CyberKnife® with a single dose of 6 Gy in six daily fractions (total dose 36 Gy). With a median follow-up of 30 months the estimated 3-year second BCR-free survival was 55% [1129].

In a smaller retrospective series including 50 men with histologically proven local recurrence with a median pre-salvage PSA of 3.9 ng/mL only 15% had received additional ADT. The estimated 5-year second BCR-free survival was 60% (median follow-up of 44 months) which is an outcome comparable to series treating patients with RP, HIFU or brachytherapy [1130]. Table 6.3.11 summarises the results of the two larger SABR series addressing oncological outcomes and morbidity.

</tr>
</tbody>
</table>

BCR = biochemical recurrence-free; FU = follow-up; mo = months; n = number of patients; RT-type = type of radiotherapy; SD = single dose; TD = total dose; yr = year.

6.3.5.2.3.2.2 Morbidity

In a retrospective single-centre study with 50 consecutive patients chronic significant toxicity was only seen for the GU domain with 5-year grade 2+ and grade 3+ GU rates of 17% and 8%, respectively. No GI toxicity > grade 1 was seen. Of note, of the fifteen patients who were sexually potent pre-salvage SBRT, twelve
subsequently lost potency [1130]. In a retrospective French (GETUG) multi-centre series (n = 100) the 3-year late grade 2+ GU and GI toxicity was 20.8% (95% CI: 13–29%) and 1% (95% CI: 0.1–5.1%), respectively [1129].

6.3.5.2.3.2.3 Summary of salvage stereotactic ablative body radiotherapy
Despite the encouraging results so far the number of patients treated with SABR is relatively limited. In view of the rates of higher grade 2+ GU side effects, SABR should only be offered to selected patients, in experienced centres as part of a clinical trial or well-designed prospective study.

6.3.5.2.4 Salvage high-intensity focused ultrasound
6.3.5.2.4.1 Oncological outcomes
Salvage HiFU has emerged as an alternative thermal ablation option for radiation-recurrent PCa. Being relatively newer than SCAP the data for salvage HiFU are even more limited. A systematic review and meta-analysis included 20 studies (n = 1,783) assessing salvage HiFU [1107]. The overwhelming majority of patients (86%) received whole-gland salvage HiFU. The adjusted pooled analysis for 2-year BCR-free survival for salvage HiFU was 54.14% (95% CI: 47.77–60.38%) and for 5-year BCR-free survival 52.72% (95% CI: 42.66–62.56%). However, the certainty of the evidence was low. Table 6.3.12 summarises the results of a selection of the largest series on salvage HiFU to date in relation to oncological outcomes (BCR only).

6.3.5.2.4.2 Morbidity
The main adverse effects and complications relating to salvage HiFU include urinary incontinence, urinary retention due to bladder outflow obstruction, rectourethral fistula and ED. The systematic review and meta-analysis showed an adjusted pooled analysis for severe GU toxicity for salvage HiFU of 22.66% (95% CI: 16.98–28.85%) [1107]. The certainty of the evidence was low. Table 6.3.13 summarises the results of a selection of the largest series on salvage HiFU to date in relation to GU outcomes.

6.3.5.2.4.3 Summary of salvage high-intensity focused ultrasound
There is a lack of high-certainty data which prohibits any recommendations regarding the indications for salvage HIFU in routine clinical practice. There is also a risk of significant morbidity associated with its use in the salvage setting. Consequently, salvage HIFU should only be performed in selected patients in experienced centres as part of a clinical trial or well-designed prospective cohort study.

6.3.6 Hormonal therapy for relapsing patients
The Panel conducted a systematic review including studies published from 2000 onwards [1135]. Conflicting results were found on the clinical effectiveness of HT after previous curative therapy of the primary tumour. Some studies reported a favourable effect of HT, including the only RCT addressing the research question of this review (86% vs. 79% advantage in OS in the early HT group) [1136]. Other studies did not find any differences between early vs. delayed, or no, HT. One study found an unfavourable effect of HT [1137]. This may be the result of selecting clinically unfavourable cases for (early) HT and more intensive diagnostic workup and follow-up in these patients.

The studied population is highly heterogeneous regarding their tumour biology and therefore clinical course. Predictive factors for poor outcomes were; CRPC, distant metastases, CSS, OS, short PSA-DT, high ISUP grade, increased age and co-morbidities. In some studies, such as the Boorjian, et al., study [1065], high-risk patients, mainly defined by a high ISUP grade and a short PSA-DT (most often less than 6 months) seem to benefit most from (early) HT, especially men with a long life expectancy.

No data were found on the effectiveness of different types of HT, although it is unlikely that this will have a significant impact on survival outcomes in this setting. Non-steroidal anti-androgens have been claimed to be inferior compared to castration, but this difference was not seen in M0 patients [1064]. One of the included RCTs suggested that intermittent HT is not inferior to continuous HT in terms of OS and CSS [1138]. A small advantage was found in some QoL domains but not overall QoL outcomes. An important limitation of this RCT is the lack of any stratifying criteria such as PSA-DT or initial risk factors. Based on the lack of definitive efficacy and the undoubtedly associated significant side effects, patients with recurrence after primary curative therapy should not receive standard HT since only a minority of them will progress to metastases or PCa-related death. The objective of HT should be to improve OS, postpone distant metastases, and improve QoL. Biochemical response to only HT holds no clinical benefit for a patient. For older patients and those with co-morbidities the side effects of HT may even decrease life expectancy; in particular cardiovascular risk factors need to be considered [1139, 1140]. Early HT should be reserved for those at the highest risk of disease progression defined mainly by a short PSA-DT at relapse (< 6–12 months) or a high initial ISUP grade (> 2/3) and a long life expectancy.

6.3.7 Observation
In unselected relapsing patients the median actuarial time to the development of metastasis will be 8 years and the median time from metastasis to death will be a further 5 years [937]. For patients with EAU Low-Risk BCR features (see Section 6.3.3), unfit patients with a life expectancy of less than 10 years or patients unwilling to undergo salvage treatment, active follow-up may represent a viable option.

Recommendations for BCR after radiotherapy

| Offer monitoring, including PSA to EAU Low-Risk BCR patients. | Weak |
| Only offer salvage radical prostatectomy (RP), brachytherapy, high-intensity focused ultrasound, or cryosurgical ablation to highly selected patients with biopsy-proven local recurrence within a clinical trial setting or well-designed prospective cohort study undertaken in experienced centres. | Strong |

Recommendations for systemic salvage treatment

| Do not offer androgen deprivation therapy to M0 patients with a PSA-doubling time > 12 months. | Strong |

6.4 Treatment: Metastatic prostate cancer

6.4.1 Introduction

All prospective data available rely on the definition of M1 disease based on CT scan and bone scan. The influence on treatment and outcome of newer, more sensitive, imaging has not been assessed yet.

6.4.2 Prognostic factors

Median survival of patients with newly diagnosed metastases is approximately 42 months with ADT alone, however, it is highly variable since the M1 population is heterogeneous [1141]. Several prognostic factors for survival have been suggested including the number and location of bone metastases, presence of visceral metastases, ISUP grade, PS status and initial PSA alkaline phosphatase, but only few have been validated [1142-1145].

‘Volume’ of disease as a potential predictor was introduced by CHAARTED (Chemo-hormonal Therapy versus Androgen Ablation Randomized Trial for Extensive Disease in Prostate Cancer) [1145-1147] and has been shown to be predictive in a powered subgroup analysis for benefit of addition of prostate RT ADT [1148].

‘Metachronous’ metastatic disease vs. synchronous (or de novo) metastatic disease has also been shown to have a better prognosis [1149].

Based on a large SWOG 9346 cohort, the PSA level after 7 months of ADT was used to create 3 prognostic groups (see Table 6.4.2) [1150]. A PSA ≤ 0.2 ng/mL at 7 months has been confirmed as a prognostic marker for men receiving ADT for metastatic disease in the CHAARTED study independent of the addition of docetaxel [1151].

6.4.3 First-line hormonal treatment

Primary ADT has been the SOC for over 50 years [775]. There is no high-level evidence in favour of a specific type of ADT for oncological outcomes, neither for orchietomy nor for a LHRH agonist or antagonist. The level of testosterone is reduced much faster with orchietomy and LHRH antagonist, therefore patients with impending spinal cord compression or other potential impending complications from the cancer should be treated with either a bilateral orchietomy or LHRH antagonists as the preferred options.

There is a suggestion in some studies that cardiovascular side effects are less frequent in patients...
treated with LHRH antagonists vs. in patients treated with LHRH agonists [795, 1152, 1153]; therefore patients with pre-existing cardiovascular disease or other cardio-vascular risk factors might be considered to be treated with antagonists if a chemical castration is chosen.

6.4.3.1 Non-steroidal anti-androgen monotherapy
Based on a Cochrane review comparing non-steroidal anti-androgen (NSAA) monotherapy to castration (either medical or surgical), NSAA was considered to be less effective in terms of OS, clinical progression, treatment failure and treatment discontinuation due to AEs [1154]. The evidence quality of the studies included in this review was rated as moderate.

6.4.3.2 Intermittent versus continuous androgen deprivation therapy
Three independent reviews [1155-1157] and two meta-analyses [1158, 1159] looked at the clinical efficacy of intermittent androgen deprivation (IAD) therapy. All of these reviews included 8 RCTs of which only 3 were conducted in patients with exclusively M1 disease. The 5 remaining trials included different patient groups, mainly locally-advanced and metastatic patients relapsing.

So far, the SWOG 9346 is the largest trial addressing IAD in M1b patients [1160]. Out of 3,040 screened patients, only 1,535 patients met the inclusion criteria. This highlights that, at best, only 50% of M1b patients can be expected to be candidates for IAD, i.e. the best PSA responders. This was a non-inferiority trial leading to inconclusive results: the actual upper limit was above the pre-specified 90% upper limit of 1.2 (HR: 1.1, CI: 0.99–1.23), the pre-specified non-inferiority limit was not achieved, and the results did not show a significant inferiority for any treatment arm. However, based on this study inferior survival with IAD cannot be completely ruled out.

Other trials did not show any survival difference with an overall HR for OS of 1.02 (0.94–1.11) [1155]. These reviews and the meta-analyses came to the conclusion that a difference in OS or CSS between IAD and continuous ADT is unlikely. A review of the available phase III trials highlighted the limitations of most trials and suggested a cautious interpretation of the non-inferiority results [1161]. None of the trials that addressed IAD vs. continuous ADT in M1 patients showed a survival benefit but there was a constant trend towards improved OS and PFS with continuous ADT. However, most of these trials were non-inferiority trials. In some cohorts the negative impact on sexual function was less pronounced with IAD. There is a trend favouring IAD in terms of QoL, especially regarding treatment-related side effects such as hot flushes [1162, 1163].

6.4.3.3 Early versus deferred androgen deprivation therapy
There is an increasing body of evidence that early start of hormonal treatment also for the newer generation hormonal treatments is beneficial. Early treatment before the onset of symptoms is recommended in the majority of patients with metastatic hormone-sensitive disease despite lack of randomised phase III data in this specific setting and specifically not with the combination therapies that are standard nowadays.

A 2002 Cochrane review included four RCTs: the VACURG I and II trials, the MRC trial, and the ECOG 7887 study [1164]. These studies were conducted in the pre-PSA era and included patients with advanced metastatic or non-metastatic PCa who received immediate vs. deferred ADT [1164]. No improvement in PCa CSS was observed, although immediate ADT significantly reduced disease progression. The Cochrane analysis was updated in 2019 and concluded that early ADT probably extends time to death of any cause and time to death from PCa [1165]. Since the analysis included only a very limited number of M1 patients who were not evaluated separately, the benefit of early ADT in this setting remains unproven. All of the trials testing the combination therapies in the metastatic hormone-sensitive setting also included asymptomatic patients.

The only candidates with metastasised disease who may possibly be considered for deferred treatment are asymptomatic patients with a strong wish to avoid treatment-related side effects. The risk of developing symptoms, and even dying from PCa, without receiving the benefit from hormone treatment with deferred treatment has been highlighted [873, 885], but in the era before next generation imaging was used.

Patients with deferred treatment for advanced PCa must be amenable to close follow-up. Another potential exception are patients with recurrent oligometastatic disease who have a strong wish to postpone the start of ADT (see Section 6.4.7).

6.4.4 Combination therapies
All of the following combination therapies have been studied with continuous ADT, not intermittent ADT.

6.4.4.1 ‘Complete’ androgen blockade with older generation NSAA
The largest RCT in 1,286 M1b patients found no difference between surgical castration with or without flutamide [1166]. However, results with other anti-androgens or castration modalities have differed and
systematic reviews have shown that CAB using a NSAA appears to provide a small survival advantage (< 5%) vs. monotherapy (surgical castration or LHRH agonists) [1167, 1168] beyond 5 years of survival [1169] but this minimal advantage in a small subset of patients must be balanced against the increased side effects associated with long-term use of NSAAs. In addition, the newer combination therapies (see Tables 6.4.3, 6.4.4, 6.4.5) are more effective as shown specifically for enzalutamide vs. NSAA in a phase III trial [1170], therefore combination with NSAAs should only be considered if the other combination therapies are not available.

6.4.4.2 Androgen deprivation combined with other agents
6.4.4.2.1 Androgen deprivation therapy combined with chemotherapy

Three large RCTs were conducted [881, 1145, 1171]. All trials compared ADT alone as the SOC with ADT combined with immediate docetaxel (75 mg/sqm, every 3 weeks within 3 months of ADT initiation). The primary objective in all three studies was to assess OS. The key findings are summarised in Table 6.4.3.

ADT = androgen deprivation therapy; CI = confidence interval; ECOG = Eastern Cooperative Oncology Group; HR = hazard ratio; ISUP = International Society for Urological Pathology; mo = month; n = number of patients; OS = overall survival; P = prednisone; PSA-DT = prostate-specific antigen-doubling time.

In the GETUG 15 trial, all patients had M1 PCa, either de novo or after a primary treatment [1171]. They were stratified based on previous treatment and Glass risk factors [1142]. In the CHAARTED trial the same inclusion criteria applied, and patients were stratified according to disease volume (see Table 6.4.1) [1145].

STAMPEDE is a multi-arm multi-stage trial in which the reference arm (ADT monotherapy) included 1,184 patients. One of the experimental arms was docetaxel combined with ADT (n = 593), another was docetaxel combined with zoledronic acid (n = 593). Patients were included with either M1 or N1 or having two of the following 3 criteria: T3/4, PSA ≥ 40 ng/mL or ISUP grade 4–5. Also relapsed patients after local treatment were included if they met one of the following criteria: PSA ≥ 4 ng/mL with a PSA-DT < 6 months or a PSA ≥ 20 ng/mL, N1 or M1. No stratification was used regarding metastatic disease volume (high/low volume) [881]. In all 3 trials toxicity was mainly haematological with around 12–15% grade 3–4 neutropenia, and 6–12% grade 3–4 febrile neutropenia. The use of granulocyte colony-stimulating factor receptor (GCSF) was shown to be beneficial in reducing febrile neutropenia. Primary or secondary prophylaxis with GCSF should be based on
Based on these data, upfront docetaxel combined with ADT should be considered as a standard in men presenting with metastases at first presentation, provided they are fit enough to receive the drug [1174]. Docetaxel is used at the standard dose of 75 mg/sqm combined with steroids as pre-medication. Continuous oral corticosteroid therapy is not mandatory.

In subgroup analyses from GETUG-AFU 15 and CHAARTED the beneficial effect of the addition of docetaxel to ADT is most evident in men with de novo metastatic high-volume disease [1146, 1147], while it was in the same range whatever the volume in the post-hoc analysis from STAMPEDE [1172]. The effects were less apparent in men who had prior local treatment although the numbers were small and the event rates lower. A systematic review and meta-analysis which included these 3 trials showed that the addition of docetaxel to SOC improved survival [1174]. The HR of 0.77 (95% CI: 0.68–0.87, p < 0.0001) translates into an absolute improvement in 4-year survival of 9% (95% CI: 5–14). Docetaxel in addition to SOC also improves failure-free survival, with a HR of 0.64 (0.58–0.70, p < 0.0001) translating into a reduction in absolute 4-year failure rates of 16% (95% CI: 12–19).

6.4.4.2.2 Combination with the new hormonal treatments (abiraterone, apalutamide, enzalutamide)

In two large RCTs (STAMPEDE, LATITUDE) the addition of abiraterone acetate (1000 mg daily) plus prednisone (5 mg daily) to ADT in men with mHSPC was studied [40, 812, 1175]. The primary objective of both trials was an improvement in OS. Both trials showed a significant OS benefit. In LATITUDE with only high-risk metastatic patients included, the HR reached 0.62 (0.51–0.76) [812]. The HR in STAMPEDE was very similar with 0.63 (0.52–0.76) in the total patient population (metastatic and non-metastatic) and a HR of 0.61 in the subgroup of metastatic patients [40]. While only high-risk patients were included in the LATITUDE trial a post-hoc analysis from STAMPEDE showed the same benefit whatever the risk or the volume stratification [1176].

All secondary objectives such as PFS, time to radiographic progression, time to pain, or time to chemotherapy were positive and in favour of the combination. The key findings are summarised in Table 6.4.4. No difference in treatment-related deaths was observed with the combination of ADT plus AAP compared to ADT monotherapy (HR: 1.37 [0.82–2.29]). However, twice as many patients discontinued treatment due to toxicity in the combination arms in STAMPEDE (20%) compared to LATITUDE (12%). Based on these data upfront AAP combined with ADT should be considered as a standard in men presenting with metastases at first presentation, provided they are fit enough to receive the drug (see Table 6.4.4) [1175].

In three large RCTs (ENZAMET, ARCHES and TITAN) the addition of AR antagonists to ADT in men with mHSPC was tested [810, 811, 1170]. In ARCHES the primary endpoint was radiographic PFS (rPFS). Radiographic PFS was significantly improved for the combination of enzalutamide and ADT with a HR of 0.39 (0.3–0.5). Approximately 36% of the patients had low-volume disease; around 25% had prior local therapy and 18% of the patients had received prior docetaxel. In ENZAMET the primary endpoint was OS. The addition of enzalutamide to ADT improved OS with a HR of 0.67 (0.52–0.86). Approximately half of the patients had concomitant docetaxel; about 40% had prior local therapy and about half of the patients had low-volume disease [811]. In the TITAN trial, ADT plus apalutamide was used and rPFS and OS were co-primary endpoints. Radiographic PFS was significantly improved by the addition of apalutamide with a HR of 0.48 (0.39–0.6); OS at 24 months was improved for the combination with a HR of 0.67 (0.51–0.89). In this trial 16% of patients had prior local therapy, 37% had low-volume disease and 11% received prior docetaxel [810].

In summary, the addition of the new AR antagonists significantly improves clinical outcomes with no convincing evidence of differences between subgroups. The majority of patients treated had de novo metastatic disease and the evidence is most compelling in this situation. In the trials with the new AR antagonists, a proportion of patients had metachronous disease (see Table 6.4.5); therefore, a combination should also be considered for men progressing after radical local therapy. Lastly, whether the addition of a new AR antagonist plus docetaxel adds further OS benefit is currently unclear. Longer follow-up data are needed before a definitive conclusion is possible. At the moment, since toxicity clearly increases, AR antagonists plus docetaxel should not be given outside of clinical trials.

The addition of abiraterone to ADT and docetaxel has been reported to have a benefit in rPFS and in OS in the PEACE-1 trial [1176b]. Formal recommendation will be considered following publication of the data.

6.4.5 Treatment selection and patient selection

An ADT-based combination therapy is the SOC for patients with newly diagnosed mHSPC. There are no head-to-head data comparing 6 cycles of docetaxel and the continuous use of AAP or of apalutamide or of enzalutamide in newly diagnosed mHSPC. However, for a period, patients in STAMPEDE were randomised to either the addition of abiraterone or docetaxel to SOC. Data from the two experimental arms has been extracted although this was not pre-specified in the protocol and therefore the data were not powered for this comparison. The survival advantage for both drugs appeared similar [1177], patients receiving AAP plus SOC reported clinically meaningful higher global-QoL scores throughout the first two years compared to patients receiving docetaxel but statistical significance was not reached [1178]. A meta-analysis also found no significant OS benefit for either drug [1179]. Limitations of network meta-analyses include variable patient populations with different treatment benefits and follow-up periods. In the STOPCAP systematic review and meta-analysis, AAP was found to have the highest probability of being the most effective treatment [1180]. Both modalities have different and agent-specific side effects and require strict monitoring of side effects during treatment. Therefore, the choice will most likely be driven by patient preference, the specific side effects, fitness for docetaxel, availability and cost.

There have been several network meta-analyses of the published data concluding that combination therapy is more efficient than ADT alone, but none of the combination therapies has been clearly proven to be superior over another [1181, 1182]. As a consequence, patients should be offered combination treatment unless there are clear contra-indications or they present with asymptomatic disease and a very short life expectancy (based on non-cancer co-morbidities).

6.4.6 Treatment of the primary tumour in newly diagnosed metastatic disease

The first reported trial evaluating prostate RT in men with metastatic castration-sensitive disease was the HORRAD trial. Four hundred and thirty-two patients were randomised to ADT alone or ADT plus IMRT with IGRT to the prostate. Overall survival was not significantly different (HR: 0.9 [0.7–1.14], median time to PSA progression was significantly improved in the RT arm (HR: 0.78 [0.63–0.97]) [1183]. The STAMPEDE trial evaluated 2,061 men with mCSPC who were randomised to ADT alone vs. ADT plus RT to the prostate. This trial confirmed that RT to the primary tumour did not improve OS in unselected patients [1148]. However, following the results from CHAARTED and prior to analysing the data, the original screening investigations were retrieved, and patients categorised as low- or high volume. In the low-volume subgroup (n = 819) there was a significant OS benefit by the addition of prostate RT and it must be highlighted that this benefit was obtained without an increased dose. The doses and template used in STAMPEDE should be considered (55 Gy in 20 daily fractions over 4 weeks or 36 Gy in 6-weekly fractions of 6 Gy or a biological equivalent total dose of 72 Gy). Therefore, RT of the prostate only in patients with low-volume metastatic disease should be considered. Of note, only 18% of these patients had additional docetaxel and no patients had additional AAP, so no clear recommendation can be made about triple combinations. In addition, it is not clear if these data can be extrapolated to RP as local treatment as results of ongoing trials are awaited.

In a systematic review and meta-analysis including the above two RCTs, the authors found that, overall, there was no evidence that the addition of prostate RT to ADT improved survival in unselected patients (HR: 0.92, 95% CI: 0.81–1.04, p = 0.195) [1184]. However, there was a clear difference in the effect of metastatic burden on survival with an absolute improvement of 7% in 3-year survival in men who had four or fewer bone metastases.

6.4.7 Metastasis-directed therapy in M1-patients

In patients relapsing after a local treatment, a metastases-targeting therapy has been proposed, with the aim to delay systemic treatment. There are two randomised phase II trials testing metastasis-directed therapy (MDT) using surgery ± SABR vs. surveillance [1185] or SABR vs. surveillance in men with oligo-recurrent PCa [1098]. Oligo-recurrence was defined as ≤ 3 lesions on choline-PET/CT only [1185] or conventional imaging with MRI/CT and/or bone scan [1098]. The sample size was small with 62 and 54 patients, respectively, and a substantial proportion of them had nodal disease only [1185]. Androgen deprivation therapy-free survival was the primary endpoint in one study which was longer with MDT than with surveillance [1185]. The primary endpoint in the ORIOLE trial was progression after 6 months which was significantly lower with SBRT than with surveillance (19% vs. 61%, p = 0.005) [1098]. Currently there is no data to suggest an improvement in OS. Two comprehensive reviews highlighted MDT (SABR) as a promising therapeutic approach that must still be considered as experimental until the results of the ongoing RCT are available [1186, 1187].

### 6.5 Treatment: Castration-resistant PCa (CRPC)

#### 6.5.1 Definition of CRPC

Castrate serum testosterone < 50 ng/dL or 1.7 nmol/L plus either:

a. **Biochemical progression:** Three consecutive rises in PSA at least one week apart resulting in two 50% increases over the nadir, and a PSA > 2 ng/mL
   or

b. **Radiological progression:** The appearance of new lesions: either two or more new bone lesions on bone scan or a soft tissue lesion using RECIST (Response Evaluation Criteria in Solid Tumours) [1188]. Symptomatic progression alone must be questioned and subject to further investigation. It is not sufficient to diagnose CRPC.

#### 6.5.2 Management of mCRPC - general aspects

Selection of treatment for mCRPC is multifactorial and in general dependent on:
- previous treatment for mHSPC and for non-mHSPC;
- previous treatment for mCRPC;
- quality of response and pace of progression on previous treatment;
- known cross resistance between androgen receptor targeted agents (ARTA);
- co-medication and known drug interactions (see approved summary of product characteristics);
- known genetic alterations and microsatellite instability–high (MSI-H)/mismatch repair–deficient (dMMR) status;
- known histological variants and DNA repair deficiency (consider platinum or targeted therapy like PARPi);
- local approval status of drugs and reimbursement situation;
- available clinical trials;
- The patient and his co-morbidities.
6.5.2.1 Molecular diagnostics

All metastatic patients should be offered somatic genomic testing for homologous repair and MMR defects, preferably on metastatic carcinoma tissue but testing on primary tumour may also be performed. Alternatively, but still less common, genetic testing on circulating tumour DNA (ctDNA) is an option and has been used in some trials. One test, the FoundationOne® Liquid CDx, has been FDA approved [1189]. Defective MMR assessment can be performed by IHC for MMR proteins (MSH2, MSH6, MLH1 and PMS2) and/or by next-generation sequencing (NGS) assays [1190]. Germline testing for BRCA1/2, ATM and MMR is recommended for high-risk and particularly for metastatic PCa if clinically indicated.

Molecular diagnostics should be performed by a certified (accredited) institution using a standard NGS multiplication procedure (minimum depth of coverage of 200 X). The genes and respective exons should be listed; not only DNA for mutations but RNA needs to be examined for fusions and protein expression to obtain all clinically relevant information. A critical asset is the decision support helping to rate the mutations according to their clinical relevance [1191, 1192].

Level 1 evidence for the use of PARP-inhibitors has been reported [1193-1195]. Microsatellite instability (MSI)-high (or MMR deficiency) is rare in PCa, but for those patients, pembrolizumab has been approved by the FDA and could be a valuable additional treatment option [1196, 1197].

Germline molecular testing is discussed in Section 5.1.3 - Genetic testing for inherited PCa. Recommendations for germline testing are provided in Section 5.1.4.

6.5.3 Treatment decisions and sequence of available options

Approved agents for the treatment of mCRPC in Europe are docetaxel, abiraterone/prednisolone, enzalutamide, cabazitaxel, olaparib and radium-223. In general, sequencing of ARTAs like abiraterone and enzalutamide is not recommended particularly if the time of response to ADT and to the first ARTA was short (≤ 12 months) and high-risk features of rapid progression are present (see detailed discussion in Section 6.5.8.2) [1198, 1199].

The use of chemotherapy with docetaxel and subsequent cabazitaxel in the treatment sequence is recommended and should be applied early enough when the patient is still fit for chemotherapy. This is supported by high-level evidence [1198].

6.5.4 Non-metastatic CRPC

Frequent PSA testing in men treated with ADT has resulted in earlier detection of biochemical progression. Of these men approximately one-third will develop bone metastases within two years, detected by conventional imaging [207].

In men with CRPC and no detectable clinical metastases using bone scan and CT-scan, baseline PSA level, PSA velocity and PSA-DT have been associated with time to first bone metastasis, bone metastasis-free survival and OS [207, 1200]. These factors may be used when deciding which patients should be evaluated for metastatic disease. A consensus statement by the PCa Radiographic Assessments for Detection of Advanced Recurrence (RADAR) group suggested a bone scan and a CT scan when the PSA reached 2 ng/mL and if this was negative, it should be repeated when the PSA reached 5 ng/mL, and again after every doubling of the PSA based on PSA testing every three months in asymptomatic men [1201]. Symptomatic patients should undergo relevant investigations regardless of PSA level. With more sensitive imaging techniques like PSMA PET/CT or whole-body MRI, more patients are diagnosed with early mCRPC [1202]. It remains unclear if the use of PSMA PET/CT in this setting improves outcome.

Three large phase III RCTs, PROSPER [1203], SPARTAN [1204] and ARAMIS [1205], evaluated metastasis-free survival as the primary endpoint in patients with nmCRPC (M0 CRPC) treated with enzalutamide (PROSPER) vs. placebo or apalutamide (SPARTAN) vs. placebo or darolutamide vs. placebo (ARAMIS), respectively (see Table 6.5.1). The M0 status was established by CT and bone scans. Only patients at high risk for the development of metastasis with a short PSA-DT of ≤ 10 months were included. Patient characteristics in trials revealed that about two-thirds of participants had a PSA-DT of < 6 months. All trials showed a significant metastasis-free survival benefit. All three trials showed a survival benefit after a follow-up of more than 30 months. In view of the long-term treatment with these AR targeting agents in asymptomatic patients, potential AEs need to be taken into consideration and the patient informed accordingly.

ADT = androgen-deprivation therapy; CI = confidence interval; HR = hazard ratio; MFS = metastasis-free survival; nmCRPC = non-metastatic castrate-resistant prostate cancer; PSA-DT = prostate-specific antigen doubling time.

6.5.5 Metastatic CRPC

The remainder of this section focuses on the management of men with proven mCRPC on conventional imaging.

6.5.5.1 Conventional androgen deprivation in CRPC

Eventually men with PCa will show evidence of disease progression despite castration. Two trials have shown only a marginal survival benefit for patients remaining on LHRH analogues during second- and third-line therapies [1209, 1210]. However, in the absence of prospective data, the modest potential benefits of continuing castration outweigh the minimal risk of treatment. In addition, all subsequent treatments have been studied in men with ongoing androgen suppression, therefore, it should be continued in these patients.

6.5.6 First-line treatment of metastatic CRPC

6.5.6.1 Abiraterone

Abiraterone was evaluated in 1,088 chemo-naive, asymptomatic or mildly symptomatic mCRPC patients in the phase III COU-AA-302 trial. Patients were randomised to abiraterone acetate or placebo, both combined with prednisone [1211]. Patients with visceral metastases were excluded. The main stratification factors were ECOG PS 0 or 1 and asymptomatic or mildly symptomatic disease. Overall survival and rPFS were the co-primary endpoints. After a median follow-up of 22.2 months there was significant improvement of rPFS (median 16.5 vs. 8.2 months, HR: 0.52, p < 0.001) and the trial was unblinded. At the final analysis with a median follow-up of 49.2 months, the OS endpoint was significantly positive (34.7 vs. 30.3 months, HR: 0.81, 95% CI: 0.70–0.93, p = 0.0033) [1212]. Adverse events related to mineralocorticoid excess and liver function abnormalities were more frequent with abiraterone, but mostly grade 1–2. Subset analysis of this trial showed the drug to be equally effective in an elderly population (> 75 years) [1213].

6.5.6.2 Enzalutamide

A randomised phase III trial (PREVAIL) included a similar patient population and compared enzalutamide and placebo [1214]. Men with visceral metastases were eligible but the numbers included were small. Corticosteroids were allowed but not mandatory. PREVAIL was conducted in a chemo-naive mCRPC population of 1,717 men and showed a significant improvement in both co-primary endpoints, rPFS (HR: 0.186, CI: 0.15–0.23, p < 0.0001), and OS (HR: 0.706, CI: 0.60–0.84, p < 0.001). A ≥ 50% decrease in PSA was seen in 78% of patients. The most common clinically relevant AEs were fatigue and hypertension. Enzalutamide
was equally effective and well tolerated in men > 75 years [1215] as well as in those with or without visceral metastases [1216]. However, for men with liver metastases, there seemed to be no discernible benefit [1216, 1217].

Enzalutamide has also been compared with bicalutamide 50 mg/day in a randomised double blind phase II study (TERRAIN) showing a significant improvement in PFS (15.7 months vs. 5.8 months, HR: 0.44, p < 0.0001) in favour of enzalutamide [1217]. With extended follow-up and final analysis the benefit in OS and rPFS were confirmed [1218].

6.5.6.3 Docetaxel
A statistically significant improvement in median survival of 2.0–2.9 months has been shown with docetaxel-based chemotherapy compared to mitoxantrone plus prednisone [1219, 1220]. The standard first-line chemotherapy is docetaxel 75 mg/m², 3-weekly doses combined with prednisone 5 mg twice a day (BID), up to 10 cycles. Prednisone can be omitted if there are contraindications or no major symptoms. The following independent prognostic factors: visceral metastases, pain, anaemia (Hb < 13 g/dL), bone scan progression, and prior estramustine may help stratify the response to docetaxel. Patients can be categorised into three risk groups: low risk (0 or 1 factor), intermediate (2 factors) and high risk (3 or 4 factors), and show three significantly different median OS estimates of 25.7, 18.7 and 12.8 months, respectively [1221].

Age by itself is not a contraindication to docetaxel [1222] but attention must be paid to careful monitoring and co-morbidities as discussed in Section 5.4 - Estimating life expectancy and health status [1223]. In men with mCRPC who are thought to be unable to tolerate the standard dose and schedule, docetaxel 50 mg/m² every two weeks seems to be well tolerated with less grade 3–4 AEs and a prolonged time to treatment failure [1224].

6.5.6.4 Sipuleucel-T
In 2010 a phase III trial of sipuleucel-T showed a survival benefit in 512 asymptomatic or minimally symptomatic mCRPC patients [1225]. After a median follow-up of 34 months, the median survival was 25.8 months in the sipuleucel-T group compared to 21.7 months in the placebo group, with a HR of 0.78 (p = 0.03). No PSA decline was observed and PFS was similar in both arms. The overall tolerance was very good, with more cytokine-related AEs grade 1–2 in the sipuleucel-T group, but the same grade 3–4 AEs in both arms. Sipuleucel-T is not available in Europe.

6.5.6.5 Ipatasertib
The AKT inhibitor ipatasertib in combination with AAP was studied in asymptomatic or mildly symptomatic patients with and without PTEN loss by IHC and previously untreated for mCRPC. The randomised phase III trial (IPAtential) showed a significant benefit for the first endpoint rPFS in the PTEN loss (IHC) population (18.5 vs. 16.5 mo; p = 0.0335, HR: 0.77, 95% CI: 0.61–0.98). The OS results are still pending. Side effects of the AKT inhibitor ipatasertib include rash and diarrhoea [818]. Grade 3 or higher AEs occurred nearly double as often in the combination group and the discontinuation rate due to AEs was 4 times higher. This combination is still investigational [1226].

### 6.5.7 Second-line treatment for mCRPC and sequence

All patients who receive treatment for mCRPC will eventually progress. All treatment options in this setting are presented in Table 6.5.3. High-level evidence exists for second-line treatments after first-line treatment with docetaxel and for third-line therapy.

#### 6.5.7.1 Cabazitaxel

Cabazitaxel is a novel taxane with activity in docetaxel-resistant cancers. It was studied in a large prospective, randomised, phase III trial (TROPIC) comparing cabazitaxel plus prednisone vs. mitoxantrone plus prednisone in 755 patients with mCRPC, who had progressed after or during docetaxel-based chemotherapy [1231]. Patients received a maximum of ten cycles of cabazitaxel (25 mg/m²) or mitoxantrone (12 mg/m²) plus prednisone (10 mg/day). Overall survival was the primary endpoint which was significantly longer with cabazitaxel (median: 15.1 vs. 12.7 months, p < 0.0001). There was also a significant improvement in PFS (median: 2.8 vs. 1.4 months, p < 0.0001), objective RECIST response (14.4% vs. 4.4%, p < 0.005), and PSA response rate (39.2% vs. 17.8%, p < 0.0002). Treatment-associated WHO grade 3–4 AEs developed significantly more often in the cabazitaxel arm, particularly haematological (68.2% vs. 47.3%, p < 0.0002) but also non-haematological (57.4 vs. 39.8%, p < 0.0002) toxicity [1232]. In two post-marketing randomised phase III trials, cabazitaxel was shown not to be superior to docetaxel in the first-line setting; in the second-line setting in terms of OS, 20 mg/m² cabazitaxel was not inferior to 25 mg/m², but less toxic. Therefore, the lower dose should be preferred [1233, 1234]. Cabazitaxel should preferably be given with prophylactic granulocyte colony-stimulating factor (G-CSF) and should be administered by physicians with expertise in handling neutropenia and sepsis [1235].
6.5.7.2 Abiraterone acetate after prior docetaxel

Positive results of the large phase III trial (COU-AA-301) were reported after a median follow-up of 12.8 months [1236] and confirmed by the final analysis [1237]. A total of 1,195 patients with mCRPC were randomised 2:1 to AAP or placebo plus prednisone. All patients had progressive disease based on the Prostate Cancer Clinical Trials Working Group 2 (PCWG2) criteria after docetaxel therapy (with a maximum of two previous chemotherapeutic regimens). The primary endpoint was OS, with a planned HR of 0.8 in favour of AAP. After a median follow-up of 20.2 months, the median survival in the AAP group was 15.8 months compared to 11.2 months in the placebo arm (HR: 0.74, p < 0.0001). The benefit was observed in all subgroups and all the secondary objectives were in favour of AAP (PSA, radiologic tissue response, time to PSA or objective progression). The incidence of the most common grade 3–4 AEs did not differ significantly between arms, but mineralocorticoid-related side effects were more frequent in the AAP group, mainly grade 1–2 (fluid retention, oedema and hypokalaemia).

6.5.7.3 Enzalutamide after docetaxel

The planned interim analysis of the AFFIRM study was published in 2012 [1238]. This trial randomised 1,199 patients with mCRPC in a 2:1 fashion to enzalutamide or placebo. The patients had progressed after docetaxel treatment, according to the PCWG2 criteria. Corticosteroids were not mandatory, but could be prescribed, and were received by about 30% of the patients. The primary endpoint was OS, with an expected HR benefit of 0.76 in favour of enzalutamide. After a median follow-up of 14.4 months, the median survival in the enzalutamide group was 18.4 months compared to 13.6 months in the placebo arm (HR: 0.83, p < 0.001). This led to the recommendation to halt and unblind the study. The benefit was observed irrespective of age, baseline pain intensity, and type of progression. In the final analysis with longer follow-up the OS results were confirmed despite crossover and extensive post-progression therapies [1218]. Enzalutamide was active also in patients with visceral metastases.

All the secondary objectives were in favour of enzalutamide (PSA, soft tissue response, QoL, time to PSA or objective progression). No difference in terms of side effects was observed in the two groups, with a lower incidence of grade 3–4 AEs in the enzalutamide arm. There was a 0.6% incidence of seizures in the enzalutamide group compared to none in the placebo arm.

6.5.7.4 Radium-223

The only bone-specific drug that is associated with a survival benefit is the α-emitter radium-223. In a large phase III trial (ALSYMPCA) 921 patients with symptomatic mCRPC, who failed or were unfit for docetaxel, were randomised to six injections of 50 kBq/kg radium-223 or placebo plus SOC. The primary endpoint was OS. Radium-223 significantly improved median OS by 3.6 months (HR: 0.70, p < 0.001) and was also associated with prolonged time to first skeletal event, improvement in pain scores and improvement in QoL [1239]. The associated toxicity was mild and, apart from slightly more haematologic toxicity and diarrhoea with radium-223, it did not differ significantly from that in the placebo arm [1239]. Radium-223 was effective and safe whether or not patients were docetaxel pre-treated [1240]. Due to safety concerns, use of radium-223 was recently restricted to after docetaxel and at least one AR targeted agent [1241]. In particular, the use of radium-223 in combination with AAP showed significant safety risks related to fractures and more deaths. This was most striking in patients without the concurrent use of anti-resorptive agents [1242].

6.5.8 Treatment after docetaxel and one line of hormonal treatment for mCRPC

For men progressing quickly on AR targeted therapy (< 12 months) it is now clear that cabazitaxel is the treatment supported by the best data. The CARD trial, an open label randomised phase III trial, evaluated cabazitaxel after docetaxel and one line of ARTA (either AAP or enzalutamide) [1198]. It included patients progressing in less than 12 months on previous abiraterone or enzalutamide for mCRPC. Cabazitaxel more than doubled rPFS vs. another ARTA and reduced the risk of death by 36% vs. ARTA. The rPFS with cabazitaxel remained superior regardless of the ARTA sequence and if docetaxel was given before, or after, the first ARTA.

The choice of further treatment after docetaxel and one line of hormonal treatment for mCRPC is open for patients who have a > 12 months response to first-line abiraterone or enzalutamide for mCRPC [1243]. Either radium-223 or second-line chemotherapy (cabazitaxel) are reasonable options. In general, subsequent treatments in unselected patients are expected to have less benefit than with earlier use [1244, 1245] and there is evidence of cross-resistance between enzalutamide and abiraterone [1246, 1247].

In this context, radioligand therapy has been discussed for many years. In pre-treated and highly selected patients, based on PSMA- and FDG PET scan results, 117Lu-PSMA-617 was compared with cabazitaxel in a randomised phase II trial. The primary endpoint PSA reduction ≥ 50% was in favour of the radioligand therapy [1248]. Pivotal phase III data for 117Lu-PSMA-617 are discussed in Section 6.5.9.2.
Poly (ADP-ribose) polymerase inhibitors have shown high rates of response in men with somatic homologous recombination repair (HRR) deficiency in initial studies. Men previously treated with both docetaxel and at least one ARTA and whose tumours demonstrated homozygous deletions or deleterious mutations in DNA-repair genes showed an 88% response rate to olaparib [1249] and in another confirmatory trial a confirmed composite response of 54.3% (95% CI: 39.0–69.1) in the 400 mg cohort and in 18 of 46 (39.1%; 25.1–54.6) evaluable patients in the 300 mg cohort [1250].

6.5.8.1 PARP inhibitors for mCRPC

So far, two PARP inhibitors, olaparib and rucaparib, are licenced by the FDA (EMA only approved olaparib) and several other PARP inhibitors are under investigation (e.g., talazoparib, niraparib).

A randomised phase III trial (PROfound) compared the PARP inhibitor olaparib to an alternative ARTA in mCRPC with alterations in ≥ 1 of any qualifying gene with a role in HRR and progression on an ARTA. Most patients were heavily pre-treated with 1–2 chemotherapies and up to 2 ARTAs [1194, 1195]. Radiographic PFS by blinded independent central review in the BRCA1/2 or ATM mutated population (Cohort A) was the first endpoint and significantly favoured olaparib (HR: 0.49, 95% CI: 0.38–0.63). The final results for OS demonstrated a significant improvement among men with BRCA1/2 or ATM mutations (Cohort A) (p = 0.0175; HR: 0.69, 95% CI: 0.50–0.97). This was not significant in men with any (other) HRR alteration (Cohort B) (HR: 0.96, 95% CI: 0.63–1.49). Of note, patients in the physician’s choice of enzalutamide/abiraterone-arm who progressed, 66% (n = 86/131) crossed over to olaparib. When looking specifically at the Cohort B patients, olaparib did not improve rPFS by blinded independent central review (HR: 0.88, 95% CI: 0.58–1.36) or OS (HR: 0.73, 95% CI: 0.45–1.23), however, investigator assessed rPFS demonstrated a benefit for olaparib (HR: 0.60, 95% CI: > 0.39–0.93) [1195, 1251].

The most common AEs were anaemia (46.1% vs. 15.4%), nausea (41.4% vs. 19.2%), decreased appetite (30.1% vs. 17.7%) and fatigue (26.2% vs. 20.8%) for olaparib vs. enzalutamide/abiraterone. Among patients receiving olaparib 16.4% discontinued treatment secondary to an AE, compared to 8.5% of patients receiving enzalutamide/abiraterone. Interestingly, 4.3% of patients receiving olaparib had a pulmonary embolism, compared to 0.8% among those receiving enzalutamide/abiraterone, none of which were fatal. There were no reports of myelodysplastic syndrome or acute myeloid leukaemia. This is the first trial to show a benefit for genetic testing and precision medicine in mCRPC.

The olaparib approval by the FDA is for patients with deleterious or suspected deleterious germline or somatic HRR gene-mutated mCRPC, who have progressed following prior treatment with enzalutamide or abiraterone. The EMA approved olaparib for patients with BRCA1 and BRCA2 alterations [1252]. The recommended olaparib dose is 600 mg daily (300 mg taken orally twice daily), with or without food.

Rucaparib has been approved for patients with deleterious BRCA mutations (germline and/or somatic) who have been treated with ARTA and a taxane-based chemotherapy [1253]. Approval was not based on OS data but on the results of the single-arm TRITON2 trial (NCT02952534). The confirmed ORR per independent radiology review in 62 patients with deleterious BRCA mutations was 43.5% (95% CI: 31–57) [1254].

6.5.8.2 Sequencing treatment

6.5.8.2.1 ARTA -> ARTA (chemotherapy-naive patients)

The use of sequential ARTAs in mCRPC showed limited benefit in retrospective series as well as in one prospective trial [1255-1262]. In particular in patients who had a short response to the first ARTA for mCRPC (< 12 months), this sequence should be avoided because of known cross resistance and the availability of chemotherapy and PARP inhibitors (if a relevant mutation is present).

In highly selected patients treated for more than 24 weeks with AAP, the sequence with enzalutamide showed some activity with a median rPFS of 8.1 months (95% CI: 6.1–8.3) and an unconfirmed PSA response rate of 27% [1263]. In case the patient is unfit for chemotherapy and a PARP inhibitor best supportive care should be considered in case no other appropriate treatment option is available (clinical trial or immunotherapy if MSI-high). An ARTA-ARTA sequence should never be the preferred option but might be considered in such patients if the PS still allows for active treatment and the potential side effects seem manageable.

First prospective cross-over data on an ARTA-ARTA sequence [1255] and a systematic review and meta-analysis suggest that for the endpoints PFS and PSA PFS, but not for OS, abiraterone followed by enzalutamide is the preferred choice [1264].
6.5.8.2.2 ARTA -> PARP inhibitor/olaparib
This sequence in patients with deleterious or suspected deleterious germline or somatic HRR gene-mutated mCRPC is supported by data from the randomised phase III PROfound trial [1195]. A subgroup of patients in this trial was pre-treated with one or two ARTAs and no chemotherapy (35%). The ARTA – docetaxel - PARP inhibitor vs. ARTA – PARP inhibitor - docetaxel sequences are still under investigation.

6.5.8.2.3 Docetaxel for mHSPC -> docetaxel rechallenge
There is limited evidence for second- or third-line use of docetaxel after treatment with docetaxel for mHSPC. Docetaxel seems to be less active than ARTA at progression to mCRPC following docetaxel for mHSPC [1265].

6.5.8.2.4 ARTA -> docetaxel or docetaxel -> ARTA followed by PARP inhibitor
Both olaparib and rucaparib are active in biomarker-selected mCRPC patients after ARTA and docetaxel in either sequence [1195, 1253].

6.5.8.2.5 ARTA before or after docetaxel
There is level 1 evidence for both sequences (see Table 6.5.3).

6.5.8.2.6 ARTA -> docetaxel -> cabazitaxel or docetaxel -> ARTA -> cabazitaxel
Both third-line treatment sequences are supported by level 1 evidence. Of note, there is high-level evidence favouring cabazitaxel vs. a second ARTA after docetaxel and one ARTA. CARD is the first prospective randomised phase III trial addressing this question (see Table 6.5.3) [1198].

*Only studies reporting survival outcomes as primary endpoints have been included.
ARTA = androgen receptor targeting agents; CI = confidence interval; ECOG = Eastern Cooperative Oncology Group; FU = follow-up; GBq = gigabecquerel; HR = hazard ratio; Lu = lutetium; mo = months OS = overall survival; OR = odds ratio; ORR = objective response rate; PSA = prostate-specific antigen; PSMA = prostate-specific membrane antigen; (r)PFS = (radiographic) progression-free survival; SOC = standard of care; yr = year; HRR= homologous recombination repair.

### 6.5.9 Second-line treatment for mCRPC and sequencing of therapy

#### 6.5.9.1 Background
During the 90s several radiopharmaceuticals including phosphorous-32, strontium-89, yttrium-90, samarium-153, and rhenium-186 were developed for the treatment of bone pain secondary to metastasis from PCa [1268]. They were effective at palliation; relieving pain and improving QoL, especially in the setting of diffuse bone metastasis. However, they never gained widespread adoption. The first radioisotope to demonstrate a survival benefit was radium-223 (see Section 6.5.7.4).

#### 6.5.9.2 PSMA-based therapy
The increasing use of PSMA PET as a diagnostic tracer and the realisation that this allowed identification of a greater number of metastatic deposits led to attempts to treat cancer by replacing the imaging isotope...
with a therapeutic isotope which accumulates where the tumour is demonstrated (theranostics) [1269]. Therefore, after identification of the target usually with diagnostic 68Gallium-labelled PSMA, therapeutic radiopharmaceuticals labelled with $\beta$-emitting isotopes such as lutetium-177 or ytrium-90 or $\alpha$-emitting isotopes (e.g., actinium-225) could be used to treat metastatic PCa.

The PSMA therapeutic radiopharmaceutical supported with the most robust data is 177Lu-PSMA-617. The first patient was treated in 2014 and early clinical studies evaluating the safety and efficacy of Lu-PSMA therapy have demonstrated promising results, despite the fact that a significant proportion of men had already progressed on multiple therapies [1270]. The early data were based on single-centre experience [1271]. Data from uncontrolled prospective phase II trials reported high response rates with low toxic effects [1272, 1273]. Positive signals are also coming from a randomised trial [1248].

In TheraP, a randomised phase II trial, patients for whom cabazitaxel was considered the next appropriate standard treatment after docetaxel and who were highly selected by 68Ga-PSMA-11 and 18FDG PET-CT scans, were randomised to receive 177Lu-PSMA-617 (6.0–8.5 GBq intravenously every 6 weeks for up to 6 cycles) or cabazitaxel (20 mg/m^2 for up to ten cycles). The primary endpoint was a reduction of at least 50% in PSA. The first endpoint was met (66% vs. 37% for 177Lu–PSMA-617 vs. cabazitaxel, respectively, by ITT; difference 29% [95% CI: 16–42; p < 0.0001; and 66% vs. 44% by treatment received; difference 23% [9–37]; p = 0.0016). Secondary endpoints included ORR, rPFS and PSA FSF as well as QoL [1248].

Finally, an open-label phase III trial (VISION) compared 177Lu–PSMA-617 radioligand therapy with protocol-permitted SOC in mCRPC patients, with PSMA expressing metastases on PET/CT, previously treated with at least one ARTA and one (around 53%) or two taxanes. Imaging-based PFS and OS were the alternate primary endpoints. Eligible patients had to present with at least one PSMA-positive metastatic lesion exceeding the uptake of the liver parenchyma on a 68Ga-PSMA-11 PET–CT and without PSMA-negative lesions in any LN with a short axis of at least 2.5 cm, in any metastatic solid-organ lesions with a short axis of at least 1.0 cm, or in any metastatic bone lesion with a soft-tissue component of at least 1.0 cm in the short axis.

More than 800 patients were randomised. 177Lu-PSMA-617 plus SOC significantly prolonged both imaging-based PFS and OS as compared with SOC alone (see Table 6.5.3). Grade 3 or above AEs were higher with 177Lu–PSMA-617 than without (52.7% vs. 38.0%), but QoL was not adversely affected. 177Lu–PSMA-617 has shown to be a valuable additional treatment option in this mCRPC population [1267].

### 6.5.10 Immunotherapy for mCRPC

The immune checkpoint inhibitor pembrolizumab was approved by the FDA for all MMR-deficient cancers or in those with instable microsatellite status (MSI-high) [1196]. This also applies to PCa but it is a very rare finding in this tumour entity [1197]. In all other PCa patients pembrolizumab monotherapy is still experimental. It shows limited anti-tumour activity with an acceptable safety profile, again in a small subset of patients. A phase II trial enrolled 258 patients treated with pembrolizumab [1274]. The objective response rate was around 4%, but those responses were durable. Combination immunotherapy is under investigation.

The CTLA-4 inhibitor ipilimumab was evaluated in docetaxel pre-treated mCRPC patients after RT to bone metastases in a placebo-controlled phase III RCT. Although the trial’s primary endpoint OS was not improved significantly, a pre-planned long-term analysis showed that OS rates at 3, 4, and 5 years were approximately two to three times higher in the ipilimumab arm (2 years [25.2% vs. 16.6%], 3 years [15.3% vs. 7.9%], 4 years [10.1% vs. 3.3%], and 5 years [7.9% vs. 2.7%]). These data support the hypothesis that a subset of mCRPC patients might derive a long-term benefit from CTLA-4 inhibition. Further prospective data are needed to support the routine use of ipilimumab [1275]. It has not been approved for the use in PCa management.

### 6.5.11 Platinum chemotherapy

Cisplatin or carboplatin as monotherapy or combinations have shown limited activity in unselected patients in the pre-docetaxel era [1276]. More recently, the combination of cabazitaxel and carboplatin was evaluated in pre-treated mCRPC patients in a randomised phase I/II trial. The combination improved the median PFS from 4.5 months (95% CI: 3.5–5.7) to 7.3 months (95% CI: 5.5–8.2; HR: 0.69, 95% CI: 0.50–0.95, p = 0.018) and the combination was well tolerated [1277]. On a histopathological and molecular level, there is preliminary evidence that platinum adds efficacy in patients with aggressive variant PCa molecular signatures including TP53, RB1, and PTEN [1278].

Patients with mCRPC and alterations in DDR genes are more sensitive to platinum chemotherapy than unselected patients [1279], also after progression on PARP inhibitors. Interestingly, in contemporary retrospective series, unselected patients as well as patients without DDR gene alterations also showed a
50% PSA decline in up to 36% of patients [1280]. In view of the excellent tolerability of e.g. carboplatin monotherapy, platinum could be offered to patients with far advanced mCRPC harbouring DDR gene aberrations after having progressed on standard treatment options. Prospective controlled trials are ongoing.

6.5.12 Monitoring of treatment
Baseline examinations should include a medical history, clinical examination as well as baseline blood tests (PSA, total testosterone level, full blood count, renal function, baseline liver function tests, alkaline phosphatase), bone scan and CT of chest, abdomen and pelvis [1281, 1282]. The use of choline or PSMA PET/CT scans for progressing CRPC is unclear and most likely not as beneficial as for patients with BCR or hormone-naïve disease. Flares, PSMA upregulation and discordant results compared with PSA response or progression on ARTA have been described [1283]. Prostate-specific antigen alone is not reliable enough [1284] for monitoring disease activity in advanced CRPC since visceral metastases may develop in men without rising PSA [1285]. Instead, the PCWG2 recommends a combination of bone scintigraphy and CT scans, PSA measurements and clinical benefit in assessing men with CRPC [1220]. A majority of experts at the 2015 Advanced Prostate Cancer Consensus Conference (APCCC) suggested regular review and repeating blood profile every two to three months with bone scintigraphy and CT scans at least every six months, even in the absence of a clinical indication [1281]. This reflects that the agents with a proven OS benefit all have potential toxicity and considerable cost and patients with no objective benefit should have their treatment modified. The APCCC participants stressed that such treatments should not be stopped for PSA progression alone. Instead, at least two of the three criteria (PSA progression, radiographic progression and clinical deterioration) should be fulfilled to stop treatment. For trial purposes, the updated PCWG3 put more weight on the importance of documenting progression in existing lesions and introduced the concept of no longer ‘clinically benefitting’ to underscore the distinction between first evidence of progression and the clinical need to terminate or change treatment [1286]. These recommendations also seem valid for clinical practice outside trials.

6.5.13 When to change treatment
The timing of mCRPC treatment change remains a matter of debate in mCRPC although it is clearly advisable to start or change treatment immediately in men with symptomatic progressing metastatic disease. Preferably, any treatment change should precede development of de novo symptoms or worsening of existing symptoms. Although, the number of effective treatments is increasing, head-to-head comparisons are still rare, as are prospective data assessing the sequencing of available agents. Therefore it is not clear how to select the most appropriate ‘second-line’ treatment, in particular in patients without HRR alterations or other biomarkers. A positive example, however, is the CARD trial which clearly established cabazitaxel as the better third-line treatment in docetaxel pre-treated patients after one ARTA compared to the use of a second ARTA [1198].

The ECOG PS has been used to stratify patients. Generally men with a PS of 0–1 are likely to tolerate treatments and those with a PS of ≥ 2 are less likely to benefit. However, it is important that treatment decisions are individualised, in particular when symptoms related to disease progression are impacting on PS. In such cases, a trial of active life-prolonging agents to establish if a given treatment will improve the PS may be appropriate. Sequencing of treatment is discussed in a summary paper published following the 2019 APCCC Conference [1287].

6.5.14 Symptomatic management in metastatic CRPC
Castration-resistant PCa is usually a debilitating disease often affecting the elderly male. A multidisciplinary approach is required with input from urologists, medical oncologists, radiation oncologists, nurses, psychologists and social workers [1287, 1288]. Critical issues of palliation must be addressed when considering additional systemic treatment, including management of pain, constipation, anorexia, nausea, fatigue and depression.

6.5.14.1 Common complications due to bone metastases
Most patients with CRPC have painful bone metastases. External beam RT is highly effective, even as a single fraction [1289, 1290]. A single infusion of a third generation bisphosphonate could be considered when RT is not available [1291]. Common complications due to bone metastases include vertebral collapse or deformity, pathological fractures and spinal cord compression. Cementation can be an effective treatment for painful spinal fracture whatever its origin, clearly improving both pain and QoL [1292]. It is important to offer standard palliative surgery, which can be effective for managing osteoblastic metastases [1293, 1294]. Impending spinal cord compression is an emergency. It must be recognised early and patients should be educated to recognise the warning signs. Once suspected, high-dose corticosteroids must be given and MRI performed as soon as possible. A systematic neurosurgery or orthopaedic surgeon consultation should be planned to discuss a possible decompression, followed by EBRT [1295]. Otherwise, EBRT with, or without, systemic therapy, is the treatment of choice.
6.5.14.2 Preventing skeletal-related events

6.5.14.2.1 Bisphosphonates

Zoledronic acid has been evaluated in mCRPC to reduce skeletal-related events (SRE). This study was conducted when no active anti-cancer treatments, but for docetaxel, were available. Six hundred and forty three patients who had CRPC with bone metastases were randomised to receive zoledronic acid, 4 or 8 mg every three weeks for 15 consecutive months, or placebo [1296]. The 8 mg dose was poorly tolerated and reduced to 4 mg but did not show a significant benefit. However, at 15 and 24 months of follow-up, patients treated with 4 mg zoledronic acid had fewer SREs compared to the placebo group (44 vs. 33%, p = 0.021) and in particular fewer pathological fractures (13.1 vs. 22.1%, p = 0.015). Furthermore, the time to first SRE was longer in the zoledronic acid group. No survival benefit has been seen in any prospective trial with bisphosphonates.

6.5.14.2.2 RANK ligand inhibitors

Denosumab is a fully human monoclonal antibody directed against RANKL (receptor activator of nuclear factor κ-B ligand), a key mediator of osteoclast formation, function, and survival. In M0 CRPC, denosumab has been associated with increased bone-metastasis-free survival compared to placebo (median benefit: 4.2 months, HR: 0.85, p = 0.028) [1289]. This benefit did not translate into a survival difference (43.9 compared to 44.8 months, respectively) and neither the FDA or the EMA have approved denosumab for this indication [1297].

The efficacy and safety of denosumab (n = 950) compared with zoledronic acid (n = 951) in patients with mCRPC was assessed in a phase III trial. Denosumab was superior to zoledronic acid in delaying or preventing SREs as shown by time to first on-study SRE (pathological fracture, radiation or surgery to bone, or spinal cord compression) of 20.7 vs. 17.1 months, respectively (HR: 0.82, p = 0.008). Both urinary N-telopeptide and bone-specific alkaline phosphatase were significantly suppressed in the denosumab arm compared with the zoledronic acid arm (p < 0.0001 for both). However, these findings were not associated with any survival benefit and in a post-hoc re-evaluation of endpoints, denosumab showed identical results when comparing SREs and symptomatic skeletal events [1298].

The potential toxicity (e.g., osteonecrosis of the jaw, hypocalcaemia) of these drugs must always be kept in mind (5–8.2% in M0 CRPC and mCRPC, respectively) [1298-1300]. Patients should have a dental examination before starting therapy as the risk of jaw necrosis is increased by several risk factors including a history of trauma, dental surgery or dental infection [1301]. Also, the risk for osteonecrosis of the jaw increased numerically with the duration of use in a pivotal trial [1302] (one year vs. two years with denosumab), but this was not statistically significant when compared to zoledronic acid [1297]. According to the EMA, hypocalcaemia is a concern in patients treated with denosumab and zoledronic acid. Hypocalcaemia must be corrected by adequate intake of calcium and vitamin D before initiating therapy [1303]. Hypocalcaemia should be identified and prevented during treatment with bone protective agents (risk of severe hypocalcaemia is 8% and 5% for denosumab and zoledronic acid, respectively) [1300]. Serum calcium should be measured in patients starting therapy and monitored during treatment, especially during the first weeks and in patients with risk factors for hypocalcaemia or on other medication affecting serum calcium. Daily calcium (≥ 500 mg) and vitamin D (≥ 400 IU equivalent) are recommended in all patients, unless in case of hypercalcaemia [1300, 1304, 1305].

6.6.1 General guidelines recommendations for treatment of prostate cancer

**Recommendations**

Inform patients that based on robust current data with up to 12 years of follow-up, no active treatment modality has shown superiority over any other active management options or deferred active treatment in terms of overall- and PCa-specific survival for clinically localised low/intermediate-risk disease.

**Strength rating**

Strong

Offer a watchful waiting policy to asymptomatic patients with clinically localised disease and with a life expectancy < 10 years (based on co-morbidities and age).

**Strength rating**

Strong

Inform patients that all active local treatments have side effects.

**Strength rating**

Strong

**Surgical treatment**

Inform patients that no surgical approach (open-, laparoscopic- or robotic radical prostatectomy) has clearly shown superiority in terms of functional or oncological results.

**Strength rating**

Weak

When a lymph node dissection (LND) is deemed necessary, perform an extended LND template for optimal staging.

**Strength rating**

Strong

Do not perform nerve-sparing surgery when there is a risk of ipsilateral extracapsular extension (based on cT stage, ISUP grade, magnetic resonance imaging, or with this information combined into a nomogram).

**Strength rating**

Weak

Do not offer neoadjuvant androgen deprivation therapy before surgery.

**Strength rating**

Strong

**Radiotherapeutic treatment**

Offer intensity-modulated radiation therapy (IMRT) or volumetric arc radiation therapy (VMAT) plus image-guided radiation therapy (IGRT) for definitive treatment of PCa by external-beam radiation therapy.

**Strength rating**

Strong

Offer moderate hypofractionation (HFX) with IMRT/VMAT plus IGRT to the prostate to patients with localised disease.

**Strength rating**

Strong

Ensure that moderate HFX adheres to radiotherapy protocols from trials with equivalent outcome and toxicity, i.e. 60 Gy/20 fractions in 4 weeks or 70 Gy/28 fractions in 6 weeks.

**Strength rating**

Strong

Offer low-dose rate (LDR) brachytherapy monotherapy to patients with good urinary function and low- or intermediate-risk disease with ISUP grade 2 and ≤ 33% of biopsy cores involved.

**Strength rating**

Strong

Offer LDR or high-dose rate (HDR) brachytherapy boost combined with IMRT/VMAT plus IGRT to patients with good urinary function intermediate-risk disease with ISUP G3 and/or PSA 10–20 ng/mL.

**Strength rating**

Weak

Offer LDR or HDR brachytherapy boost combined with IMRT/VMAT plus IGRT to patients with good urinary function and high-risk and/or locally advanced disease.

**Strength rating**

Weak

**Active therapeutic options outside surgery or radiotherapy**

Offer whole-gland cryotherapy and high-intensity focused ultrasound within a clinical trial setting or well-designed prospective cohort study.

**Strength rating**

Strong

<tr>
<td><strong>Active surveillance (AS)</strong></td>
<td>Selection of patients</td>
</tr>
<tr>
<td>Offer AS to patients with a life expectancy &gt; 10 years and low-risk disease.</td>
<td>Strong</td>
</tr>
<tr>
<td>Patients with intraductal and cribriform histology on biopsy should be excluded from AS.</td>
<td>Strong</td>
</tr>
<tr>
<td>Perform MRI before a confirmatory biopsy if no MRI has been performed before the initial biopsy.</td>
<td>Strong</td>
</tr>
<tr>
<td>Take both targeted biopsy (of any PI-RADS ≥ 3 lesion) and systematic biopsy if a confirmatory biopsy is performed.</td>
<td>Strong</td>
</tr>
<tr>
<td>If MRI is not available, per-protocol confirmatory prostate biopsies should be performed.</td>
<td>Weak</td>
</tr>
<tr>
<td>If a patient has had upfront MRI followed by systematic and targeted biopsies there is no need for confirmatory biopsies.</td>
<td>Weak</td>
</tr>
<tr>
<td><strong>Follow-up strategy</strong></td>
<td></td>
</tr>
<tr>
<td>Repeat biopsies should be performed at least once every 3 years for 10 years.</td>
<td>Weak</td>
</tr>
<tr>
<td>In case of PSA progression or change in DRE or MRI findings, do not progress to active treatment without a repeat biopsy.</td>
<td>Strong</td>
</tr>
<tr>
<td><strong>Active treatment</strong></td>
<td></td>
</tr>
<tr>
<td>Offer surgery or radiotherapy (RT) as alternatives to AS to patients suitable for such treatments and who accept a trade-off between toxicity and prevention of disease progression.</td>
<td>Weak</td>
</tr>
<tr>
<td><strong>Pelvic lymph node dissection (PLND)</strong></td>
<td>Do not perform a PLND.</td>
</tr>
<tr>
<td><strong>Radiotherapeutic treatment</strong></td>
<td>Offer low-dose rate (LDR) brachytherapy to patients with low-risk PCa and good urinary function.</td>
</tr>
<tr>
<td>Use intensity-modulated radiation therapy (IMRT)/volumetric modulated arc therapy (VMAT) plus image-guided radiation therapy (IGRT) with a total dose of 74–80 Gy or moderate hypofractionation (60 Gy/20 fx in 4 weeks or 70 Gy/28 fx in 6 weeks), without androgen deprivation therapy (ADT).</td>
<td>Strong</td>
</tr>
<tr>
<td><strong>Other therapeutic options</strong></td>
<td>Do not offer ADT monotherapy to asymptomatic men not able to receive any local treatment.</td>
</tr>
<tr>
<td>Only offer whole gland treatment (such as cryotherapy, high-intensity focused ultrasound [HIFU], etc.) or focal treatment within a clinical trial setting or well-designed prospective cohort study.</td>
<td>Strong</td>
</tr>
<tr>
<td><strong>Intermediate-risk disease</strong></td>
<td></td>
</tr>
<tr>
<td><strong>Active surveillance</strong></td>
<td></td>
</tr>
<tr>
<td>Offer AS to highly selected patients with ISUP grade group 2 disease (i.e. &lt; 10% pattern 4, PSA &lt; 10 ng/mL, ≤ cT2a, low disease extent on imaging and low biopsy extent [defined as ≤ 3 positive cores and cancer involvement ≤ 50% core involvement [CI]/per core]), or another single element of intermediate-risk disease with low disease extent on imaging and low biopsy extent, accepting the potential increased risk of metastatic progression.</td>
<td>Weak</td>
</tr>
<tr>
<td>Patients with ISUP grade group 3 disease must be excluded from AS protocols.</td>
<td>Strong</td>
</tr>
<tr>
<td>Re-classify patients with low-volume ISUP grade group 2 disease included in AS protocols, if repeat non-MRI-based systematic biopsies performed during monitoring reveal &gt; 3 positive cores or maximum CI &gt; 50%/core of ISUP 2 disease.</td>
<td>Weak</td>
</tr>
<tr>
<td><strong>Radical Prostatectomy (RP)</strong></td>
<td>Offer RP to patients with intermediate-risk disease and a life expectancy &gt; 10 years.</td>
</tr>
<tr>
<td>Offer nerve-sparing surgery to patients with a low risk of extracapsular disease.</td>
<td>Strong</td>
</tr>
<tr>
<td><strong>Extended pelvic lymph node dissection (ePLND)</strong></td>
<td>Perform an ePLND in intermediate-risk disease based on predicted risk of lymph node invasion (validated nomogram, see Section 6.1.2.3.2).</td>

<td>Strong</td>
</tr>
</tbody>
</table>
7. FOLLOW-UP

The rationale for following up patients is to assess immediate- and long-term oncological results, ensure treatment compliance and allow initiation of further therapy, when appropriate. In addition, follow-up allows monitoring of side effects or complications of therapy, functional outcomes and an opportunity to provide psychological support to PCa survivors, all of which is covered in Chapter 8.

7.1 Follow-up: After local treatment

7.1.1 Definition

Local treatment is defined as RP or RT, either by IMRT plus IGRT or LDR- or HDR-brachytherapy, or any combination of these, including neoadjuvant and adjuvant therapy. Unestablished alternative treatments such as HIFU, cryosurgery and focal therapy options do not have a well-defined, validated, PSA cut-off to define BCR but follow the general principles as presented in this section. In general, a confirmed rising PSA is considered a sign of disease recurrence.

7.1.2 Why follow-up?

The first post-treatment clinic visit focuses on detecting treatment-related complications and assist patients in coping with their new situation apart from providing information on the pathological analysis. Men with PCa are at increased risk of depression and attention for mental health status is required [1306, 1307]. Tumour or patient characteristics may prompt changing the follow-up schedule. Follow-up of men diagnosed with PCa may allow early treatment of disease and treatment-related problems. The use of salvage treatment should be considered in light of the expected life-expectancy, especially when below 10 years in asymptomatic patients.

7.1.3 How to follow-up?

The procedures indicated at follow-up visits vary according to the clinical situation. A disease-specific history is mandatory at every follow-up visit and includes psychological aspects, signs of disease progression, and treatment-related complications. Evaluation of treatment-related complications in the post-treatment period is highlighted in Sections 6.1.2.4, 6.1.2.4.3, 6.3.9.2, 6.3.10.2.2, 6.3.11.2 and 8.2. The examinations used for cancer-related follow-up after curative surgery or RT are discussed below.

7.1.3.1 Prostate-specific antigen monitoring

Measurement of PSA is the cornerstone of follow-up after local treatment. While PSA thresholds depend on the local treatment used, PSA recurrence almost always precedes clinical recurrence [1003, 1308]. The key question is to establish when a PSA rise is clinically significant since not all PSA increases have the same clinical value (see Section 6.3) [1005]. No prospective studies are available on the optimal timing for PSA testing.

7.1.3.1.1 Active surveillance follow-up

Patients included in an AS programme should be monitored according to the recommendations presented in Section 6.2.2.

7.1.3.1.2 Prostate-specific antigen monitoring after radical prostatectomy

Following RP, the PSA level is expected to be undetectable. Biochemical recurrence is any rising PSA after prostatectomy as defined in Chapter 6. Prostate-specific antigen level is expected to be undetectable 2 months after a successful RP [1309]. Prostate-specific antigen is generally determined every 6 months until 3 years and yearly thereafter but the evidence for a specific interval is low [516] and mainly based on the observation that early recurrences are more likely to be associated with more rapid progression [1005, 1310, 1311]. A rising PSA may occur after longer intervals up to 20 years after treatment and depends on the initial risk group [932]. A yearly PSA after 3 years is considered adequate considering the fact that a longer interval to BCR is correlated with a lower EAU-BCR risk score but around 50% of recurrence should be expected beyond 3 years. As mentioned in Section 6.3.2 no definitive threshold can be given for relapse after RP. Persistently measurable PSA in patients treated with RP is discussed in Section 6.2.6.

Ultrasensitive PSA assays remain controversial for routine follow-up after RP. Men with a PSA nadir < 0.01 ng/mL have a high (96%) likelihood of remaining relapse-free within 2 years [1312]. In addition, post-RP PSA levels > 0.01 ng/mL in combination with clinical characteristics such as ISUP grade and surgical margin status may predict PSA progression and can be useful to establish follow-up intervals [1311]. However, up to 86% of men were reported to have PSA values below 0.2 ng/mL at 5 years after an initial PSA nadir below 0.1 ng/mL within 6 months after surgery [1313]. Lastly, PSA and associated PSA-DT [1314] calculated prior to 0.2 ng/mL may help identify suitable candidates for early intervention [1315]. Prostate-specific antigen monitoring after salvage
RT to the prostatic fossa is done at similar intervals and an early and rapid PSA rise predicts more rapid progression [1310] and is correlated to metastases-free and PCa-specific survival [1316].

7.1.3.1.3 Prostate-specific antigen monitoring after radiotherapy
Following RT, PSA drops more slowly as compared to post RP. A nadir < 0.5 ng/mL is associated with a favourable outcome after RT although the optimal cut-off value remains controversial [1317]. The interval before reaching the nadir can be up to 3 years, or more. At the 2006 RTOG-ASTRO Consensus Conference the Phoenix definition of radiation failure was proposed to establish a better correlation between definition and clinical outcome (mainly metastases), namely, an increase of 2 ng/mL above the post-treatment PSA nadir [1004]. This definition also applies to patients who received HT [1004].

7.1.3.1.4 Digital rectal examination
Local recurrence after curative treatment is possible without a concomitant rise in PSA level although rarely [1318]. However, this has only been proven in patients with unfavourable undifferentiated tumours. Prostate-specific antigen measurement and DRE comprise the most useful combination for first-line examination in follow-up after RT but the role of DRE was questioned since it failed to detect any local recurrence in the absence of a rising PSA in a series of 899 patients [1319]. In a series of 1,118 prostatectomy patients, no local histologically proven recurrence was found by DRE alone and PSA measurement may be the only test needed after RP [1320, 1321].

7.1.3.1.5 Transrectal ultrasound, bone scintigraphy, CT, MRI and PET/CT
Imaging techniques have no place in routine follow-up of localised PCa as long as the PSA is not rising. Imaging is only justified in patients for whom the findings will affect treatment decisions, either in case of BCR or in patients with symptoms (see Section 6.3.4 for a more detailed discussion).

7.1.4 How long to follow-up?
Most patients who fail treatment for PCa do so within 7 years after local therapy [534]. Patients should be followed more closely during the initial post-treatment period when risk of failure is highest. PSA measurement, disease-specific history and DRE (if considered) are recommended every 6 months until 3 years and then annually. Whether follow-up should be stopped if PSA remains undetectable (after RP) or stable (after RT) remains an unanswered question.

Risk assessment to predict metastases-free and PCa-specific survival after recurrence after primary treatment may guide individual decisions on a need for longer follow-up [937, 1005, 1322]. Even in men with a PSA-DT less than 10 months after RP who choose to defer treatment, a median metastasis-free survival of 192 months and OS of 204 months from RP was observed, indicating the relatively long disease-free intervals observed in men with a rising PSA after local treatment [1323].

Symptomatic recurrence without a PSA rise is extremely rare, however, the symptoms typical for recurrent disease may vary and are poorly defined by published data. In case of the following symptoms PSA testing should be performed to exclude a possible cancer recurrence in particular in men not followed up by regular testing of their PSA levels: skeletal pain, haematuria, progressive voiding complaints, progressive lower body oedema, progressive bowel complaints or complaints of fatigue, sarcopenia or unexplained weight loss [1324].

7.1.5 Summary of evidence and guidelines for follow-up after treatment with curative intent

7.2 Follow-up: During first line hormonal treatment (androgen sensitive period)

7.2.1 Introduction

Androgen deprivation therapy is used in various situations: combined with RT for localised or locally-advanced
disease, as monotherapy for a relapse after a local treatment, or in the presence of metastatic disease often in
combination with other treatments. All these situations are based on the benefits of testosterone suppression
either by drugs (LHRH agonists or antagonists) or orchidectomy. Inevitably, the disease will become castrateresistant, although ADT will be maintained.

This section addresses the general principles of follow-up of patients on ADT alone. As treatment
of CRPC and follow-up are closely linked, Section 6.5.7 includes further information on other drug treatments.
Furthermore the specific follow-up needed for every single drug is outside the scope of this text, as is follow-up
after chemotherapy.

To detect disease- and treatment-related complaints, regular clinical follow-up is mandatory and
cannot be replaced by imaging or laboratory tests alone. Complementary investigations must be restricted to
those that are clinically helpful to avoid unnecessary examinations and costs.

7.2.2 Purpose of follow-up

The main objectives of follow-up in patients receiving ADT are to ensure treatment compliance, to monitor
treatment response, to detect side effects early, and to guide treatment at the time of CRPC. After the initiation
of ADT, it is recommended that patients are evaluated every 3 to 6 months. This must be individualised and
each patient should be advised to contact his physician in the event of troublesome symptoms.

7.2.3 General follow-up of men on ADT

Patients under ADT require regular follow-up, including monitoring of serum testosterone, creatinine, liver
function and metabolic parameters at 3 to 6 month intervals. Men on ADT can experience toxicity independent
of their disease stage.

7.2.3.1 Testosterone monitoring

Testosterone monitoring should be considered standard clinical practice in men on ADT. Many men receiving
medical castration will achieve a castrate testosterone level (< 20 ng/dL), and most a testosterone level
< 50 ng/dL. However, approximately 13–38% of patients fail to achieve these levels and up to 24% of men
may experience temporary testosterone surges (testosterone > 50 ng/dL) during long-term treatment [1309]
referred to as ‘acute on-chronic effect’ or ‘breakthrough response’ [1325]. Breakthrough rates for the < 20 ng/dL
threshold were found to be more frequent (41.3%) and an association with worse clinical outcomes was
suggested [1325].

The timing of measurements is not clearly defined. A 3 to 6-month testosterone level assessment
has been suggested to ensure castration is achieved (especially during medical castration) and maintained.
In case a castrate testosterone level is not reached, switching to another agonist or antagonist or to an
orchiectomy should be considered. In patients with a confirmed rising PSA and/or clinical progression,
serum testosterone must be evaluated in all cases to confirm a castration-resistant state. Ideally, suboptimal
testosterone castrate levels should be confirmed with mass spectrometry or an immunoassay [1326, 1327].
After ADT cessation (intermittent treatment or temporary ADT use as with EBRT) testosterone recovery is
dependent on patients age and the duration of ADT [1328, 1329].

7.2.3.2 Liver function monitoring

Liver function tests will detect treatment toxicity (especially applicable for NSAA), but rarely indicate disease
progression. Men on combined ADT should have their transaminase levels checked at least yearly but in
particular in the first 6 months of treatment initiation since liver function disorders were observed relatively
early in the majority of patients in larger trials [1330]. In view of potential liver toxicity a more frequent check
is needed with some drugs (like abiraterone acetate) [1331]. Alkaline phosphatase may increase secondary to
bone metastases and androgen-induced osteoporosis, therefore it may be helpful to determine bone-specific
isoenzymes as none are directly influenced by ADT [1332].

7.2.3.3 Serum creatinine and haematological parameters

Estimated glomerular filtration rate monitoring is good clinical practice as an increase may be linked to ureteral
obstruction or bladder retention. A decline in haemoglobin is a known side effect of ADT. A significant decline
after 3 months of ADT is independently associated with shorter progression-free and OS rates and might
explain significant fatigue although other causes should be considered [1333]. Anaemia is often multi-factorial
and other possible aetiologies should be excluded. An early decrease in haemoglobin 3 months after ADT
initiation predicted better survival whereas a decrease beyond 6 months was associated with poor outcome
in the SPCG-5 population [1334]. Radiotherapy to more extensive bone metastases locations may result in
myelosuppression and haematological toxicity [1335, 1336].
7.2.3.4 Monitoring of metabolic complications

The most severe complications of androgen suppression are metabolic syndrome, cardiovascular morbidity, mental health problems, and bone resorption (see Section 8.2.4.5).

All patients should be screened for diabetes by checking fasting glucose and HbA1c (at baseline and routinely) in addition to checking blood lipid levels. Men with impaired glucose tolerance and/or diabetes should be referred for an endocrine consultation. Prior to starting ADT a cardiology consultation should be considered in men with a history of cardiovascular disease and in men older than 65 years. Men on ADT are at increased risk of cardiovascular problems and hypertension and regular checks are required [1337]. More profound androgen ablation resulted in a higher cardiovascular toxicity [1338] and cardio-respiratory fitness decreased even after 6 months of ADT [1339]. Although LHRH antagonists have been suggested to provide a more favourable cardiovascular toxicity profile compared to LHRH agonists, the prematurely closed PRONOUNCE study found no difference at 12 months in major adverse cardiovascular events between men receiving degarelix or leuprolide [1340].

7.2.3.5 Monitoring bone problems

Androgen deprivation therapy increases the risk of osteoporosis. Administration of ADT for more than a year, as compared to less than one year, showed a higher risk of osteoporosis (HR: 1.77 and 1.38, respectively) [1341].

Several scores (e.g., Fracture Risk Assessment Tool [FRAX score], Osteoporosis Self-Assessment Tool [OST], Osteoporosis Risk Assessment Instrument [ORA]), Osteoporosis Index of Risk [OSIRIS], Osteoporosis Risk Estimation [SCORE]) can help identify men at risk of osteoporotic complications but validation of these scores in the ADT setting is required (see Section 8.3.2.2) [1342-1344].

Routine bone monitoring for osteoporosis should be performed using dual emission X-ray absorptiometry (DEXA) scan [1345-1347]. Presence of osteoporosis should prompt the use of bone protective agents. The criteria for initiation of bone protective agents are mentioned in Section 8.3.2.2. If no bone protective agents are given, a DEXA scan should be done regularly, at least every 2 years [1348].

A review summarising the incidence of bone fractures showed an almost doubling of the risk of fractures when using ADT depending on patients’ age and duration and type of ADT with the highest incidence in older men and men on additional novel ARTA medication across the entire spectrum of disease [1349]. In case of an osteoporotic fracture a bone protective agent is mandatory. Vitamin D and calcium levels should be regularly monitored when patients receive ADT and patients should be supplemented if needed. (see Section 8.3.2.2).

7.2.3.6 Monitoring lifestyle, cognition and fatigue

Lifestyle (e.g., diet, exercise, smoking status, etc.) affects QoL and potentially outcome [1332, 1333]. During follow-up men should be counselled on the beneficial effects of exercise to avoid ADT-related toxicity [1350]. Androgen deprivation therapy may affect mental and cognitive health and men on ADT are three times more likely to report depression [1351]. Attention to mental health should therefore be an integral part of the follow-up scheme. Men on ADT may experience complaints of fatigue possibly related to systemic inflammation [1352]. Cognitive performance and fatigue may arise within 6 months after initiation of ADT but can increase over time [1353]. These aspects affect patients as well as their partners and couple counselling should be considered [1354].

7.2.4 Methods of follow-up in men on ADT without metastases

7.2.4.1 Prostate-specific antigen monitoring

Prostate-specific antigen is a key marker for following the course of androgen-sensitive non-metastasised PCa. Imaging should be considered when PSA is rising > 2 ng/mL or in case of symptoms suggestive of metastasis.

7.2.4.2 Imaging

In general, asymptomatic patients with a stable PSA level do not require further imaging, although care needs to be taken in patients with aggressive variants when PSA levels may not reflect tumour progression [1355]. New bone pain requires at least targeted imaging and potentially a bone scan. When PSA progression suggests CRPC status and treatment modification is considered, imaging, by means of a bone and CT scan, is recommended for restaging. Detection of metastases greatly depends on imaging (see Section 6.3.4).

7.2.5 Methods of follow-up in men under ADT for metastatic hormone-sensitive PCa

In metastatic patients it is of the utmost importance to counsel about early signs of spinal cord compression, urinary tract complications (ureteral obstruction, bladder outlet obstruction) or bone lesions that are at an increased fracture risk. The intervals for follow-up in M1 patients should be guided by patients’ complaints and can vary. Since most men will receive another anti-cancer therapy combined with ADT such as ARTA, chemotherapy or local RT, follow-up frequency should also be dependent on the treatment modality.
7.2.5.1 PSA monitoring
In men on ADT alone, a PSA decline to < 4 ng/mL suggests a likely prolonged response and follow-up visits may be scheduled every 3 to 6 months provided the patient is asymptomatic or clinically improving. This applied to men on ADT monotherapy as well as after ADT plus docetaxel [1151]. Depending on symptoms and risk assessment, more frequent visits may be indicated. Treatment response may be evaluated based on a change in serum PSA level [1150, 1151] and bone and CT scan although there is no consensus about how frequently these should be performed [1287]. A rise in PSA level usually precedes the onset of clinical symptoms by several months. A rising PSA should prompt assessment of testosterone level, which is mandatory to define CRPC status, as well as restaging using imaging. However, it is now recognised that a stable PSA during ADT is not enough to characterise a non-progressive situation [1356].

7.2.5.2 Imaging as a marker of response in metastatic PCa
Treatment response in soft-tissue metastases can be assessed by morphological imaging methods using the Response Evaluation Criteria in Solid Tumours (RECIST) criteria. However, these criteria cannot be used in bone where response assessment is difficult [1357, 1358].

When bone scan is used to follow bone metastases, a quantitative estimation of tracer uptake at bone scan can be obtained through automated methods such as the Bone Scan Index [1359]. Nonetheless, bone scan is limited by the so-called ‘flare’ phenomenon which is defined by the development of new images induced by treatment on a first follow-up scan which, after longer observation, actually represent a favourable response. Flare is observed within 8 to 12 weeks of treatment initiation and can lead to a false-positive diagnosis of disease progression. Computed tomography cannot be used to monitor sclerotic bone lesions because bone sclerosis can occur under effective treatment and reflects bone healing. Magnetic resonance imaging can directly assess the bone marrow and demonstrate progression based on morphologic criteria or changes in apparent diffusion coefficient. A standardisation for reporting is available [1360]. The ability of PET/CT to assess response has been evaluated in a few studies. Until further data are available, MRI and PET/CT should not be used outside trials for treatment monitoring in metastatic patients [1361].

Men with metastasised PCa on ADT should also in the absence of a PSA rise be followed up with regular imaging since twenty-five percent of men with, or without, docetaxel in the CHAARTED trial developed clinical progression without a PSA rise [1356]. One in eight men with a PSA < 2 ng/mL showed clinical progression [1356]. The addition of docetaxel to ADT in the CHAARTED trial population did not reduce the incidence of clinical progression at low PSA values and this rate was similar for both low- and high-volume disease as per CHAARTED criteria [1356]. However, the optimal timing and image modality to be used remain unclear, as is the real clinical value of any findings.

7.2.6 Guidelines for follow-up during hormonal treatment

8. QUALITY OF LIFE OUTCOMES IN PROSTATE CANCER

This chapter is presented in two parts. The first (Section 8.2) will summarise long-term consequences (> 12 months) of therapies for PCa. Based on two systematic reviews, the second (Section 8.3) provides evidence-based recommendations for supporting patients when selecting primary treatment options for localised disease and also supportive interventions aimed at improving disease-specific QoL across all stages of disease.

8.1 Introduction

Quality of life and personalised care go hand in hand. Treating PCa can affect an individual both physically and mentally, as well as close relations and work or vocation. These multifaceted issues all have a bearing on an individual’s perception of QoL [1362]. Approaching care from a holistic point of view requires the intervention of a multi-disciplinary team including urologists, medical oncologists, radiation oncologists, oncology nurses, behavioural practitioners and many others including fellow patients. Attention to the psychosocial concerns of people with PCa is integral to quality clinical care, and this can include the needs of carers and partners [1363]. Prostate cancer care should not be reduced to focusing on the organ in isolation: side effects or late adverse effects of treatment can manifest systemically and have a major influence on the patient’s QoL. Psychological distress can be caused by the cancer diagnosis itself, cancer symptoms and/or treatment side effects [1364]. Taking QoL into consideration relies on understanding the patient’s values and preferences so that optimal treatment proposals can be formulated and discussed. Cross-sectional patient-reported outcomes studies in general PCa populations show the impact of treatment on global and disease-specific QoL is greater than that described in clinical trial populations who often have less co-morbidity and belong to higher socio-economic groups. Individuals undergoing two or more treatments have more symptoms and greater impact on QoL [1365, 1366].

8.2 Adverse effects of PCa therapies

8.2.1 Surgery

A lack of clear consensus in reporting surgical complications following RP, specifically urinary incontinence and stricture rates, and the introduction of different techniques has resulted in a wide variation in the types of complications reported, as well as variation in the overall incidence of complications [1367-1370]. The most common post-operative complication is ED but other related issues to consider include dry ejaculation, which occurs with removal of the prostate, change in the quality of orgasm and occasional pain on orgasm. Men also complain of loss of penile length (3.73%, 19/510 men) [1371]. The second most commonly occurring complication is long-term incontinence [1367-1370] but voiding difficulties may also occur associated with bladder neck contracture (e.g., 1.1% after RALP) [1372].

For those undergoing minimally invasive procedures port site hernia has been reported in 0.66% after inserting 12 mm bladeless trocar and can occur more rarely with 8 mm and 5 mm trocars [1373]. A key consideration is whether long-term consequences of surgery are reduced by using newer techniques such as RALP. Systematic reviews have documented complication rates after RALP [555, 645-648], and can be compared with contemporaneous reports after RRP [649]. From these reports, the mean continence rates at 12 months were 89–100% for patients treated with RALP and 80–97% for patients treated with RRP. A prospective controlled non-randomised trial of patients undergoing RP in 14 centres using RALP or RRP demonstrated that at 12 months after RALP, 21.3% were incontinent, as were 20.2% after RRP. The unadjusted OR was 1.08 (95% CI: 0.87–1.34). Erectile dysfunction was observed in 70.4% after RALP and 74.7% after RRP. The unadjusted OR was 0.81 (95% CI: 0.66–0.98) [650, 1374]. Further follow-up demonstrates similar functional outcomes with both techniques at 24 months [1374, 1375]. A single-centre randomised phase III study comparing RALP and RRP (n = 326) also demonstrates similar functional outcomes with both techniques at 24 months [550]. Prostatectomy was found to increase the risk of complaints from an inguinal hernia, in particular after an open procedure when compared to minimal invasive approaches [1376, 1377].

8.2.2 Radiotherapy

8.2.2.1 Side-effects of external beam radiotherapy

Analysis of the toxicity outcomes of the ProtecT trial shows that patients treated with EBRT and 6 months of ADT report bowel toxicity including persistent diarrhoea, bowel urgency and/or incontinence and rectal bleeding (described in detail in Section 8.3.1.1 below) [1378]. Participants in the ProtecT study were treated with 3D-CRT and more recent studies using IMRT demonstrate less bowel toxicity than noted previously with 3D-CRT [1379].

A systematic review and meta-analysis of observational studies comparing patients exposed or unexposed to RT in the course of treatment for PCa demonstrates an increased risk of developing second cancers for bladder (OR: 1.39), colorectal (OR: 1.68) and rectum (OR: 1.62) with similar risks over lag times of...
5 and 10 years. Absolute excess risks over 10 years are small (1–4%) but should be discussed with younger patients in particular [1380].

8.2.2.2 Side effects from brachytherapy
Some patients experience significant urinary complications following implantation such as urinary retention (1.5–22%), with post-implantation TURP reported as being required in up to 8.7% of cases, and incontinence (0–19%) [1381]. Chronic urinary morbidity is more common with combined EBRT and BT and can occur in up to 20% of patients, depending on the severity of the symptoms before brachytherapy. Urethral strictures account for at least 50% of urinary complications and can be resolved with dilation in the majority [763, 769]. Prevention of morbidity depends on careful patient selection and IPSS score, backed up by urodynamic studies.

8.2.3 Local primary whole-gland treatments other than surgery or radiotherapy
8.2.3.1 Cryosurgery
In Ramsay et al.’s systematic review and meta-analysis there was evidence that the rate of urinary incontinence at one year was lower for cryotherapy than for RP, but the size of the difference decreased with longer follow-up [827]. There was no significant difference between cryotherapy vs. EBRT in terms of urinary incontinence at one year (< 1%); cryotherapy had a similar ED rate (range 0–40%) to RP at one year. There were insufficient data to compare cryotherapy vs. EBRT in terms of ED.

8.2.3.2 High-intensity focused ultrasound
In terms of toxicity there are insufficient data on urinary incontinence, ED or bowel dysfunction to draw any conclusions, although at one year HIFU had lower incontinence rates than RP (OR: 0.06, 95% CI: 0.01–0.48) [827].

8.2.4 Hormonal therapy
A summary of impacts on psychological factors due to the use of ADT such as sexual function, mood, depression, cognitive function and impact on partners can be found in two clinical reviews [1382, 1383].

A small RCT evaluated the QoL at one-year follow-up in patients with non-localised PCa, between various ADT regimens, or no treatment. Patients treated by ADT reported a significant decline in spatial reasoning, spatial abilities and working memory as well as increased depression, tension, anxiety, fatigue and irritability during treatment [1384]. Conversely, a prospective observational study with follow-up to 3 years failed to demonstrate an association with cognitive decline in men on ADT when compared to men with PCa not treated with ADT and healthy controls [1385]. A prospective observational study of non-metastatic PCa found that immediate ADT was associated with a lower overall QoL compared to deferred treatment [1386]. Another retrospective non-randomised study suggested that men receiving LHRH agonists reported more worry and physical discomfort and poorer overall health, and were less likely to believe themselves free of cancer than patients undergoing orchiectomy. The stage at diagnosis had no effect on health outcomes [1387].

Using a specific non-validated questionnaire, bicalutamide monotherapy showed a significant advantage over castration in the domains of physical capacity and sexual interest (not sexual function) at 12 months [1388]. A post-hoc analysis, including only patients with sexual interest suggested that bicalutamide was associated with better sexual preservation, including maintained sexual interest [1389], preserved libido and erectile function [1390]. Intermittent androgen deprivation has been discussed elsewhere (see Section 6.4.3.2).

8.2.4.1 Sexual function
Cessation of sexual activity is very common in people undergoing ADT, affecting up to 93% [1391]. Androgen deprivation therapy reduces both libido and the ability to gain and maintain erections. The management of acquired ED is mostly non-specific [1392].

8.2.4.2 Hot flushes
Hot flushes are a common side-effect of ADT (prevalence estimated between 44–80% of men on ADT) [1391]. They appear 3 months after starting ADT, usually persist long-term and have a significant impact on QoL.

Serotonin re-uptake inhibitors (e.g., venlafaxine or sertraline) also appear to be effective in men but less than hormone therapies based on a prospective RCT comparing venlafaxine, 75 mg daily, with medroxyprogesterone, 20 mg daily, or cyproterone acetate, 100 mg daily [1393]. After 6 months of LHRH (n = 919), 311 men had significant hot flushes and were randomised to one of the treatments. Based on median daily hot-flush score, venlafaxine was inferior -47.2% (interquartile range -74.3 to -2.5) compared to -94.5% (-100.0 to -74.5) in the cyproterone group, and -83.7% (-98.9 to -64.3) in the medroxyprogesterone group.

With a placebo effect influencing up to 30% of patients [1394], the efficacy of clonidine, verapilride,
gabapentine [1395] and acupuncture [1396] need to be compared in prospective RCTs.

8.2.4.3 Non-metastatic bone fractures

Due to increased bone turnover and decreased bone mineral density (BMD) in a time-dependent manner, ADT use is linked to an increased risk of fracture (up to 45% RR with long-term ADT) [1397]. Severe fractures in men are associated with a significant risk of death [1398]. A precise evaluation of BMD should be performed by DEXA, ideally before or shortly after starting long-term ADT. An initial low BMD (T-score < -2.5 or < -1, with other risk factors) indicates a high risk of subsequent non-metastatic fracture and causes should be investigated. Other risk factors include increasing age, body mass index of 19 or less, history of previous fracture or parent with fractured hip, current smoking, use of glucocorticoids, rheumatoid arthritis, alcohol consumption > 2 units per day, history of falls and a number of other chronic medical conditions [1399]. Fracture risk algorithms which combine BMD and clinical risk factors such as FRAX score can be used to guide treatment decisions but uncertainty exists regarding the optimal intervention threshold, therefore no specific risk algorithm can be recommended for men on ADT for PCa. Obesity (increase in body fat mass by up to 10% and/or body mass index > 30) and sarcopenia (decrease in lean tissue mass by up to 3%) as well as weight loss are common and occur during the first year of ADT [1400]. These changes increase the fracture risk [1401]. Bicalutamide monotherapy may have less impact on BMD but is limited by its suboptimal efficacy [1402, 1403] (see Section 6.1.4.1.5.2.3). The intermittent LHRH-agonist modality might be associated with less bone impact [1404].

8.2.4.4 Metabolic effects

Lipid alterations are common and may occur as early as the first 3 months of treatment [1400]. Androgen deprivation therapy also decreases insulin sensitivity and increases fasting plasma insulin levels, which is a marker of insulin resistance. In diabetic patients, metformin appears to be an attractive option for protection against metabolic effects based on retrospective analysis [1405], but there is insufficient data to recommend its use in non-diabetic patients.

Metabolic syndrome is an association of independent cardiovascular disease risk factors, often associated with insulin resistance. The definition requires at least three of the following criteria [1406]:

- waist circumference > 102 cm;
- serum triglyceride > 1.7 mmol/L;
- blood pressure > 130/80 mmHg or use of medication for hypertension;
- high-density lipoprotein (HDL) cholesterol < 1 mmol/L;
- glycaemia > 5.6 mmol/L or the use of medication for hyperglycaemia.

The prevalence of a metabolic-like syndrome is higher during ADT compared with men not receiving ADT [1407]. Skeletal muscle mass heavily influences basal metabolic rate and is in turn heavily influenced by endocrine pathways [1408]. Androgen deprivation therapy-induced hypogonadism results in negative effects on skeletal muscle health. A prospective longitudinal study involving 252 men on ADT for a median of 20.4 months reported lean body mass decreases progressively over 3 years; 1.0% at one year, 2.1% at 2 years, and 2.4% at 3 years which appears more pronounced in men at ≥ 70 years of age [1409].

8.2.4.5 Cardiovascular morbidity

Cardiovascular mortality is a common cause of death in PCa patients [1140, 1410, 1411]. Several studies showed that ADT after only 6 months was associated with an increased risk of diabetes mellitus, cardiovascular disease, and myocardial infarction [1412]. The RTOG 92-02 [1413] and 94-08 [1414] trials confirmed an increased cardiovascular risk, unrelated to the duration of ADT and not accompanied by an overall increased cardiovascular mortality. No increase in cardiovascular mortality has been reported in a systematic meta-analysis of trials RTOG 8531, 8610, 9202, EORTC 30891 and EORTC 22863 [1415]. However, serious concerns about the conclusions of this meta-analysis have been raised due to poor consideration of bias in the included studies [1416, 1417]. A meta-analysis of observational data reports consistent links between ADT and the risk of cardiovascular disease patients treated for PCa, e.g. the associations between GnRH agonists and nonfatal or fatal myocardial infarction or stroke RR: 1.57 (95% CI: 1.26–1.94) and RR: 1.51 (95% CI: 1.24–1.84), respectively [1418]. An increase in cardiovascular mortality has been reported in patients suffering from previous congestive heart failure or myocardial infarction in a retrospective database analysis [1419] or presenting with a metabolic syndrome [1420]. It has been suggested that antagonists might be associated with less cardiovascular morbidity compared to agonists, but, as yet, there is no definite evidence [1340]. In a phase III RCT the use of relugolix, an oral LHRH antagonist, was associated with a reduced risk of major adverse cardiovascular events when compared to leuprolide, an injectable LHRH agonists, at 2.9% vs.
6.2%, respectively, over a follow-up time of 48 weeks (HR 0.46, 95% CI: 0.24–0.88 [795]).

These concerns about LHRH agonists resulted in an FDA warning and consensus paper from the American Heart, Cancer Society and Urological Associations [1139]. Preventive advice includes non-specific measures such as loss of weight, increased exercise, minimising alcohol intake, improved nutrition and smoking cessation [71, 1421].

8.2.4.6 Fatigue
Fatigue often develops as a side-effect of ADT. Regular exercise appears to be the best protective measure. Reporting clinically significant fatigue is associated with severe psychological distress and should prompt screening for anxiety and/or depression [1422]. Anaemia may be a cause of fatigue [1391, 1423]. Anaemia requires an aetiological diagnosis (medullar invasion, renal insufficiency, iron deficiency, chronic bleeding) and individualised treatment. Iron supplementation (using injectable formulations only) must be systematic if deficiency is observed. Regular blood transfusions may be required in patients with severe anaemia. Erythropoiesis-stimulating agents might be considered in dedicated cases, taking into account the possible increased risk of thrombovascular events [1424].

8.2.4.7 Neurological side effects
Castration seems also to be associated with an increased risk of stroke [1425], and is suspected to be associated with an increased risk for depression and cognitive decline such as Alzheimer disease [1426].

8.3 Overall quality of life in men with PCa
Living longer with PCa does not necessarily equate to living well [1362, 1363]. There is clear evidence of unmet needs and ongoing support requirements for some individuals after diagnosis and treatment for PCa [1427]. Cancer impacts on the wider family and cognitive behavioural therapy can help reduce depression, anxiety and stress in caregivers [1428]. Radical treatment for PCa can negatively impact long-term QoL (e.g., sexual, urinary and bowel dysfunction) as can ADT used in short- or long-term treatment, e.g., sexual problems, fatigue, psychological morbidity, adverse metabolic sequelae and increased cardiovascular and bone fracture risk [1382, 1429]. Direct symptoms from advanced or metastatic cancer, e.g., pain, hypercalcaemia, spinal cord compression and pathological fractures, also adversely affect health [1430, 1431]. Patients’ QoL including domains such as sexual function, urinary function and bowel function is worse after treatment for PCa compared to non-cancer controls [1432, 1433].

The concept of ‘quality of life’ is subjective and can mean different things to different people, but there are some generally common features across virtually all patients. Drawing from these common features, specific tools or ‘patient-reported outcome measures’ (PROMs) have been developed and validated for men with PCa. These questionnaires assess common issues after PCa diagnosis and treatment and generate scores which reflect the impact on perceptions of HRQoL. During the process of undertaking two dedicated systematic reviews around cancer-specific QoL outcomes in patients with PCa as the foundation for our guideline recommendations, the following validated PROMs were found in our searches (see Table 8.3.1).

The tools with the best evidence for psychometric properties and feasibility for use in routine practice and research settings to assess PROMs in patients with localised PCa were EORTC QLQ-C30 and QLQ-PR25. Since EORTC QLQ-C30 is a general module that does not directly assess PCa-specific issues, it should be adopted in conjunction with the QLQ-PR25 module [1434].

8.3.1 Long-term (> 12 months) quality of life outcomes in men with localised disease

8.3.1.1 Men undergoing local treatments

The results of the ProtecT trial (n = 1,643 men) reported no difference in EORTC QLQ-C30 assessed global QoL, up to 5 years of follow-up in men aged 50–69 years with T1–T2 disease randomised for treatment with AM, RP or RT with 6 months of ADT [1378]. However, EPIC urinary summary scores (at 6 years) were worse in men treated with RP compared to AM or RT (88.7 vs. 89.0 vs. 91.4, respectively) as were urinary incontinence (80.9 vs. 85.8 vs. 89.4, respectively) and sexual summary, function and bother scores (32.3 vs. 40.6 vs. 41.3 for sexual summary, 23.7 vs. 32.5 vs. 32.7 for sexual function and 51.4 vs. 57.9 vs. 60.1 for sexual bother, respectively) at 6 years of follow-up. Minimal clinically important differences for the 50 item EPIC questionnaire are not available. For men receiving RT with 6 months of ADT, EPIC bowel scores were poorer compared to AM and RP in all domains: function (90.8 vs. 92.3 vs. 92.3, respectively), bother (91.7 vs. 94.2 vs. 93.7, respectively) and summary (91.2 vs. 93.2 vs. 93.0, respectively) at 6 years of follow-up in the ProtecT trial.

The findings regarding RP and RT are supported by other observational studies [1370, 1444]. The Prostate Cancer Outcomes Study (PCOS) studied a cohort of 1,655 men, of whom 1,164 had undergone RP and 491 RT [1370]. The study reported that at 5 years of follow-up, men who underwent RP had a higher prevalence of urinary incontinence and ED, while men treated with RT had a higher prevalence of bowel dysfunction. However, despite these differences detected at 5 years, there were no significant differences in the adjusted odds of urinary incontinence, bowel dysfunction or ED between RP and RT at 15 years. More recently, investigators reported that although EBRT was associated with a negative effect in bowel function, the difference in bowel domain score was below the threshold for clinical significance 12 months after treatment [1379]. As 81% of patients in the EBRT arm of the study received IMRT, these data suggest that the risk of side effects is reduced with IMRT compared to older 3D-CRT techniques. This is supported by a contemporary 5-year prospective, population-based cohort study where PROMs were compared in men with favourable- and unfavourable-risk localised disease [1444]. In the 1,386 men with favourable risk, comparison between AS and nerve-sparing prostatectomy, EBRT or LDR brachytherapy demonstrates that surgery is associated with worse urinary incontinence at 5 years and sexual dysfunction at 3 years when compared to AS. External beam RT is associated with changes not clinically different from AS, and LDR brachytherapy is associated with worse irritative urinary-, bowel- and sexual symptoms at one year. In 619 men with unfavourable-risk disease, comparison between non-nerve sparing RP and EBRT with ADT demonstrates that surgery is associated with worse urinary incontinence and sexual function through 5 years.

With respect to brachytherapy cancer-specific QoL outcomes, one small RCT (n = 200) evaluated bilateral nerve-sparing RP and brachytherapy in men with localised disease (up to T2a), which reported worsening of physical functioning as well as irritative urinary symptomatology in 20% of brachytherapy patients at one year of follow-up. However, there were no significant differences in EORTC QLQ-C30/PR-25 scores at 5 years of follow-up when compared to pre-treatment values [1445]. It should be noted of this trial, within group tests only were reported. In a subsequent study by the same group comparing bilateral nerve-sparing RARP and brachytherapy (n = 165), improved continence was noted with brachytherapy in the first 6 months but lower potency rates up to 2 years [1446]. These data and a synthesis of 18 randomised and non-randomised studies in a systematic review involving 13,604 patients are the foundation of the following recommendations [1447].
8.3.1.2 Guidelines for quality of life in men undergoing local treatments

**Recommendations**

8.3.2 Improving quality of life in men who have been diagnosed with PCa

8.3.2.1 Men undergoing local treatments

In men with localised disease, nurse-led multi-disciplinary rehabilitation (addressing sexual functioning, cancer worry, relationship issues, depression, managing bowel and urinary function problems) provided positive short-term effects (4 months) on sexual function (effect size 0.45) and long-term (12 months) positive effects on sexual limitation (effect size 0.5) and cancer worry (effect size 0.51) [1448].

Exercise programs during RT combined with ADT result in consistent benefits for cardiovascular fitness (standardised mean difference [SMD], 0.83; 95% CI: 0.31–1.36; p < 0.01) and muscle function (SMD, 1.30; 95% CI: 0.53–2.07; p < 0.01) with a reduction in urinary toxicity (SMD, -0.71; 95% CI: -1.25 to -0.18; p < 0.01) [1449].

Evidence of moderate quality shows that supervised exercise therapy probably is superior to no exercise therapy in improving ‘disease-specific quality of life’ and ‘walking performance’ in patients with PCa undergoing ADT. The results apply to all patients receiving ADT regardless of cancer stage [1450].

In men with post-surgical urinary incontinence, conservative management options include pelvic floor muscle training with or without biofeedback, electrical stimulation, extra-corporeal magnetic innervation (ExMi), compression devices (penile clamps), lifestyle changes, or a combination of methods. Uncertainty around the effectiveness and value of these conservative interventions remains [1451]. Surgical interventions including sling and artificial urinary sphincter significantly decrease the number of pads used per day and increase the QoL compared with before intervention. The overall cure rate is around 60% and results in improvement in incontinence by about 25% [1452].

The use of PDE5 inhibitors in penile rehabilitation has been subject to some debate. A single centre, double blind RCT of 100 men undergoing nerve-sparing surgery reported no benefit of nightly sildenafil (50 mg) compared to on-demand use [1453]. However, a multi-centre double blind RCT (n = 423) in men aged < 68 years, with normal pre-treatment erectile function undergoing either open, conventional or robot-assisted laparoscopic nerve-sparing RP, tadalafl (5 mg) once per day improved participants EPIC sexual domain-scores (least squares mean difference +9.6, 95% CI: 3.1–16.0) when compared to 20 mg ‘on demand’ or placebo at 9 months of follow-up [678]. Therefore, based on discordant results, no clear recommendation is possible, even if a trend exists for early use of PDE5 inhibitors after RP for penile rehabilitation [1454]. A detailed discussion can be found in the EAU Sexual and Reproductive Health Guidelines [1455].

8.3.2.2 Men undergoing systemic treatments

Similar to men treated with a radical approach (see above), in men with T1-T3 disease undergoing RT and ADT, a combined nurse-led psychological support and physiotherapist-led multi-disciplinary rehabilitation has reported improvements in QoL. Specifically this intervention involved action planning around patients’ needs related to lifestyle changes, weight control, toilet habits, sexuality, and psychological problems. This was complemented with pelvic floor muscle therapy. Improvements in urinary (adjusted mean 4.5, 95% CI: 0.6–8.4), irritative (adjusted mean 5.8, 95% CI: 1.4–10.3) and hormonal (adjusted mean 4.8, 95% CI: 0.8–8.8) EPIC domains were found up to 22 weeks of follow-up [1456]. In a 3-year follow-up with 92% response rate from the initial study, fewer participants had moderate-severe bowel problems in the intervention (n = 2; 3%) vs. control group (n = 10; 14%) (p = 0.016) but the benefits in terms of urinary function were maintained only in those participants with moderate-severe urinary problems at baseline [1457].

Providing supervised aerobic and resistance exercise training of a moderate intensity improves EORTC QLQ-C30 role (adjusted mean 15.8, 95% CI: 6.6–24.9) and cognitive domain outcomes (adjusted mean 11.4, 95% CI: 3.3–19.6) as well as symptom scales for fatigue (adjusted mean 11.0, 95% CI: 20.2–1.7), nausea (adjusted mean 4.0, 95% CI: 7.4–0.25), and dyspnoea (adjusted mean 12.4, 95% CI: 22.5–2.3) up to 3 months in men treated with ADT [1458]. Such interventions have also reported clinically relevant improvements in FACT-P (mean difference 8.9, 95% CI: 3.7–14.2) in men on long-term ADT [1459, 1460]. These findings are supported by a systematic review which reported improvements up to 12 weeks in cancer-specific
QoL in a meta-analysis of high quality trials (SMD 0.33, 95%, CI: 0.08–0.58) [1423]. Supervised exercise interventions delivered over 12 months are effective in reducing psychological distress; particularly in those men with highest levels of baseline anxiety and depression [1461]. In untrained older men, systematic review suggests lower volume exercise programs at moderate-to-high intensity are as effective as higher volume resistance training for enhancing body composition, functional capacity and muscle strength and may reduce barriers to exercise and enhance adherence [1462].

If dietary intake is not adequate, vitamin D and calcium supplementation should be offered, as there is evidence that vitamin D and calcium have modest effects on bone in men on ADT [1463]. Online tools are available to calculate daily calcium intake for individual patients. For vitamin D deficiency a dose of at least 800 IU/day colecalciferol can be recommended. Use of a 25(OH) assay may be helpful to measure vitamin D levels [1464, 1465].

Anti-resorptive therapy is recommended for men on ADT for > 6 months with either a BMD T score of < -2.5 or with an additional risk factor for osteoporosis or annual bone loss confirmed to exceed 5%, or in cases of severe fracture. Referral to a bone specialist should be considered in complex cases with severe fracture and/or multiple risk factors. Alendronate, risedronate, zoledronate and denosumab have all been shown to prevent bone loss in men with hormone-sensitive locally-advanced and metastatic PCAs on ADT [1466-1469]. Patients should be warned about the < 5% risk of osteonecrosis of the jaw and/ or atypical femoral fractures associated with these drugs. Bisphosphonates increase BMD in the hip and spine by up to 7% in one year [1468, 1470]. The optimal regimen for zoledronic acid for men on ADT with hormone-sensitive locally-advanced and metastatic PCAs remains unclear: quarterly [1471] or yearly [1472] injections. The question is relevant as the risk of jaw necrosis is both dose- and time-related [1473]. A quarterly regimen should be considered for a BMD ≤ 2.5 as a yearly injection is unlikely to provide sufficient protection [1474, 1475]. Care should be taken when discontinuing treatment as rebound increased bone resorption can occur.

In M0 patients, denosumab has been shown to increase the lumbar BMD by 5.6% compared to a 1% decrease in the placebo arm after 2 years, using a 60 mg subcutaneous regimen every 6 months [1476]. This was associated with a significant decrease in vertebral fracture risk (1.5% vs. 3.9%, p = 0.006). The benefits were similar whatever the age (< or > 70 years), the duration or type of ADT, the initial BMD, the patient’s weight or the initial BMI. This benefit was not associated with any significant toxicity, e.g. jaw osteonecrosis or delayed healing in vertebral fractures. In M0 patients, with the use of a higher dosage (120 mg every 4 weeks), a delay in bone metastases of 4.2 months has been shown [1298] without any impact on OS, but with an increase in side effects. Therefore, this later regimen cannot be recommended.

### 8.3.2.3 Decision regret

Several treatments with curative intent for localised PCAs are available all with comparable 10-year OS [516]. They vary in terms of the incidence of major side effects, including urinary symptoms, bowel symptoms and compromised sexual functioning [1378, 1379, 1477]. For this reason, patients’ treatment preferences, in which they weigh expected benefits against likely side effects, are a central consideration in shared decision-making and in making informed treatment decisions [1478-1480].

It remains challenging, however, to evaluate whether the decision-making process can be viewed as successful; that is, whether the choice of treatment best reflects the patient’s preferences and expectations [1481, 1482]. According to Decision Justification Theory (DJT), it is the more specific information on which treatment experiences lead to regret that decision regret needs to be better understood and to minimise it in future patients [1483]. Maguire et al., found that about 25% of men with PCAs undergoing either single or combined modality treatments report experiencing worse side effects than expected [1484]. Schroeck et al., found urinary incontinence most strongly correlated with regret after prostatectomy [1485].

Unmet expectations are comparable among the treatment groups, except for fatigue. Fatigue is less frequently reported as worse than expected by patients who received BT when compared to patients who received RP or EBRT. This could be explained by the less invasive treatment course of BT in comparison to EBRT with or without ADT and RP [1486]. Unmet expectations were more frequently reported by patients with positive surgical margins following surgery; having had a passive role in the decision-making process; and who had higher scores on the decisional conflict scale (i.e. more uncertainty about the treatment decision). Interestingly, positive surgical margins are not directly associated with an increased risk of PC-related mortality [1064]. Active participation and support in the process of forming a preference increases the chance of choosing a treatment that is in line with patients’ expectations [1480, 1487-1489].

While it may seem desirable to tailor the patients’ role in decision-making to their initial preference, and particularly to a preference for deferring to the advice of the clinician, this does not result in less decisional conflict or regret. Increasing patients knowledge regardless of initial preference may actually be preferable [1485].
8.3.2.4 Decision aids in prostate cancer

Shared decision-making can increase patients’ comfort when confronted with management decisions but has been shown to improve health outcome [1490] and more training seems needed for health care professionals guiding patients [1491]. Patient education decreased PSA testing [1492] and increased adherence to active surveillance protocols [1493, 1494]. Autonomous active decision-making by patients was associated with less regret after prostatectomy regardless of the method chosen and decision aids reduce decisional conflict [1495]. Still, guidance is needed to optimise patients’ understanding of the options [1496]. Patients prioritised effectiveness and pain control over mode of administration and risk of fatigue when confronted with treatment choice in metastasised PCa [1497]. When implementing decision aids clinical validity and utility should be carefully evaluated and distinguished [1498]. A decision aid should educate as well as promote shared decision-making to optimise efficacy [1499] and pay attention to communicative aspects [1500].

8.3.2.5 Guidelines for quality of life in men undergoing systemic treatments

1. INTRODUCTION

1.1 Aims and scope
The European Association of Urology (EAU) Renal Cell Cancer (RCC) Guidelines Panel has compiled these clinical guidelines to provide urologists with evidence-based information and recommendations for the management of RCC.

It must be emphasised that clinical guidelines present the best evidence available to the experts but following guideline recommendations will not necessarily result in the best outcome. Guidelines can never replace clinical expertise and judgement when making treatment decisions for individual patients, but rather help to focus decisions whilst also taking personal values and preferences/individual circumstances of patients into account. Guidelines are not mandates and do not purport to be a legal standard of care.

1.2 Panel composition
The RCC Guidelines Panel is an international group of clinicians consisting of urological surgeons, oncologists, methodologists, a pathologist and a radiologist, with particular expertise in the field of renal cancer care. Since 2015, the Panel has incorporated a patient advocate to provide a consumer perspective for its guidelines. All experts involved in the production of this document have submitted potential conflict of interest statements, which can be viewed on the EAU website Uroweb: http://uroweb.org/guideline/renal-cell-carcinoma/.

1.3 Acknowledgement
The RCC Guidelines Panel is most grateful for the continued methodological and scientific support provided by Prof. Dr. O. Hes (pathologist, Pilsen, Czech Republic) for two sections of this document: Histological diagnosis and Other renal tumours.

1.4 Available publications
A quick reference document (Pocket Guidelines) is available, both in print and as an app for iOS and Android devices, presenting the main findings of the RCC Guidelines. These are abridged versions which may require consultation together with the full text version. Several scientific publications are available, as are a number of translations of all versions of the EAU RCC Guidelines [1]. All documents can be accessed on the EAU website: http://uroweb.org/guideline/renal-cell-carcinoma/.

1.5 Publication history and summary of changes
1.5.1 Publication history
The EAU RCC Guidelines were first published in 2000. This 2022 RCC Guidelines document presents a substantial update of the 2021 publication.

1.5.2 Summary of changes
All chapters of the 2022 RCC Guidelines have been updated, based on the 2021 version of the Guidelines. References have been added throughout the document.

New data have been included in the following sections, resulting in changed evidence summaries and recommendations in:

5.4 Summary of evidence and recommendations for the diagnostic assessment of RCC

2. METHODS

2.1 Data identification

For the 2022 Guidelines, new and relevant evidence has been identified, collated and appraised through a structured assessment of the literature for the chapters as listed in Table 2.1.

A broad and comprehensive scoping search was performed, which was limited to studies representing high certainty of evidence (i.e., systematic reviews with or without meta-analysis, randomised controlled trials (RCTs), and prospective non-randomised comparative studies only for therapeutic interventions, and systematic reviews and prospective studies with well-defined reference standards for diagnostic accuracy studies) published in the English language. In case no higher level data exists for a particular topic, lower level evidence is considered for inclusion. The search was restricted to articles published between June 25th, 2020 and May 28th, 2021. Databases covered included Medline, EMBASE, and the Cochrane Library. After de-duplication, a total of 2,644 unique records were identified, retrieved and screened for relevance.

A total of 71 new references have been included in the 2022 RCC Guidelines publication. A search strategy is published online: https://uroweb.org/guideline/renal-cell-carcinoma/?type=appendices-publications.

For each recommendation within the guidelines there is an accompanying online strength rating form, the basis of which is a modified GRADE methodology [2]. Each strength rating form addresses a number of key elements, namely:

1. the overall quality of the evidence which exists for the recommendation; references used in this text are graded according to a classification system modified from the Oxford Centre for Evidence-Based Medicine Levels of Evidence [3];
2. the magnitude of the effect (individual or combined effects);
3. the certainty of the results (precision, consistency, heterogeneity and other statistical or study-related factors);
4. the balance between desirable and undesirable outcomes;
5. the impact of patient values and preferences on the intervention;
6. the certainty of those patient values and preferences.

These key elements are the basis which panels use to define the strength rating of each recommendation.

The strength of each recommendation is represented by the words ‘strong’ or ‘weak’ [4]. The strength of each recommendation is determined by the balance between desirable and undesirable consequences of alternative management strategies, the quality of the evidence (including certainty of estimates), and nature and variability of patient values and preferences. The strength rating forms will be available online.

Specific chapters were updated by way of systematic reviews, commissioned and undertaken by the Panel, based on prioritised topics or questions. These reviews were performed using standard Cochrane systematic review methodology: http://www.cochranelibrary.com/about/aboutcochrane-systematic-reviews.html.

<tr>
<td>8. Follow-up in RCC &amp; Surveillance following radical or partial nephrectomy or ablative therapies</td>
<td>This chapter was updated by a narrative review, based on a structured literature assessment. The findings of a prospective database set up by the RCC Panel have been included [10, 12].</td>
</tr>
</tbody>
</table>

Additional methodology information can be found in the general Methodology section of this print, and online at the EAU website: http://uroweb.org/guidelines/. A list of Associations endorsing the EAU Guidelines can also be viewed online at the above address.
2.2 Review
All publications ensuing from systematic reviews have been peer reviewed. The 2021 print of the RCC Guidelines was peer-reviewed prior to publication.

2.3 Future goals
The RCC Guideline Panel supports the focus on patient-reported outcomes as well as the development of clinical quality indicators. A number of key quality indicators for this patient group have been selected:

- the proportion of patients undergoing thorax computed tomography (CT) for staging of pulmonary metastasis;
- proportion of patients with T1aN0M0 tumours undergoing nephron-sparing surgery (NSS) as first treatment;
- the proportion of patients with metastatic RCC (mRCC) offered systemic therapy;
- the proportion of patients who undergo minimally invasive or operative treatment as first treatment who die within 30 days.

The Panel have set up a database to investigate current practice in follow-up of RCC patients in a number of European centres. Assessing patterns of recurrence and use of imaging techniques are primary outcomes for this project.

The results of ongoing and new systematic reviews will be included in future updates of the RCC Guidelines:

- What is the best treatment option for ≥ T2 tumours?
- Adjuvant targeted therapy for renal cell carcinoma at high risk for recurrence;
- Systematic review of prevalence of intraperitoneal recurrences following robotic/laparoscopic partial nephrectomy;
- Systematic review of individual, unit and hospital surgical volume for radical and partial nephrectomy and their impact on outcomes;
- RECUR database analysis of recurrent disease/follow-up.

3. EPIDEMIOLOGY, AETIOLOGY AND PATHOLOGY

3.1 Epidemiology
Renal cell carcinoma represents around 3% of all cancers, with the highest incidence occurring in Western countries [13, 14]. In Europe, and worldwide, the highest incidence rates are found in the Czech Republic and Lithuania [14]. Generally, during the last two decades until recently, there has been an annual increase of about 2% in incidence both worldwide and in Europe leading to approximately 99,200 new RCC cases and 39,100 kidney cancer-related deaths within the European Union in 2018 [13, 14]. In Europe, overall mortality rates for RCC increased until the early 1990s, with rates generally stabilising or declining thereafter [15]. There has been a decrease in mortality since the 1980s in Scandinavian countries and since the early 1990s in France, Germany, Austria, the Netherlands, and Italy. However, in some European countries (Croatia, Estonia, Greece, Ireland, Slovakia), mortality rates still show an upward trend [13, 14].

Renal cell carcinoma is the most common solid lesion within the kidney and accounts for approximately 90% of all kidney malignancies. It comprises different RCC subtypes with specific histopathological and genetic characteristics [16]. There is a 1.5:1 predominance in men over women with a higher incidence in the older population [14, 17].

3.2 Aetiology
Established risk factors include lifestyle factors such as (hazard ratio [HR]: 1.23-1.58), obesity (HR 1.71), BMI (> 35 vs. < 25), and hypertension (HR: 1.70) [14, 17]. 50.2% of patients with RCC are current or former smokers. By histology, the proportions of current or former smokers range from 38% in patients with chromophobe carcinoma to 61.9% in those with collecting duct/medullary carcinoma [18]. In a recent systematic review diabetes was also found to be detrimental [19]. Having a first-degree relative with kidney cancer is also associated with an increased risk of RCC. Moderate alcohol consumption appears to have a protective effect for reasons as yet unknown, while any physical activity level also seems to have a small protective effect [14, 19-23]. A number of other factors have been suggested to be associated with higher or lower risk of RCC, including specific dietary habits and occupational exposure to specific carcinogens, but the literature is inconclusive [17]. The most effective prophylaxis is to avoid cigarette smoking and reduce obesity [14, 17].

3.3 Histological diagnosis
Renal cell carcinomas comprise a broad spectrum of histopathological entities described in the 2016 World Health Organization (WHO) classification [16]. There are three main RCC types: clear cell (ccRCC), papillary (pRCC type I and II) and chromophobe (chRCC). The RCC type classification has been confirmed by cytogenetic and genetic analyses [16, 24] (LE: 2b). Collecting duct carcinoma and other rare renal tumours are discussed in Section 3.3.

Histological diagnosis includes, besides RCC type; evaluation of nuclear grade, sarcomatoid features, vascular invasion, tumour necrosis, and invasion of the collecting system and peri-renal fat, pT, or even pN categories. The four-tiered WHO/ISUP (International Society of Urological Pathology) grading system has replaced the Fuhrman grading system [16].

3.3.1 Clear-cell RCC
Overall, clear-cell RCC (ccRCC) is well circumscribed and a capsule is usually absent. The cut surface is golden-yellow, often with haemorrhage and necrosis. Loss of chromosome 3p and mutation of the von Hippel-Lindau (VHL) gene at chromosome 3p25 are frequently found. The loss of von Hippel-Lindau protein function contributes to tumour initiation, progression, and metastases. The 3p locus harbours at least four additional ccRCC tumour suppressor genes (UTX, JARID1C, SETD2, PBRM1) [24]. In general, ccRCC has a worse prognosis compared to pRCC and chRCC, but this difference disappears after adjustment for stage and grade [25, 26]. For details about prognosis, see Section 6.3 – Histological factors.

3.3.2 Papillary RCC
Papillary RCC is the second most commonly encountered morphotype of RCC. Papillary RCC has traditionally been subdivided into two types [16]. Type I and II pRCC, which were shown to be clinically and biologically distinct; pRCC type I is associated with activating germline mutations of MET and pRCC type II is associated with activation of the NRF2-ARE pathway and at least three subtypes [27]. Type II pRCC presents a heterogeneous group of tumours and future substratification is expected, e.g., oncocytic pRCC [16].

A typical histology of pRCC type I (narrow papillae without any binding, and only microcapillaries in papillae) explains its typical clinical signs. Narrow papillae without any binding and a tough pseudocapsule explain the ideal rounded shape (Pascal's law) and fragility (specimens have a “minced meat” structure). Tumour growth causes necrotisation of papillae, which is a source of hypodense proteins that cause subsequent “growth” of the tumour, fluid inside the tumour, and only a serpiginous, contrast-enhancing margin. Stagnation in the microcapillaries explain the minimal post-contrast attenuation on CT. Papillary RCC type 1 can imitate a pathologically changed cyst (Bosniak IIF or III). The typical signs of pRCC type 1 are as follows: an ochre colour, more frequently exophytic, extrarenal growth, low grade, and low malignant potential; over 75% of these tumours can be treated by NSS surgery. A substantial risk of renal tumour biopsy tract seeding exists (12.5%), probably due to the fragility of the tumour papillae [28]. Papillary RCC type I is more common and generally considered to have a better prognosis than pRCC type II [16, 26, 29].

3.3.3 Chromophobe RCC
Overall, chRCC is a pale tan, relatively homogenous and tough, well-demarcated mass without a capsule. Chromophobe RCC cannot be graded by the Fuhrman grading system because of its innate nuclear atypia. An alternative grading system has been proposed, but has yet to be validated [16]. Loss of chromosomes Y, 1, 2, 6, 10, 13, 17 and 21 are typical genetic changes [16]. The prognosis is relatively good, with high five-year recurrence-free survival (RFS), and ten-year cancer-specific survival (CSS) [30]. The five- and ten-year recurrence-free survival rates were 94.3% and 89.2%, respectively. Recurrent disease developed in 5.7% of patients, and 76.5% presented with distant metastases with 54% of metastatic disease diagnoses involving a single organ, most commonly bone. Recurrence and death after surgically resected chRCC is rare. For completely excised lesions ≤ pT2a without coagulative necrosis or sarcomatoid features, prognosis is excellent [31]. The new WHO/ISUP grading system merges former entity ‘hybrid oncocytic chromophobe tumour’ with chRCC.
3.4 Other renal tumours

Other renal tumours constitute the remaining renal cortical tumours. These include a variety of uncommon, sporadic, and familial carcinomas, some only recently described, as well as a group of unclassified carcinomas. A summary of these tumours is provided in Table 3.1, but some clinically relevant tumours and extremely rare entities are mentioned below.

3.4.1 Renal medullary carcinoma
Renal medullary carcinoma (RMC) is a very rare tumour, comprising < 0.5% of all RCCs [32], predominantly diagnosed in young adults (median age 28 years) with sickle haemoglobinopathies (including sickle cell trait). It is mainly centrally located with ill-defined borders. Renal medullary carcinoma is one of the most aggressive RCCs [33, 34] and most patients (~67%) will present with metastatic disease [33, 35]. Even patients who present with seemingly localised disease may develop macrometastases shortly thereafter, often within a few weeks (for treatment see chapter 7).

3.4.2 Carcinoma associated with end-stage renal disease; acquired cystic disease-associated RCC
Cystic degenerative changes (acquired cystic kidney disease [ACKD]) and a higher incidence of RCC, are typical features of end-stage renal disease (ESRD). Renal cell carcinomas of native end-stage kidneys are found in approximately 4% of patients. Their lifetime risk of developing RCCs is at least ten times higher than in the general population. Compared with sporadic RCCs, RCCs associated with ESRD are generally multicentric and bilateral, found in younger patients (mostly male), and are less aggressive. Whether the relatively indolent outcome of tumours in ESRD is due to the mode of diagnosis or a specific ACKD-related molecular pathway still has to be determined. Although the histological spectrum of ESRD tumours is similar to that of sporadic RCC; pRCC occur relatively more frequently [36, 37]. A specific subtype of RCC occurring only in end-stage kidneys has been described as Acquired Cystic Disease-associated RCC (ACD-RCC) with indolent clinical behaviour, likely due to early detection in patients with ESRD on periodic follow-up [16, 24, 38].

3.4.3 Papillary adenoma
These tumours have a papillary or tubular architecture of low nuclear grade and may be up to 15 mm in diameter, or smaller [39], according to the WHO 2016 classification [16].

3.4.4 Hereditary kidney tumours
Five to eight percent of RCCs are hereditary; to date there are ten hereditary RCC syndromes associated with specific germline mutations, RCC histology, and comorbidities. Hereditary RCC syndromes are often suggested by family history, age of onset and presence of other lesions typical for the respective syndromes. Median age for hereditary RCC is 37 years; 70% of hereditary RCC tumours are found in the lowest decile (46 years old) of all RCC tumours [40]. Hereditary kidney tumours are found in the following entities: VHL syndrome, hereditary pRCC, Birt-Hogg-Dube syndrome, hereditary leiomyomatosis and RCC (HLRCC), tuberous sclerosis, germline succinate dehydrogenase (SDH) mutation, non-polypsis colorectal cancer syndrome, hyperparathyroidism-jaw tumour syndrome, phosphatase and tensin homolog (PTEN) hamartoma syndrome (PHTS), constitutional chromosome 3 translocation, familial non-syndromic ccRCC and BAP1 associated RCC [41]. Renal medullary carcinoma can be included because of its association with hereditary haemoglobinopathies [39, 42–44].

Patients with hereditary kidney cancer syndromes may require repeated surgical intervention [45, 46]. In most hereditary RCCs nephron-sparing approaches are recommended. The exceptions are HLRCC and SDH syndromes for which immediate surgical intervention is recommended due to the aggressive nature of this lesion. For other hereditary syndromes such as VHL, surveillance is recommended until the largest tumour reaches 3 cm in diameter, to reduce interventions [47]. Active surveillance (AS) for VHL, SDH and HLRCC should, in individual patients, follow the growth kinetics, size and location of the tumours, rather than apply a standardised follow-up interval. Regular screening for both renal and extra-renal lesions should follow international guidelines for these syndromes. Multidisciplinary and co-ordinated care should be offered, where appropriate [48]. In HLRCC, renal screening in relatives detects early-stage RCCs [49], with HLRCC RCCs appearing to have unique molecular profiles.

Although not hereditary, somatic fusion translocations of TFE3 and TFEB may affect 15% of patients with RCC younger than 45 years and 20–45% of children and young adults diagnosed with RCC [50].

A recent phase II trial demonstrated clinical activity of an oral HIF-2α (hypoxia-inducible factor) inhibitor MK-6482 in VHL patients [51]. Additional information on treatment of VHL can be found in Section 7.4.4.
3.4.5 **Angiomyolipoma**

Angiomyolipoma (AML) is a benign mesenchymal tumour, which can occur sporadically or as part of tuberous sclerosis complex [52]. Overall prevalence is 0.44%, with 0.6% in female and 0.3% in male populations. Only 5% of these patients present with multiple AMLs [53]. Angiomyolipoma belongs to a family of so-called PEComas (perivascular epithelioid cell tumours), characterised by the proliferation of perivascular epithelioid cells. Some PEComas can behave aggressively and can even produce distant metastases. Classic AMLs are completely benign [16, 39, 54]. Ultrasound (US), CT, and magnetic resonance imaging (MRI) often lead to the diagnosis of AMLs due to the presence of adipose tissue; however, in fat-poor AML, diagnostic imaging cannot reliably identify these lesions. Percutaneous biopsy is rarely useful. Renal tumours that cannot be clearly identified as benign during the initial diagnostic work-up should be treated according to the recommendations provided for the treatment of RCC in these Guidelines. In tuberous sclerosis, AML can be found in enlarged lymph nodes (LN), which does not represent metastatic spread but a multicentric spread of AMLs. In rare cases, an extension of a non-malignant thrombus into the renal vein or inferior vena cava can be found, associated with an angiographically-type growth of AML. Epithelioid AML, a very rare variant of AML, consists of at least 80% epithelioid cells [39, 54]. Epithelioid AMLs are potentially malignant with a highly variable proportion of cases with aggressive behaviour [55]. Criteria to predict the biological behaviour in epithelioid AML were proposed by the WHO 2016 [39, 54]. Angiomyolipoma, in general, has a slow and consistent growth rate, and minimal morbidity [5].

In some cases, larger AMLs can cause local pain. The main complication of AMLs is spontaneous bleeding in the retroperitoneum or into the collecting system, which can be life threatening. Bleeding is caused by spontaneous rupture of the tumour. Little is known about the risk factors for bleeding, but it is believed to increase with tumour size and may be related to the angiogenic component of the tumour that includes irregular blood vessels [5]. The major risk factors for bleeding are tumour size, grade of the angiogenic component, and the presence of tuberous sclerosis [56, 57].

3.4.5.1 **Treatment**

Active surveillance is the most appropriate option for most AMLs (48%). In a group of patients on AS, only 11% of AMLs showed growth, and spontaneous bleeding was reported in 2%, resulting in active treatment in 5% of patients [5, 58] (LE: 3). The association between AML size and the risk of bleeding remains unclear and the traditionally used 4-cm cut-off should not per se trigger active treatment [5]. When surgery is indicated, NSS is the preferred option, if technically feasible. Main disadvantages of less invasive selective arterial embolisation (SAE) are more recurrences and a need for secondary treatment (0.85% for surgery vs. 31% for SAE). For thermal ablation only limited data are available, and this option is used less frequently [5].

Active treatment (SAE, surgery or ablation) should be instigated in case of persistent pain, ruptured AML (acute or repeated bleeding) or in case of a very large AML. Specific patient circumstances may influence the choice to offer active treatment; such as patients at high risk of abdominal trauma, females of childbearing age or patients in whom follow-up or access to emergency care may be inadequate. Selective arterial embolisation is an option in case of life-threatening AML bleeding.

In patients diagnosed with tuberous sclerosis, size reduction of often bilateral AMLs can be induced by inhibiting the mTOR pathway using everolimus, as demonstrated in RCTs [59, 60]. In a small phase II trial (n = 20), efficacy of everolimus was demonstrated in sporadic AML as well. A 25% or greater reduction in tumour volume at four and six months was demonstrated in 55.6% and 71.4% of patients, respectively. Twenty percent (n = 20), efficacy of everolimus was demonstrated in sporadic AML as well. A 25% or greater reduction in tumour volume at four and six months was demonstrated in 55.6% and 71.4% of patients, respectively. Twenty percent of patients were withdrawn due to toxicities and 40% self-withdrew from the study due to side effects [61].

3.4.6 **Renal oncocytoma**

Oncocytoma is a benign tumour representing 3–7% of all solid renal tumours and its incidence increases to 18% when tumours < 4 cm are considered [16, 58]. The diagnostic accuracy of imaging modalities (CT, MRI) in renal oncocytoma is limited and histopathology remains the only reliable diagnostic modality [16, 58]. However, the new imaging technology 99mTc-sestamibi (SestaMIBI, MIBI) SPECT/CT has shown promising initial results.

In patients diagnosed with tuberous sclerosis, size reduction of often bilateral AMLs can be induced by inhibiting the mTOR pathway using everolimus, as demonstrated in RCTs [59, 60]. In a small phase II trial (n = 20), efficacy of everolimus was demonstrated in sporadic AML as well. A 25% or greater reduction in tumour volume at four and six months was demonstrated in 55.6% and 71.4% of patients, respectively. Twenty percent of patients were withdrawn due to toxicities and 40% self-withdrew from the study due to side effects [61].

Renal cysts

Simple cysts are frequently occurring, while occurring septa, calcifications and solid components require follow-up and/or management.

Malignant or benign

Treatment or follow-up recommendation based on Bosniak classification. See Table 5.1

### 3.4.7 Cystic renal tumours

Cystic renal lesions are classified according to the Bosniak classification (see Section 5.2.5). Bosniak I and II cysts are benign lesions which do not require follow-up [72]. Bosniak IV cysts are mostly (83%) malignant tumours [73] with pseudocystic changes only. Bosniak IIF and III cysts remain challenging for clinicians. The differentiation of benign and malignant tumour in categories IIF/III is based on imaging, mostly CT, with an increasing role of MRI and contrast-enhanced ultrasound (CEUS). Computed tomography shows poor sensitivity (36%) and specificity (76%; $\kappa$ [kappa coefficient] = 0.11) compared with 71% sensitivity and 91% specificity ($\kappa$ = 0.64) for MRI and 100% sensitivity and 97% specificity for CEUS ($\kappa$ = 0.95) [74]. Surgical and radiological cohorts pooled estimates show a prevalence of malignancy of 0.51 (0.44–0.58) in Bosniak III and 0.89 (0.83–0.92) in Bosniak IV cysts, respectively. In a systematic review, less than 1% of stable Bosniak IIF cysts showed malignancy during follow-up. Twelve percent of Bosniak IIF cysts had to be reclassified to Bosniak III/IV during radiological follow-up, with 85% of these showing malignancy, which is comparable to the malignancy rates of Bosniak IV cysts [72]. The updated Bosniak classification strengthens the classification and includes also MRI diagnostic criteria [75].

The most common histological type for Bosniak III cysts is ccRCC with pseudocystic changes and low malignant potential [76, 77]; multilocular cystic renal neoplasm of low malignant potential ([mCRNLMP], formerly mcRCC (see Section 3.2 and Table 3.1); pRCC type I (very low malignant potential); benign multilocular cyst; benign group of renal epithelial and stromal tumours (REST); and other rare entities. Surgery in Bosniak III cysts will result in over-treatment in 49% of the tumours which are lesions with a low malignant potential. In view of the excellent outcome of these patients in general, a surveillance approach is an alternative to surgical treatment [72, 75, 78, 79].

4. STAGING AND CLASSIFICATION SYSTEMS

4.1 Staging

The Tumour Node Metastasis (TNM) classification system is recommended for clinical and scientific use [80], but requires continuous re-assessment [16, 81]. A supplement was published in 2012, and the latter's prognostic value was confirmed in single and multi-institution studies [82, 83]. Tumour size, venous invasion, renal capsular invasion, adrenal involvement, and LN and distant metastasis are included in the TNM classification system (Table 4.1). However, some uncertainties remain:

- The sub-classification of T1 tumours using a cut-off of 4 cm might not be optimal in NSS for localised cancer.
- The value of size stratification of T2 tumours has been questioned [84].
- Renal sinus fat invasion might carry a worse prognosis than perinephric fat invasion, but, is nevertheless included in the same pT3a stage group [85-88] (LE: 3).
- Sub T-stages (pT2b, pT3a, pT3c and pT4) may overlap [83].
- For adequate M staging, accurate pre-operative imaging (chest and abdominal CT) should be performed [89, 90] (LE: 4).

A help desk for specific questions about TNM classification is available at http://www.uicc.org/tnm.

*Adapted based on the American Joint Committee on Cancer (AJCC), 8th Edn. 2017 [91].

4.2 Anatomic classification systems

Objective anatomic classification systems, such as the Preoperative Aspects and Dimensions Used for an Anatomical (PADUA) classification system, the R.E.N.A.L. nephrometry score, the C-index, an Arterial Based Complexity (ABC) Scoring System and Zonal NePhRO scoring system, have been proposed to standardise the
description of renal tumours [92-94]. These systems include assessment of tumour size, exophytic/endophytic properties, proximity to the collecting system and renal sinus, and anterior/posterior or lower/upper pole location.

The use of such a system is helpful as it allows objective prediction of potential morbidity of NSS and tumour ablation techniques. These tools provide information for treatment planning, patient counselling, and comparison of partial nephrectomy (PN) and tumour ablation series. However, when selecting the most optimal treatment option, anatomic scores must be considered together with patient features and surgeon experience.

5. DIAGNOSTIC EVALUATION

5.1 Symptoms
Many renal masses remain asymptomatic until the late disease stages. The majority of RCCs are detected incidentally by non-invasive imaging investigating various non-specific symptoms and other abdominal diseases [95] (LE: 3). In a recent prospective observational cohort study, 60% of patients overall, 87% of patients with stage 1a renal tumours and 36% of patients with stage III or IV disease presented incidentally [96]. The classic triad of flank pain, visible haematuria, and palpable abdominal mass is rare (6–10%) and correlates with aggressive histology, advanced disease and poorer outcomes [96-98] (LE: 3). Paraneoplastic syndromes are found in approximately 30% of patients with symptomatic RCCs [99] (LE: 4). Some symptomatic patients present with symptoms caused by metastatic disease, such as bone pain or persistent cough [100] (LE: 3).

5.1.1 Physical examination
Physical examination has a limited role in RCC diagnosis. However, the following findings should prompt radiological examinations:
• palpable abdominal mass;
• palpable cervical lymphadenopathy;
• non-reducing varicocele and bilateral lower extremity oedema, which suggests venous involvement.

5.1.2 Laboratory findings
Commonly assessed laboratory parameters are serum creatinine, glomerular filtration rate (GFR), complete cell blood count, erythrocyte sedimentation rate, liver function study, alkaline phosphatase, lactate dehydrogenase (LDH), serum corrected calcium [101], coagulation study, and urinalysis (LE: 4). For central renal masses abutting or invading the collecting system, urinary cytology and possibly endoscopic assessment should be considered in order to exclude urothelial cancer (LE: 4).

Split renal function should be estimated using renal scintigraphy in the following situations [102, 103] (LE: 2b):
• when renal function is compromised, as indicated by increased serum creatinine or significantly decreased GFR;
• when renal function is clinically important; e.g., in patients with a solitary kidney or multiple or bilateral tumours.
Renal scintigraphy is an additional diagnostic option in patients at risk of future renal impairment due to comorbid disorders.

5.2 Imaging investigations
Most renal tumours are diagnosed by abdominal US or CT performed for other medical reasons [95] (LE: 3). Renal masses are classified as solid or cystic based on imaging findings.

5.2.1 Presence of enhancement
With solid renal masses, the most important criterion for differentiating malignant lesions is the presence of enhancement [104] (LE: 3). Traditionally, US, CT and MRI are used for detecting and characterising renal masses. Most renal masses are diagnosed accurately by imaging alone.

5.2.2 Computed tomography or magnetic resonance imaging
Computed tomography or MRI are used to characterise renal masses. Imaging must be performed unenhanced, in an early arterial phase, and in a parenchymal phase with intravenous contrast material to demonstrate enhancement. In CT imaging, enhancement in renal masses is determined by comparing Hounsfield units (Hus) before, and after, contrast administration. A change of fifteen HU, or more, in the solid
tumour parts demonstrates enhancement and thus vital tumour parts [105] (LE: 3). Computed tomography or MRI allows accurate diagnosis of RCC, but cannot reliably distinguish oncocytoma and fat-free AML from malignant renal neoplasms [106-109] (LE: 3). Abdominal CT provides information on [110]:

- function and morphology of the contralateral kidney [111] (LE: 3);
- primary tumour extension;
- venous involvement;
- enlargement of locoregional LNs;
- condition of the adrenal glands and other solid organs (LE: 3).

Abdominal contrast-enhanced CT angiography is useful in selected cases when detailed information on the renal vascular supply is needed [112, 113]. If the results of CT are indeterminate, CEUS is a valuable alternative to further characterise renal lesions [6, 114-116] (LE: 1b).

Magnetic resonance imaging may provide additional information on venous involvement if the extent of an inferior vena cava (IVC) tumour thrombus is poorly defined on CT [117-120] (LE: 3). In MRI, especially high-resolution T2-weighted images provide a superior delineation of the uppermost tumour thrombus, as the inflow of the enhanced blood may be reduced due to extensive occlusive tumour thrombus growth in the inferior vena cava. The T2-weighted image with its intrinsic contrast allows a good delineation [120].

Magnetic resonance imaging is indicated in patients who are allergic to intravenous CT contrast medium and in pregnancy without renal failure [120, 121] (LE: 3). Magnetic resonance imaging allows the evaluation of a dynamic enhancement without radiation exposure. Advanced MRI techniques such as diffusion-weighted (DWI) and perfusion-weighted imaging are being explored for renal mass assessment [122]. Recently, the use of multiparametric MRI (mpMRI) to diagnose ccRCC via a clear cell likelihood score (ccLS) in small renal masses was reported [123]. The ccLS is a 5-tier classification that denotes the likelihood of a mass representing ccRCC, ranging from ‘very unlikely’ to ‘very likely’. The authors prospectively validated the diagnostic performance of ccLS in 57 patients with cT1a tumours and found a high diagnostic accuracy. The diagnostic performance of mpMRI-based ccLS was further validated in a larger retrospective cohort (n = 434) across all tumour sizes and stages [124], and ccLS was found to be an independent prognostic factor for identifying ccRCC. The system is promising and deserves further validation.

For the diagnosis of complex renal cysts (Bosniak IIF-III) MRI may be preferable. The accuracy of CT is limited in these cases, with poor sensitivity (36%) and specificity (76%; κ = 0.11); MRI, due to a higher sensitivity for enhancement, showed a 71% sensitivity and 91% specificity (κ = 0.64). Contrast-enhanced US showed high sensitivity (100%) and specificity (97%), with a negative predictive value of 100% (κ = 0.95) [74].

In younger patients who are worried about the radiation exposure of frequent CT scans, MRI may be offered as alternative although only limited data exist correlating diagnostic radiation exposure to the development of secondary cancers [125].

A recent systematic review and meta-analysis [126] compared the diagnostic performance of CEUS vs. contrast-enhanced CT and contrast-enhanced MRI (CEMRI) in the assessment of benign and malignant cystic and solid renal masses. Sixteen studies were included in the pooled analysis. The results suggested comparable diagnostic performance of CEUS compared with CECT (pooled sensitivity 0.96 (95% CI: 0.94-0.98), vs. 0.90 (95% CI: 0.86-0.93), for studies with a final diagnosis of benign or malignant renal masses by pathology), and CEUS vs. CEMRI (pooled sensitivity 0.98 (95% CI: 0.94-1.0), vs. 0.78 (95% CI: 0.66-0.91), for studies with final diagnosis by pathology report or reaffirmed diagnosis by follow-up imaging without pathology report. However, there were significant limitations in the data, including very few studies for CEMRI, clinical and statistical heterogeneity and inconsistency, and high risks of confounding.

5.2.3 Other investigations
Renal arteriography and inferior venacavography have a limited role in the work-up of selected RCC patients (LE: 3). In patients with any sign of impaired renal function, an isotope renogram and total renal function evaluation should be considered to optimise treatment decision-making [102, 103] (LE: 2a). Positron-emission tomography (PET) is not recommended [6, 127] (LE: 1b).

5.2.4 Radiographic investigations to evaluate RCC metastases
Chest CT is accurate for chest staging [89, 90, 128-130] (LE: 3). Use of nomograms to calculate risk of lung metastases have been proposed based on tumour size, clinical stage and presence of systemic symptoms [131, 132]. These are based on large, retrospective datasets, and suggest that chest CT may be omitted in patients with cT1a and cN0, and without systemic symptoms, anaemia or thrombocytemia, due to the low
incidence of lung metastases (< 1%) in this group of patients. There is a consensus that most bone metastases are symptomatic at diagnosis; thus, routine bone imaging is not generally indicated [128, 133, 134] (LE: 3). However, bone scan, brain CT, or MRI may be used in the presence of specific clinical or laboratory signs and symptoms [133, 135, 136] (LE: 3). A recent prospective comparative blinded study involving 92 consecutive mRCC patients treated with first-line VEGFR-tyrosine kinase inhibitor (TKI) (median follow-up 35 months) found that whole-body DWI/MRI detected a statistically significant higher number of bony metastases compared with conventional thoraco-abdomino-pelvic contrast-enhanced CT, with higher number of metastases being an independent prognostic factor for progression-free survival (PFS) and overall survival (OS) [137].

The incidence of brain metastasis without neurological symptoms was retrospectively evaluated in 1,689 mRCC patients, selected to be included in 68 clinical trials between 2001-2019 [138]. All patients had a mandatory brain screening by CT/MRI. There were 72 patients (4.3%) diagnosed with occult brain metastases, 39% multi-focal. Most patients (61%) were in IMDC intermediate risk, and 26% had a favourable risk. A majority (86%) of the patients had ≥ 2 extracranial metastatic sites, including lung metastases in 92%. After predominantly radiotherapy, performed in 93%, a median patient’s overall survival of 10.3 months (range 7.0–17.9 months) was observed.

5.2.5 Bosniak classification of renal cystic masses
This system classifies renal cysts into five categories, based on CT imaging appearance, to predict malignancy risk [139, 140] (LE: 3), and also advocates treatment for each category (Table 5.1). A new updated Bosniak classification has been proposed that strengthens the classification and includes MRI diagnostic criteria [75]; however, it requires further validation. The management of cystic renal tumours is also discussed in Section 3.4.7.

5.3 Renal tumour biopsy
5.3.1 Indications and rationale
Percutaneous renal tumour biopsy can reveal histology of radiologically indeterminate renal masses and can be considered in patients who are candidates for AS of small masses, to obtain histology before ablative treatments, and to select the most suitable medical and surgical treatment strategy in the setting of metastatic disease [141-146] (LE: 3).

A multicentre study assessing 542 surgically removed small renal masses showed that the likelihood of benign findings at pathology is significantly lower in centres where biopsies are performed (5% vs. 16%), suggesting that biopsies can reduce surgery for benign tumours and the potential for short-term and long-term morbidity associated with these procedures [147].
Renal biopsy is not indicated for comorbid and frail patients who can be considered only for conservative management (watchful waiting) regardless of biopsy results. Due to the high diagnostic accuracy of abdominal imaging, renal tumour biopsy is not necessary in patients with a contrast-enhancing renal mass for whom surgery is planned (LE: 4).

Core biopsies of cystic renal masses have a lower diagnostic yield and accuracy and are not recommended, unless areas with a solid pattern are present (Bosniak IV cysts) [141, 144, 148] (LE: 2b/3). Histological characterisation by percutaneous biopsy of undefined retroperitoneal masses at imaging may be useful for decision making especially in the younger population.

5.3.2 Technique

Percutaneous sampling can be performed under local anaesthesia with needle core biopsy and/or fine needle aspiration (FNA). Biopsies can be performed under US or CT guidance, with a similar diagnostic yield [144, 149] (LE: 2b). Eighteen-gauge needles are ideal for core biopsies, as they result in low morbidity and provide sufficient tissue for diagnosis [141, 145, 150] (LE: 2b). A coaxial technique allowing multiple biopsies through a coaxial cannula should always be used to avoid potential tumour seeding [141, 145] (LE: 3).

Core biopsies are preferred for the characterisation of solid renal masses while a combination with FNA can provide complimentary results and improve accuracy for complex cystic lesions [148, 151, 152] (LE: 2a). A systematic review and meta-analysis of the diagnostic performance and complications of renal tumour biopsy was performed by the Panel, including 57 publications and a total of 5,228 patients. Needle core biopsies were found to have better accuracy for the diagnosis of malignancy compared with FNA [148]. Other studies showed that solid pattern, larger tumour size and exophytic location are predictors of a diagnostic core biopsy [141, 144, 149] (LE: 2b).

5.3.3 Diagnostic yield and accuracy

In experienced centres, core biopsies have a high diagnostic yield, specificity, and sensitivity for the diagnosis of malignancy. The above-mentioned meta-analysis showed that sensitivity and specificity of diagnostic core biopsies for the diagnosis of malignancy are 99.1% and 99.7%, respectively [148] (LE: 2b). However, 0–22.6% of core biopsies are non-diagnostic (8% in the meta-analysis) [142-146, 149, 150, 153] (LE: 2a). If a biopsy is non-diagnostic, and radiologic findings are suspicious for malignancy, a further biopsy or surgical exploration should be considered (LE: 4). Repeat biopsies have been reported to be diagnostic in a high proportion of cases (83-100%) [141, 154-156].

Accuracy of renal tumour biopsies for the diagnosis of tumour histotype is good. The median concordance rate between tumour histotype on renal tumour biopsy and on the surgical specimen of the following PN or RN was 90.3% in the pooled analysis [148].

Assessment of tumour grade on core biopsies is challenging. In the pooled analysis the overall accuracy for nuclear grading was poor (62.5%), but significantly improved (87%) using a simplified two-tier system (high vs. low grade) [148] (LE: 2a).

The ideal number and location of core biopsies are not defined. However, at least two good quality cores should be obtained and necrotic areas should be avoided to maximise diagnostic yield [141, 144, 157, 158] (LE: 2b). Peripheral biopsies are preferable for larger tumours, to avoid areas of central necrosis [159] (LE: 2b). In cT2 or greater renal masses, multiple core biopsies taken from at least four separate solid enhancing areas in the tumour were shown to achieve a higher diagnostic yield and a higher accuracy to identify sarcomatoid features, without increasing the complication rate [160].

5.3.4 Morbidity

Overall, percutaneous biopsies have a low morbidity [148]. Tumour seeding along the needle tract has been regarded as anecdotal in large series and pooled analyses on renal tumour biopsies. Especially the coaxial technique has been regarded as a safe method to avoid any seeding of tumour cells. However, authors recently reported on seven patients in whom tumour seeding was identified on histological examination of the resection specimen after surgical resection of RCC following diagnostic percutaneous biopsy [161]. Six of the seven cases were of the pRCC type. The clinical significance of these findings is still uncertain but only one of these patients developed local tumour recurrence at the site of the previous biopsy [161].

Spontaneously resolving subcapsular/perinephric haematomas are reported in 4.3% of cases in a pooled analysis, but clinically significant bleeding is unusual (0–1.4%; 0.7% in the pooled analysis) and generally self-limiting [148].

Percutaneous biopsy of renal hilar masses is technically feasible with a diagnostic yield similar to that of cortical masses, but with significantly higher post-procedural bleeding compared with cortical masses [162].
5.3.5 Genetic assessment

Renal cancer can be related to an inherited or de novo monogenic germline alteration and this recognition has significant implications [163]. Hereditary kidney cancer is thought to account for 5–8% of all kidney cancer cases, although this number is likely an underestimation since a more recent study found germline mutations in up to 38% of all metastatic kidney cancer patients [164] (see Section 3.4.4. Hereditary kidney tumours). Patients with a germline predisposition to kidney cancer often require multidisciplinary approaches, it is critical for clinicians to be familiar with how and when referral for counselling is warranted, methods of genetic testing, implications of the findings, screening of at-risk (non-renal) organs, and the screening protocol for family members. Well-defined renal cancer management strategies exist, and specific therapeutic strategies are available or in development (see Section 3.4.4). Lack of a syndromic manifestation does not exclude a genetic contribution to cancer development. Moreover, other genetic components or polymorphisms are heritable and may confer a mildly increased risk. When several risk alleles are present, they can significantly increase cancer risk.

Many factors are associated with an increased risk of hereditary renal cancer syndromes. For instance, even in the absence of clinical manifestations and personal/family history, an age of onset of 46 years or younger should trigger consideration for genetic counselling/germline mutation testing [40]. Moreover, presence of bilateral or multifocal tumours/cysts and/or a first- or second-degree relative with RCC and/or a close blood relative with a known pathogenic variant significantly increases the risk to detect hereditary cancer. The presence of renal cysts can be associated with BHD and VHL, and form part of the clinical diagnostic spectrum. Moreover, specific histologic characteristics can support differential diagnosis of a particular renal cell carcinoma syndrome (e.g., multifocal papillary histology, hereditary leiomyomatosis-associated RCC, RCC with fumarate hydratase deficiency, multiple chromophobe, oncocytoma or oncocytic hybrid, succinate dehydrogenase-deficient RCC histology). Finally, additional tuberous sclerosis complex criteria should be assessed in individuals with AML [40, 165-173].

If additional risk factors are established in a patient, referral to a comprehensive clinical care centre, or a hospital with demonstrated expertise in managing hereditary cancer syndromes, will provide a dedicated working team, tailored clinical decisions, research translational program, appropriate patient psychosocial support, and prospective collection of clinical data and biological samples. This can contribute to a better patient’s care and further improvements in cancer care.

<td>Weak</td>
</tr>
</tbody>
</table>
Do not routinely use bone scan and/or positron-emission tomography CT for staging of renal cell carcinoma.  
Perform a renal tumour biopsy before ablative therapy and systemic therapy without previous pathology.  
Perform a percutaneous biopsy in select patients who are considering active surveillance.  
Use a coaxial technique when performing a renal tumour biopsy.  
Do not perform a renal tumour biopsy of cystic renal masses unless a significant solid component is visible at imaging.  
Use a core biopsy technique rather than fine needle aspiration for histological characterisation of solid renal tumours.

6. PROGNOSTIC FACTORS

6.1 Classification
Prognostic factors can be classified into: anatomical, histological, clinical, and molecular.

6.2 Anatomical factors
Tumour size, venous invasion and extension, collecting system invasion, perinephric- and sinus fat invasion, adrenal involvement, and LN and distant metastasis are included in the TNM classification system [174, 175] (Table 4.1).

6.3 Histological factors
Histological factors include tumour grade, RCC subtype, lymphovascular invasion, tumour necrosis, and invasion of the collecting system [176, 177]. Tumour grade is considered one of the most important histological prognostic factors. Fuhrman nuclear grade is based on simultaneous investigation of nuclear size, nuclear shape and nucleolar prominence [178]. It has been the most widely accepted grading system for several decades, but has now been largely replaced by the WHO/ISUP grading classification [179]. This relies solely on nucleolar prominence for grade 1-3 tumours, allowing for less inter-observer variation [180]. It has been shown that the WHO/ISUP grading provides superior prognostic information compared to Fuhrman grading, especially for grade 2 and grade 3 tumours [181]. Rhabdoid and sarcomatoid changes can be found in all RCC types and are equivalent to grade 4 tumours. Sarcomatoid changes are more often found in chRCC than other subtypes [182]. The percentage of the sarcomatoid component appears to be prognostic as well, with a larger percentage of involvement being associated with worse survival. However, there is no agreement on the optimal prognostic cut-off for sub-classifying sarcomatoid changes [183, 184]. The WHO/ISUP grading system is applicable to both ccRCC and pRCC. It is currently not recommended to grade chRCC. However,
a recent study suggested a two-tiered chRCC grading system (low vs. high grade) based on the presence of sarcomatoid differentiation and/or tumour necrosis, which was statistically significant on multivariable analysis [185]. Both the WHO/ISUP and chRCC grading systems need to be validated for prognostic systems and nomograms [179].

Renal cell carcinoma subtype is regarded as another important prognostic factor. On univariable analysis, patients with chRCC vs. pRCC vs. ccRCC had a better prognosis [186, 187] (Table 6.1). However, prognostic information provided by the RCC type is lost when stratified according to tumour stage [187, 188] (LE: 3).

In a recent cohort study of 1,943 patients with ccRCC and pRCC significant survival differences were only shown between pRCC type I and ccRCC [189]. Papillary RCC has been traditionally divided into type 1 and 2, but a subset of tumours shows mixed features. For more details, see Section 3.2 – Histological diagnosis. Data also suggest that type 2 pRCC is a heterogeneous entity with multiple molecular subgroups [27]. Some studies suggest poorer survival for type 2 than type 1 [190], but this association is often lost in the multivariable analysis [191]. A meta-analysis did not show a significant survival difference between both types [192, 193].

Renal cell carcinoma with Xp11.2 translocation has a poor prognosis [194]. Its incidence is low, but its presence should be systematically assessed in young patients. Renal cell carcinoma type classification has been confirmed by cytogenetic and genetic analyses [195-197] (LE: 2b). Surgically excised malignant complex cystic masses contain ccRCC in the majority of cases, and more than 80% are pT1. In a recent series, five-year CSS was 98% [198]. Differences in tumour stage, grade and CSS between RCC types are illustrated in Table 6.1.

CSS = cancer-specific survival.

In all RCC types, prognosis worsens with stage and histopathological grade (Table 6.2). The five-year OS for all types of RCC is 49%, which has improved since 2006, probably due to an increase in incidentally detected RCCs and new systemic treatments [199, 200]. Although not considered in the current N classification, the number of metastatic regional LNs is an important predictor of survival in patients without distant metastases [201].

</table>

CI = confidence interval; HR = hazard ratio.

6.4 Clinical factors
Clinical factors include performance status (PS), local symptoms, cachexia, anaemia, platelet count, neutrophil count, lymphocyte count, C-reactive protein (CRP) [202], albumin, and various indices deriving from these factors such as the neutrophil-to-lymphocyte ratio (NLR) [100, 203-208] (LE: 3). As a marker of systemic inflammatory response, a high pre-operative NLR has been associated with poor prognosis [209], but there is significant heterogeneity in the data and no agreement on the optimal prognostic cut-off. Even though obesity is an aetiological factor for RCC, it has also been observed to provide prognostic information. A high body mass index (BMI) appears to be associated with improved survival outcomes in both non-metastatic and metastatic RCC [210-212]. This association is linear with regards to cancer-specific mortality, while obese RCC
patients show increasing all-cause mortality with increasing BMI [213]. There is also evolving evidence on the prognostic value of body composition indices measured on cross-sectional imaging, such as sarcopenia and fat accumulation [208, 214, 215].

6.5 Molecular factors
Numerous molecular markers such as carbonic anhydrase IX (CaIX), VEGF, hypoxia-inducible factor (HIF), Ki67 (proliferation), p53, p21 [216], PTEN (phosphatase and tensin homolog) cell cycle [217], E-cadherin, osteopontin [218] CD44 (cell adhesion) [219, 220], CXCR4 [221], PD-L1 [222], miRNA, SNPs, gene mutations, and gene methylations have been investigated (LE: 3) [25]. While the majority of these markers are associated with prognosis and many improve the discrimination of current prognostic models, there has been very little emphasis on external validation studies. Furthermore, there is no conclusive evidence on the value of molecular markers for treatment selection in mRCC [202, 222, 223]. Their routine use in clinical practice is therefore not recommended.

Several prognostic and predictive marker signatures have been described for specific systemic treatments in mRCC. In the JAVELIN Renal 101 trial (NCT02684006), a 26-gene immunomodulatory gene signature predicted PFS in those treated with avelumab plus axitinib, while an angiogenesis gene signature was associated with PFS for sunitinib. Mutational profiles and histocompatibility leukocyte antigen (HLA) types were also associated with PFS, while PD-L1 expression and tumour mutational burden were not [224]. In Immotion151 (NCT02420821), a T effector/IFN-γ-high or angiogenesis-low gene expression signature predicted improved PFS for atezolizumab plus bevacizumab compared to sunitinib. The angiogenesis-high gene expression signature correlated with longer PFS in patients treated with sunitinib [225]. In CheckMate 214 (NCT02231749), a higher angiogenesis gene signature score was associated with better overall response rates and PFS for sunitinib, while a lower angiogenesis score was associated with higher ORR in those treated with nivolumab plus ipilimumab. Progression-free survival ≥ 18 months was more often seen in patients with higher expression of Hallmark inflammatory response and Hallmark epithelial mesenchymal transition gene sets [208].

Urinary and plasma Kidney-Injury Molecule-1 (KIM-1) has been identified as a potential diagnostic and prognostic marker. KIM-1 concentrations were found to predict RCC up to five years prior to diagnosis and were associated with a shorter survival time [226]. KIM-1 is a glycoprotein marker of acute proximal tubular injury and therefore mainly expressed in RCC derived from the proximal tubules such as ccRCC and pRCC [227]. While early studies are promising, more high-quality research is required. Several retrospective studies and large molecular screening programs have identified mutated genes and chromosomal changes in ccRCC with distinct clinical outcomes. The expression of the BAP1 and PBRM1 genes, situated on chromosome 3p in a region that is deleted in more than 90% of ccRCCs, have shown to be independent prognostic factors for tumour recurrence [228-230]. These published reports suggest that patients with BAP1-mutant tumours have worse outcomes compared with patients with PBRM1-mutant tumours [229]. Loss of chromosome 9p and 14q have been consistently shown to be associated with poorer survival [231-233]. The TRACERx renal consortium has proposed a genetic classification based on RCC evolution (punctuated vs. branched vs. linear), which correlates with tumour aggressiveness and survival [232]. Additionally, a 16-gene signature was shown to predict disease-free survival (DFS) in patients with non-metastatic RCC [234]. However, these signatures have not been validated by independent researchers yet.

6.6 Prognostic models
Prognostic models combining independent prognostic factors have been developed and externally validated [235-241]. These models are more accurate than TNM stage or grade alone for predicting clinically relevant oncological outcomes (LE: 3). Before being adopted, new prognostic models should be evaluated and compared to current prognostic models with regards to discrimination, calibration and net benefit. In metastatic disease, risk groups assigned by the Memorial Sloan Kettering Cancer Center (MSKCC) (primarily created in the pre-targeted therapy, and validated in patients receiving targeted therapy) and the International Metastatic Renal Cell Carcinoma Database Consortium (IMDC) (initially created in the targeted therapy era) differ in 23% of cases [242]. The IMDC model has been used in the majority of recent randomised trials, including those with immune checkpoint inhibitors (ICIs), and may therefore be the preferred model for clinical practice. The discrimination of the IMDC model may be improved by addition of a seventh variable, namely presence of brain, bone, and/or liver metastases [243]. IMDC intermediate risk disease may also be sub-classified according to presence of bone metastasis or by platelet count [244, 245]. There is no conclusive evidence that one prognostic model is more accurate than another. Tables 6.3 and 6.4 summarise the current most relevant prognostic models.

7. DISEASE MANAGEMENT

7.1 Treatment of localised RCC

7.1.1 Introduction

Sections 7.1.2 and 7.2.4.2 are underpinned by a systematic review which includes all relevant published literature comparing surgical management of localised RCC (T1-2N0M0). Randomised or quasi-RCTs were included. However, due to the very limited number of RCTs, non-randomised studies (NRS), prospective observational studies with controls, retrospective matched-pair studies, and comparative studies from the databases of well-defined registries were also included. Historically, surgery has been the benchmark for the treatment of localised RCC.

7.1.2 Surgical treatment

7.1.2.1 Nephron-sparing surgery versus radical nephrectomy in localised RCC

7.1.2.1.1 T1 RCC

Outcome 1: Cancer-specific survival

Most studies comparing the oncological outcomes of PN and RN are retrospective and include cohorts of varied and, overall, limited size [252, 253]. There is only one, prematurely closed, prospective RCT including patients with organ-confined RCCs of limited size (< 5 cm), showing comparable non-inferiority of CSS for PN vs. RN (HR: 2.06 [95% CI: 0.62–6.84]) [254].

Outcomes 2 & 3: Overall mortality and renal function

Partial nephrectomy preserved kidney function better after surgery, thereby potentially lowering the risk of development of cardiovascular disorders [252, 255-259]. When compared with a radical surgical approach, several retrospective analyses of large databases have suggested a decreased cardiovascular-specific mortality [256, 260] as well as improved OS for PN compared to RN. However, in some series this held true only for younger patients and/or patients without significant comorbidity at the time of the surgical intervention [261, 262]. An analysis of the U.S. Medicare database [263] could not demonstrate an OS benefit for patients ≥ 75 years of age when RN or PN were compared with non-surgical management.

Conversely, another series that addressed this question and also included Medicare patients, suggested an OS benefit in older patients (75–80 years) when subjected to surgery rather than non-surgical management. Shuch et al. compared patients who underwent PN for RCC with a non-cancer healthy control group via a retrospective database analysis; showing an OS benefit for the cancer cohort [264]. These conflicting results may be an indication that unknown statistical confounders hamper the retrospective analysis of population-based tumour registries. In the only prospectively randomised, but prematurely closed, heavily underpowered, trial, PN seems to be less effective than RN in terms of OS in the intention to treat (ITT) population (HR: 1.50 [95% CI: 1.03–2.16]). However, in the targeted RCC population of the only RCT, the trend in favour of RN was no longer significant [254]. Taken together, the OS advantage suggested for PN vs. RN remains an unresolved issue.

Patients with a normal pre-operative renal function and a decreased GFR due to surgical treatment (either RN or PN), generally present with stable long-term renal function [259]. Adverse OS in patients with a pre-existing GFR reduction does not seem to result from further renal function impairment following surgery, but rather from other medical comorbidities causing pre-surgical chronic kidney disease (CKD) [265]. However, in particular in patients with pre-existing CKD, PN is the treatment of choice to limit the risk of development of ESRD which requires haemodialysis. Huang et al. found that 26% of patients with newly diagnosed RCC had an GFR < 60 mL/min, even though their baseline serum creatinine levels were in the normal range [103].

Outcome 4 & 5: Peri-operative outcomes and quality of life

In terms of the intra- and peri-operative morbidity/complications associated with PN vs. RN, the European Organisation for Research and Treatment of Cancer (EORTC) randomised trial showed that PN for small, easily resectable, incidentally discovered RCC, in the presence of a normal contralateral kidney, can be performed safely with slightly higher complication rates than after RN [266].

Only a limited number of studies are available addressing quality of life (QoL) following PN vs. RN, irrespective of the surgical approach used (open vs. minimally invasive). Quality of life was ranked higher following PN as compared to RN, but in general patients’ health status deteriorated following both approaches [266, 267].

In view of the above, and since oncological safety (CSS and RFS) of PN, so far, has been found non-differing from RN outcomes, PN is the treatment of choice for T1 RCC since it preserves kidney function better and in the long term potentially limits the incidence of cardiovascular disorders. Whether decreased mortality from
any cause can be attributed to PN is still unresolved, but in patients with pre-existing CKD, PN is the preferred surgical treatment option as it avoids further deterioration of kidney function; the latter being associated with a higher risk of development of ESRD and the need for haemodialysis. Irrespective of the available data, in frail patients, treatment decisions should be individualised, weighing the risks and benefits of PN vs. RN, the increased risk of peri-operative complications and the risk of developing or worsening CKD post-operatively.

7.1.2.1.2 T2 RCC
There is very limited evidence on the optimal surgical treatment for patients with larger renal masses (T2). Some retrospective comparative studies of PN vs. RN for T2 RCC have been published [268]. A trend for lower tumour recurrence- and cancer-specific mortality is reported in PN groups. The estimated blood loss is reported to be higher for PN groups, as is the likelihood of post-operative complications [268]. A recent multicentre study compared the survival outcomes in patients with larger (≥ 7 cm) ccRCC treated with PN vs. RN with long-term follow-up (median 102 months). Compared to the RN group, the PN group had a significantly longer median OS (p = 0.014) and median CSS (p = 0.04) [269]. Retrospective comparative studies of cT1 and cT2 RCC patients upstaged to pT3a RCC show contradictory results: some reports suggest similar oncologic outcomes between PN and RN [270], whilst another recent report suggests that PN of clinical T1 in pathologically upstaged pT3a of cT1 RCC is associated with a significantly shorter recurrence-free survival than RN [271]. Overall the level of the evidence is low. These studies including T2 masses all have a high risk of selection bias due to imbalance between the PN and RN groups regarding patient's age, comorbidities, tumour size, stage, and tumour position. These imbalances in covariation factors may have a greater impact on patient outcome than the choice of PN or RN. The Panel's confidence in the results is limited and the true effects may be substantially different.

In view of the above, the risks and benefits of PN should be discussed with patients with T2 tumours. In this setting PN should be considered, if technically feasible, in patients with a solitary kidney, bilateral renal tumours or CKD with sufficient parenchymal volume preserved to allow sufficient post-operative renal function.

7.1.2.1.3 T3 RCC
A recent meta-analysis of nine articles including 1,278 patients with PN and 2,113 patients with RN in pT3a RCC showed no difference in CSS, OS, CSM and RFS, indicating that PN techniques can be used for functional benefits and if technically feasible [272].

7.1.2.2 Associated procedures
7.1.2.2.1 Adrenalectomy
One prospective non-randomised study compared the outcomes of RN with or without, ipsilateral adrenalectomy [273]. Multivariable analysis showed that upper pole location was not predictive of adrenal involvement, but tumour size was. No difference in OS at five or ten years was seen with, or without, adrenalectomy. Adrenalectomy was justified using criteria based on radiographic- and intra-operative findings. Only 48 of 2,065 patients underwent concurrent ipsilateral adrenalectomy of which 42 of the 48 interventions were for benign lesions [273].

7.1.2.2.2 Lymph node dissection for clinically negative lymph nodes (cN0)
The indication for LN dissection (LND) together with PN or RN is still controversial [274]. The clinical assessment of LN status is based on the detection of an enlargement of LNs either by CT/MRI or intra-operative palpability of enlarged nodes. Less than 20% of suspected metastatic nodes (cN+) are positive for metastatic disease at histopathological examination (pN+) [275]. Both CT and MRI are unsuitable for detecting malignant disease in nodes of normal shape and size [276]. For clinically positive LNs (cN+) see Section 7.2.2. Smaller retrospective studies have suggested a clinical benefit associated with a more or less extensive LND preferably in patients at high risk for lymphogenic spread. In a large retrospective study, the outcomes of LN, with or without LND, in patients with high-risk non-mRCC were compared using a propensity score analysis. In this study LND was not significantly associated with a reduced risk of distant metastases, cancer-specific or all-cause mortality. The extent of the LND was not associated with improved oncologic outcomes [277]. The number of LN metastases (< / > 4) as well as the intra- and extracapsular extension of intra-nodal metastasis correlated with the patients’ clinical prognosis in some studies [276, 278-280]. Better survival outcomes were seen in patients with a low number of positive LNs (< 4) and no extranodal extension. On the basis of a retrospective Surveillance, Epidemiology and End Results (SEER) database analysis of > 9,000 patients no effects of an extended LND (eLND) on the disease-specific survival (DSS) of patients with pathologically confined negative nodes was demonstrated [281]. However, in patients with pathologically proven lymphogenic spread (pN+), an increase of 10 for the number of nodes dissected resulted in a 10% absolute increase in DSS.
In addition, in a larger cohort of 1,983 patients, Capitanio et al. demonstrated that eLND results in a significant prolongation of CSS in patients with unfavourable prognostic features (e.g., sarcomatoid differentiation, large tumour size) [282]. As to morbidity related to eLND, a recent retrospective propensity score analysis from a large single-centre database showed that eLND is not associated with an increased risk of Clavien grade ≥ 3 complications. Furthermore, LND was not associated with length of hospital stay or estimated blood loss [283].

Only one prospective RCT evaluating the clinical value of LND combined with surgical treatment of primary RCC has been published so far. With an incidence of LN involvement of only 4%, the risk of lymphatic spread appears to be very low. Recognising the latter, only a staging effect was attributed to LND [275]. This trial included a very high percentage of patients with pT2 tumours, which are not at increased risk for LN metastases. Only 25% of patients with pT3 tumours underwent a complete LND and the LN template used by the authors was not clearly stated.

The optimal extent of LND remains controversial. Retrospective studies suggest that an eLND should involve the LNs surrounding the ipsilateral great vessel and the inter-aortocaval region from the crus of the diaphragm to the common iliac artery. Involvement of inter-aortocaval LNs without regional hilar involvement is reported in up to 35–45% of cases [276, 284, 285]. At least fifteen LNs should be removed [282, 286]. Sentinel LND is an investigational technique [287, 288].

### 7.1.2.2.3 Embolisation

Before routine nephrectomy, tumour embolisation has no benefit [289, 290]. In patients unfit for surgery, or with non-resectable disease, embolisation can control symptoms, including visible haematuria or flank pain [291, 292]. These indications will be revisited in Sections 7.2 and 7.3 with cross reference to the summary of evidence and recommendations below.

#### 7.1.3 Radical and partial nephrectomy techniques

##### 7.1.3.1 Radical nephrectomy techniques

No RCTs have assessed the oncological outcomes of laparoscopic vs. open RN. A cohort study [293] and retrospective database reviews are available, mostly of low methodological quality, showing similar oncological outcomes even for higher stage disease and locally more advanced tumours [294-296]. Based on a systematic review, less morbidity was found for laparoscopic vs. open RN [252].

Data from one RCT [268] and two non-randomised studies [297, 298] showed a significantly shorter hospital stay and lower analgesic requirement for the laparoscopic RN group as compared with the open group. Convalescence time was also significantly shorter [298]. No difference in the number of
patients receiving blood transfusions was observed, but peri-operative blood loss was significantly less in the laparoscopic arm in all three studies [295, 297, 298]. Surgical complication rates were low with very wide confidence intervals. There was no difference in complications, but operation time was significantly shorter in the open nephrectomy arm. Post-operative QoL scores were similar [297].

Some comparative studies focused on the peri-operative outcomes of laparoscopic vs. RN for renal ≥T2 tumours. Overall, patients who underwent laparoscopic RN were shown to have lower estimated blood loss, less post-operative pain, shorter length of hospital stay and convalescence compared to those who underwent open RN [296, 298, 299]. Intra-operative and post-operative complications were similar in the two groups and no significant differences in CSS, PFS and OS were reported [296, 298, 299] (LE: 2b). Another multicentre propensity matched analysis compared laparoscopic- and open surgery for pT3a RCC, showing no significant difference in three-year RFS between groups [300]. The best approach for laparoscopic RN was the retroperitoneal or transperitoneal approach with similar oncological outcomes in two RTCs [301, 302] and one quasi-randomised study [276]. Quality of life variables were similar for both approaches. Hand-assisted vs. standard laparoscopic RN was compared in one quasi-randomised study [303] and one database review and estimated five-year OS, CSS, and RFS rates were comparable [304]. Duration of surgery was significantly shorter in the hand-assisted approach, while length of hospital stay and time to non-strenuous activities were shorter for the standard laparoscopic RN cohort [303, 304]. However, the sample size was small.

Data of a large retrospective cohort study on robot-assisted laparoscopic vs. laparoscopic RN showed robot-assisted laparoscopic RN was not associated with increased risk of any or major complications but had a longer operating time and higher hospital costs compared with laparoscopic RN [305]. A recent systematic review and meta-analysis of seven studies with 1,832 patients showed no difference between the two approaches in peri-operative outcomes, including operative time, blood loss, conversion rates and complications [306]. A systematic review reported on robot-assisted laparoscopic vs. conventional laparoscopic RN, showing no substantial differences in local recurrence rates, nor in all-cause cancer-specific mortality [307]. Similar results were seen in observational cohort studies comparing ‘portless’ and 3-port laparoscopic RN, with similar perioperative outcomes [308, 309].

7.1.3.2 Partial nephrectomy techniques

7.1.3.2.1 Open versus laparoscopic approach

Studies comparing laparoscopic and open PN found no difference in PFS [310-313] and OS [312, 313] in centres with laparoscopic expertise. However, the oncological safety of laparoscopic vs. open PN has, so far, only been addressed in studies with relatively limited follow-up [300]. However, the higher number of patients treated with open surgery in this series might reflect a selection bias by offering laparoscopic surgery in case of a less complex anatomy [300]. The mean estimated blood loss was found to be lower with the laparoscopic approach [310, 312, 314], while post-operative mortality, deep vein thrombosis, and pulmonary embolism events were similar [310, 312]. Operative time is generally longer with the laparoscopic approach [311-313] and warm ischaemia time is shorter with the open approach [310, 312, 314, 315]. In a matched-pair comparison, GFR decline was greater in the laparoscopic PN group in the immediate post-operative period [313], but not after 3.6 years follow-up. In another comparative study, the surgical approach was not an independent predictor for post-operative CKD [315]. Retroperitoneal and transperitoneal laparoscopic PN have similar peri-operative outcomes [316]. Simple tumour enucleation also had similar PFS and CSS rates compared to standard PN and RN in a large study [317]. The feasibility of laparo-endoscopic single-site PN has been shown in selected patients but larger studies are needed to confirm its safety and clinical role [318].

7.1.3.2.2 Open versus robotic approach

One study prospectively compared the peri-operative outcomes of a series of robot-assisted and open PN performed by the same experienced surgeon. Robot-assisted PN was superior to open PN in terms of lower estimated blood loss and shorter hospital stay. Warm ischaemia time, operative time, immediate- and short-term complications, variation in creatinine levels and pathologic margins were similar between groups [319].

A multicentre French prospective database compared the outcomes of 1,800 patients who underwent open PN and robot-assisted PN. Although the follow-up was shorter, there was a decreased morbidity in the robot-assisted PN group with less overall complications, less major complications, less transfusions and a much shorter hospital stay [320].

7.1.3.2.3 Open versus hand-assisted approach

Hand-assisted laparoscopic PN (HALPN) is rarely performed. A recent comparative study of open vs. HALPN showed no difference in OS or RFS at intermediate-term follow-up. The authors observed a lower rate of intra-operative and all-grade post-operative 30-day complications in HALPN vs. open PN patients, but there was no significant difference in high Clavien grade complications. Three months after the operation, GFR was lower in the HALPN than in the open PN group [321].
7.1.3.2.4 Open versus laparoscopic versus robotic approaches

In a retrospective propensity-score-matched study, comparing open-, laparoscopic- and robot-assisted PN, after five-year of median follow-up, similar rates of local recurrence, distant metastasis and cancer-related death rates were found [322].

7.1.3.2.5 Laparoscopic versus robotic approach

Another study included the 50 last patients having undergone laparoscopic and robotic PN for T1-T2 renal tumours by two different surgeons with an experience of over 200 procedures each in laparoscopic and robotic PN and robot-assisted partial nephrectomy (RAPN), respectively, at the beginning of the study. Peri-operative and short-term oncological and functional outcomes appeared broadly comparable between RAPN and LPN when performed by highly experienced surgeons [323].

A meta-analysis, including a series of NSS with variable methodological quality compared the peri-operative outcomes of robot-assisted- and laparoscopic PN. The robotic group had a significantly lower rate of conversion to open surgery and to radical surgery, shorter warm ischaemia time, smaller change in estimated GFR after surgery and shorter length of hospital stay. No significant differences were observed between the two groups regarding complications, change of serum creatinine after surgery, operative time, estimated blood loss and positive surgical margins [324].

A recent multi-institutional prospective study of 105 patients with hilar tumours demonstrated a reduced warm ischaemia time (20.2 min vs. 27.7 min) and a comparable PSM rate of 1.9% when compared with a historical laparoscopic control group which was defined by literature research and meta-analysis for warm ischaemia time and PSM, respectively [325].

7.1.3.2.6 Laparoscopic transperitoneal versus retroperitoneal approach

Data from the Italian RECORD 2 project, a multi-institutional prospective observational project, compared the transperitoneal vs. the retroperitoneal approach for laparoscopic PN. After propensity score matching (each group n = 413) no differences in post-operative complications (surgical and medical), positive surgical margins, early and late eGFR levels were observed. Intra-operative and surgical complications were slightly higher and operative times lower in the transperitoneal vs. the retroperitoneal approach [326].

7.1.3.2.7 Surgical volume

In a recent analysis of 8,753 patients who underwent PN, an inverse non-linear relationship of hospital volume with morbidity of PN was observed, with a plateauing seen at 35 to 40 cases per year overall, and 18 to 20 cases for the robotic approach [327]. A retrospective study of a U.S. National Cancer Database looked at the prognostic impact of hospital volume and the outcomes of robot-assisted PN, including 18,724 cases. This study shows that undergoing RAPN at higher-volume hospitals may have better peri-operative outcomes (conversion to open and length of hospital stay) and lower positive surgical margin rates [328]. A French study, including 1,222 RAPN patients, has shown that hospital volume is the main predictive factor of Trifecta achievement (no complications, warm ischaemia time < 25 min, and negative surgical margins) after adjustment for other variables, including surgeon volume [329]. The prospective Registry of Conservative and Radical Surgery for cortical renal tumour Disease (RECORd-2) study including 2,076 patients showed that the hospital volume (> 60 PN/year) is an independent predictor for positive surgical margins [330].

7.1.3.2.8 Pre-operative embolisation prior to partial nephrectomy

A systematic review and meta-analysis of 270 patients demonstrated significantly reduced blood loss in patients with selective renal artery embolisation (n = 222; 154 ± 22.6 mL vs. n = 48; 353.4 ± 69.6 mL) prior to partial nephrectomy [331].

7.1.3.3 Positive surgical margins on histopathological specimens

A positive surgical margin is encountered in about 2–8% of PNs [324]. Studies comparing surgical margins with different surgical approaches (open, laparoscopic, robotic) are inconclusive [332, 333]. Most trials showed that intra-operative frozen section analysis had no influence on the risk of definite positive surgical margins [334]. A positive surgical margin status occurs more frequently in cases in which surgery is imperative (solitary kidneys and bilateral tumours) and in patients with adverse pathological features (pT2a, pT3a, grade III-IV) [335-338]. The potential negative impact of a positive margin status on the oncologic outcome is still controversial [332].

The majority of retrospective analyses reported so far indicated that positive surgical margins do not translate into a higher risk of metastases or a decreased CSS [336, 337]. On the other hand, another retrospective study of a large single institutional series showed that positive surgical margins are an independent predictor of PFS...
due to a higher incidence of distant and local relapses [339]. Another retrospective study of 42,114 PN patients with 2,823 PSM patients (6.7%) showed an increased presence of PSM in upstaged pT3a tumours (14.1%), increased all-cause mortality in PSM patients and a decreased five-year OS rate in pT3a tumours (PSM: 69% vs. NSM: 90.9 %) [340].

However, only a proportion of patients with an uncertain margin status actually harbour residual malignancy [341]. Local tumour bed recurrences were found in 16% in patients with positive surgical margins compared with 3% in those with negative margins [335]. Therefore, RN or re-resection of margins can result in over-treatment in many cases. Patients with positive surgical margins should be informed that they will need a more intense surveillance (imaging) follow-up and that they are at increased risk of secondary local therapies [336, 342]. On the other hand, protection from recurrence is not ensured by negative surgical margins [343].

7.1.4 Therapeutic approaches as alternatives to surgery

7.1.4.1 Surgical versus non-surgical treatment

Population-based studies compared the oncological outcomes of surgery (RN or PN) and non-surgical management for tumours < 4 cm. The analyses showed a significantly lower cancer-specific mortality in patients treated with surgery [263, 344, 345]. However, the patients assigned to the surveillance arm were older and likely to be frailer and less suitable for surgery. Other-cause mortality rates in the non-surgical group significantly exceeded that of the surgical group [344]. Analyses of older patients (> 75 years) failed to show the same benefit in cancer-specific mortality for surgical treatment [346-348].

7.1.4.2 Active surveillance and watchful waiting

Elderly and comorbid patients with incidental small renal masses have a low RCC-specific mortality and significant competing-cause mortality [349, 350]. Active surveillance is defined as the initial monitoring of tumour size by serial abdominal imaging (US, CT, or MRI) with delayed intervention reserved for tumours showing clinical progression during follow-up [351]. The concept of AS differs from the concept of watchful waiting; watchful waiting is reserved for patients whose comorbidities contraindicate any subsequent active treatment and do not require follow-up imaging, unless clinically indicated.

In the largest reported series of AS the growth of renal tumours was low and progression to metastatic disease was reported in only a limited number of patients [352, 353].

A single-institutional comparative study evaluating patients aged > 75 years showed decreased OS for those who underwent surveillance and nephrectomy relative to NSS for clinically T1 renal tumours. However, at multivariate analysis, management type was not associated with OS after adjusting for age, comorbidities, and other variables [349]. No statistically significant differences in OS and CSS were observed in
another study of RN vs. PN vs. AS for T1a renal masses with a follow-up of 34 months [354]. The prospective non-randomised multi-institutional Delayed Intervention and Surveillance for Small Renal Masses (DISSRM) study enrolled 497 patients with solid renal masses < 4 cm who selected either AS or primary active intervention. Patients who selected AS were older, had worse ECOG scores, more comorbidities, smaller tumours, and more often had multiple and bilateral lesions. In patients who elected AS in this study the overall median small renal mass growth rate was 0.09 cm/year with a median follow-up of 1.83 years. The growth rate and variability decreased with longer follow-up. No patients developed metastatic disease or died of RCC [355, 356].

Overall survival for primary intervention and AS was 98% and 96% at two years, and 92% and 75% at five years, respectively ($p = 0.06$). At five years, CSS was 99% and 100%, respectively ($p = 0.3$). Active surveillance was not predictive of OS or CSS in regression modelling with relatively short follow-up [355]. Overall, both short- and intermediate-term oncological outcomes indicate that in selected patients with advanced age and/or comorbidities, AS is appropriate for initially monitoring of small renal masses, followed, if required, by treatment for progression [351-353, 357-360].

A multicentre study assessed QoL of patients undergoing immediate intervention vs. AS. Patients undergoing immediate intervention had higher QoL scores at baseline, specifically for physical health. The perceived benefit in physical health persisted for at least one year following intervention. Mental health, which includes domains of depression and anxiety, was not adversely affected while on AS [361].

In 136 biopsy-proven small renal mass (SRM) RCCs managed by AS median follow-up for patients who remained on AS was 5.8 years (interquartile range 3.4-7.5 years). Clear cell RCC grew faster than papillary type 1 SRMs (0.25 and 0.02 cm/year on average, respectively, $p = 0.0003$). Overall, 60 (44.1 %) of the malignant SRM progressed: 49 (82%) by rapid growth (volume doubling), seven (12%) increasing to $\geq$ 4 cm, and four (6.7%) by both criteria. Six patients developed metastases, and all were of ccRCC histology [362].

### 7.1.4.3 Role of renal tumour biopsy before active surveillance
Histological characterisation of small renal masses by renal tumour biopsy is useful to select tumours at lower risk of progression based on grade and histotype, which can be safely managed with AS. Pathology can also help to tailor surveillance imaging schedules. In the largest cohort of biopsy-proven, small, sporadic RCCs followed with AS, a significant difference in growth and progression among different RCC subtypes was observed. Clear cell RCC small renal masses grew faster than papillary type 1 small renal masses (0.25 and 0.02 cm/year on average, respectively, $p = 0.0003$) [362].

### 7.1.4.4 Tumour ablation
#### 7.1.4.4.1 Role of renal mass biopsy
A RMB is required prior to tumour ablation (TA) (see Sections 5.3 Renal tumour biopsy and 5.4 Summary of evidence and recommendations for the diagnostic assessment of RCC). Historically, up to 45% of patients underwent TA of a benign or non-diagnostic mass [363, 364]. A RMB in a separate session reduces over-treatment significantly, with 80% of patients with benign lesions opting not to proceed with TA [364]. Additionally, there is some evidence that the oncological outcome following TA differs according to RCC subtype which should therefore be factored into the decision-making process. In a series of 229 patients with cT1a tumours (mean size 2.5 cm) treated with RFA, the five-year DFS rate was 90% for ccRCC and 100% for pRCC [365]. In another series, the total TA effectiveness rate was 90.9% for ccRCC and 100% for pRCC [366]. A study comparing RFA with surgery suggested worse outcomes of RFA vs. PN in cT1b ccRCC, while no difference was seen in those with non-ccRCC [367]. Furthermore, patients with high-grade RCC or metastasis may choose different treatments over TA. Finally, patients without biopsy or a non-diagnostic biopsy are often assumed to have RCC and will undergo potentially unnecessary radiological follow-up or further treatment.

#### 7.1.4.4.2 Cryoablation
Cryoablation is performed using either a percutaneous- or a laparoscopic-assisted approach, with technical success rates of > 95% [368]. In comparative studies, there was no significant difference in the overall complication rates between laparoscopic- and percutaneous cryoablation [369-371]. One comparative study reported similar OS, CSS, and RFS in 145 laparoscopic patients with a longer follow-up vs. 118 patients treated percutaneously with a shorter follow-up [370]. A shorter average length of hospital stay was found with the percutaneous technique [370-372]. A systematic review including 82 articles reported complication rates ranging between 8 and 20% with most complications being minor [373]. Although a precise definition of tumour recurrence is lacking, the authors reported a lower RFS as compared to that of PN.

Oncological outcomes after cryoablation have generally been favourable for cT1a tumours. In a recently published series of 308 patients with cT1a and cT1b tumours undergoing percutaneous cryoablation, local recurrence was seen in 7.7% of cT1a tumours vs. 34.5% of cT1b tumours. On multivariable regression, the risk
of disease progression increased by 32% with each 1 cm increase in tumour size (HR: 1.32, p < 0.001). Mean decline in eGFR was 11.7 mL/min/1.73 m² [374]. In another large series of 220 patients with biopsy proven cT1 RCC, five-year local RFS was 93.9%, while metastasis-free survival approached 94.4% [368]. A series of 134 patients with T1 RCC (median tumour size 2.8 cm) submitted to percutaneous cryoablation yielded a ten-year DSF of 94% [375].

For cT1b tumours, local tumour control rates drop significantly. One study showed local tumour control in only 60.3% at three years [376]. In another series, the PFS rate was 66.7% at twelve months [377]. Furthermore, recent analyses demonstrated five-year cancer-specific mortality rates of 7.6–9% [378, 379]. On multivariable analysis, cryoablation of cT1b tumours was associated a 2.5-fold increased risk of death from RCC compared with PN [378].

Recurrence after initial cryoablation is often managed with re-cryoablation, but only 45% of patients remain disease-free at two years [380].

7.1.4.4.3 Radiofrequency ablation
Radiofrequency ablation is performed laparoscopically or percutaneously. Several studies compared patients with cT1a tumours treated by laparoscopic or percutaneous RFA [381-384]. Complications occurred in up to 29% of patients but were mostly minor. Complication rates, recurrence rates and CSS were similar in patients treated laparoscopically and percutaneously.

The initial technical success rate on early (i.e., one month) imaging after one session of RFA is 94% for cT1a and 81% for cT1b tumours [385]. This is generally managed by re-RFA, approaching overall total technical success rates > 95% with one or more sessions [386].

Long-term outcomes with over five years of follow-up following RFA have been reported. In recent studies, the five-year OS rate was 73–79% [385, 386], due to patient selection. Oncological outcomes for cT1a tumours have been favourable. In a recent study, the ten-year disease-free survival rate was 82%, but there was a significant drop to 68% for tumours > 3 cm [386]. In series focusing on clinical T1b tumours (4.1–7.0 cm), the five-year DFS rate was 74.5% to 81% [385, 387]. Oncological outcomes appear to be worse than after surgery, but comparative data are severely biased (see Section 7.1.4.3.4). In general, most disease recurrences occur locally and recurrences beyond five years are rare [386, 387].

7.1.4.4.4 Tumour ablation versus surgery
The Guideline Panel performed a protocol-driven systematic review of comparative studies (including > 50 patients) of TA with PN for T1N0M0 renal masses [7]. Twenty-six non-randomised comparative studies published between 2000 and 2019 were included, recruiting a total of 16,780 patients. Four studies compared laparoscopic TA vs. laparoscopic/robotic PN; sixteen studies compared laparoscopic or percutaneous TA vs. open-, laparoscopic- or robotic PN; two studies compared different techniques of TA and four studies compared TA vs. PN vs. RN. In this systematic review, TA as treatment for T1 renal masses was found to be safe in terms of complications and adverse events (AEs), but its long-term oncological effectiveness compared with PN remained unclear. The primary reason for the persisting uncertainty was related to the nature of the available data; most studies were retrospective observational studies with poorly matched controls, or single-arm case series with short follow-up. Many studies were poorly described and lacked a clear comparator. There was also considerable methodological heterogeneity. Another major limitation was the absence of clearly defined primary outcome measures. Even when a clear endpoint such as OS was reported, data were difficult to interpret because of the varying length and type of follow-up amongst studies. The Panel also appraised the published systematic reviews based on the AMSTAR 2 tool which showed critically low or low ratings [7].

Tumour ablation has been demonstrated to be associated with good long-term survival in several single-arm non-comparative studies [388, 389]. Due to the lack of controls, this apparent benefit is subject to significant uncertainties. Whether such benefit is due to the favourable natural history of such tumours or due to the therapeutic efficacy of TA, as compared to PN, remains unknown. In addition, there are data from comparative studies suggesting TA may be associated with worse oncological outcomes in terms of local recurrence and metastatic progression and cancer-specific mortality [261, 378, 379, 390, 391]. However, there appears to be no clinically significant difference in five-year cancer-specific mortality between TA and AS [345].

The Panel concluded that the current data are inadequate to reach conclusions regarding the clinical effectiveness of TA as compared with PN. Given these uncertainties in the presence of only low-quality evidence, TA can only be recommended to frail and/or comorbid patients with small renal masses.

7.1.4.4.5 Stereotactic ablative radiotherapy
Stereotactic ablative radiotherapy (SABR) has been emerging as a treatment option for medically inoperable patients with localised cT1a and cT1b tumours. Patients usually receive 26 Gy in a single fraction, three
fractions of 14 Gy or five fractions of 6 Gy [392, 393]. In a systematic review or non-comparative single-arm studies, the local control rate was 97.2% and the mean change in eGFR was 7.7 mL/min/1.73 m². Grade 3 or 4 toxicities occurred in 1.5% of patients. However, viable tumour cells are often seen in post-SABR biopsies, although their clinical significance remains unclear [393]. Although early results of SABR are encouraging, more evidence from randomised trials is needed.

7.1.4.4.6 Other ablative techniques
Some studies have shown the feasibility of other ablative techniques, such as microwave ablation, high-intensity focused US ablation and non-thermal irreversible electroporation. However, these techniques are still considered experimental. The best evidence base for these techniques exists for percutaneous microwave ablation. In a study of 185 patients with a median follow-up of 40 months, the five-year local progression rate was 3.2%, while 4.3% developed distant metastases [394]. Results appear to be favourable for cT1b tumours as well [395]. Overall, current data on cryoablation, RFA and microwave ablation of cT1a renal tumours indicate short-term equivalence with regards to complications, oncological and renal functional outcomes [396].

7.2 Treatment of locally advanced RCC

7.2.1 Introduction
In addition to the summary of evidence and recommendations outlined in Section 7.1 for localised RCC, certain therapeutic strategies arise in specific situations for locally advanced disease.

7.2.2 Role of lymph node invasion in locally advanced RCC
In locally advanced RCC, the role of LND is still controversial. The only available RCT demonstrated no survival benefit for patients undergoing LND but this trial mainly included organ-confined disease cases [275]. In the setting of locally advanced disease, several papers addressed the topic with contradictory results, as did several systematic reviews. Bhindi et al. could not confirm any survival benefit in patients at high risk of progression treated with LND [397]. More recently, Luo et al. reported a systematic review and meta-analyses showing a survival benefit in patients with locally advanced disease treated with LND [398]. More specifically, thirteen studies on patients with LND and non-LND were identified and included in the analysis. In the subgroup of locally advanced RCC (cT3-T4NxM0), LND showed a significantly better OS rate in patients who had undergone LND compared to those without LND (HR: 0.73, 95% CI: 0.60–0.90, p = 0.003).

7.2.2.1 Management of clinically negative lymph nodes (cN-) in locally advanced RCC
In case of cN-, the probability of finding pathologically confirmed LN metastases ranges between 0 and 25%, depending mainly on primary tumour size and the presence of distant metastases [399]. In case of clinically negative LNs (cN-) at imaging, removal of LNs is justified only if visible or palpable during surgery [400], at least for staging, prognosis and follow-up implications although a benefit in terms of cancer control has not yet been demonstrated [277, 397]. Whether to extend the LND also to retroperitoneal areas without cN+ remains controversial [276].
7.2.2.2 Management of clinically positive lymph nodes (cN+) in locally advanced RCC
In case of cN+, the probability to find pathologically confirmed LN metastases ranges between 10.3% (cT1 tumours) up to 54.5% in case of locally advanced disease. In cN+, removal of visible and palpable nodes during lymphadenectomy is always justified [400], at least for staging, prognosis and follow-up implications, although a benefit in terms of cancer control has not yet been demonstrated [277, 397].

7.2.3 Management of locally advanced unresectable RCC
In case of locally advanced unresectable RCC, a multi-disciplinary evaluation, including urologists, medical oncologists and radiation therapists is suggested to maximise cancer control, pain control and the best supportive care. In patients with non-resectable disease, embolisation can control symptoms, including visible haematuria or flank pain [291, 292, 401]. The use of systemic therapy to downsize tumours is experimental and cannot be recommended outside clinical trials.

7.2.4 Management of RCC with venous tumour thrombus
Tumour thrombus formation in RCC patients is a significant adverse prognostic factor. Traditionally, patients with venous tumour thrombus undergo surgery to remove the kidney and tumour thrombus. Aggressive surgical resection is widely accepted as the default management option for patients with venous tumour thrombus [402-410].

7.2.4.1 The evidence base for surgery in patients with venous tumour thrombus
Data whether patients with venous tumour thrombus should undergo surgery is derived from case series only. In one of the largest published studies a higher level of thrombus was not associated with increased tumour dissemination to LNs, perinephric fat or distant metastasis [407]. Therefore, all patients with non-metastatic disease and venous tumour thrombus, and an acceptable PS, should be considered for surgical intervention, irrespective of the extent of tumour thrombus at presentation. The surgical technique and approach for each case should be selected based on the extent of tumour thrombus.

7.2.4.2 The evidence base for different surgical strategies
A systematic review was undertaken which included only comparative studies on the management of venous tumour thrombus in non-metastatic RCC [411, 412]. Only five studies were eligible for final inclusion, with a high risk of bias across all studies.

Minimal access techniques resulted in significantly shorter operating time compared with traditional median sternotomy [413-416].

The surgical method selected depended on the level of tumour thrombus and the grade of occlusion of the IVC [411, 413, 414, 417]. The relative benefits and harms of other strategies and approaches regarding access to the IVC and the role of IVC filters and bypass procedures remain uncertain.

7.2.5 Neoadjuvant and adjuvant therapy
Neoadjuvant therapy is currently under investigation and available in clinical trials.

There is currently no evidence from a recent systematic review (including ten retrospective studies and two RCTs) that adjuvant radiation therapy increases survival [418].

The impact on OS of adjuvant tumour vaccination in selected patients undergoing nephrectomy for T3 renal carcinomas remains unconfirmed [419-423] (LE: 1b). A similar observation was made in an adjuvant trial of girentuximab, a monoclonal antibody against carbonic anhydrase IX (CAIX) (ARISER Study) [424].
At present, there is no OS data supporting the use of adjuvant VEGFR or mTOR inhibitors. Thus far, several RCTs comparing VEGFR-TKI vs. placebo have been published [425-432]. One of the largest adjuvant trials compared sunitinib vs. sorafenib vs. placebo (ASSURE). Its interim results published in 2015 demonstrated no significant differences in DFS or OS between the experimental arms and placebo [391]. The study published its updated analysis on a subset of high-risk patients in 2018, which demonstrated five-year DFS rates of 47.7%, 49.9%, and 50.0%, respectively for sunitinib, sorafenib, and placebo and five-year OS of 75.2%, 80.2%, and 76.5%, respectively, without significant difference. The results indicated that adjuvant therapy with sunitinib or sorafenib have no survival effect [425, 426].

The PROTECT study included 1,135 patients treated with pazopanib (n = 571) vs. placebo (n = 564) in a 1:1 randomisation [427]. The primary endpoint was amended after 403 patients received a starting dose of pazopanib 800 mg vs. placebo, to DFS with pazopanib 600 mg. The primary analysis results of DFS in the ITT pazopanib 600 mg arm were not significant (HR: 0.86, 95% CI: 0.7–1.06, p = 0.16). Disease-free survival in the ITT pazopanib 800 mg population was improved (HR: 0.69, 95% CI: 0.51–0.94, p = 0.02). No benefit in OS was seen in the ITT pazopanib 600 mg population (HR: 0.79 [0.57–1.09, p = 0.16]). A subset analysis of these studies suggests that full-dose therapy is associated with improved DFS. Furthermore, no strong association of DFS with OS has been established [428].

The ATLAS study, a randomised, double-blind phase III trial including patients receiving (1:1) oral twice-daily axitinib 5 mg or placebo for ≤ 3 years, for a minimum of one year unless patients experienced a recurrence, had a second primary malignancy, significant toxicity, or withdrew consent. The primary endpoint was DFS. A total of 724 patients (363 vs. 361, for axitinib vs. placebo) were randomised. The trial was stopped due to futility at a pre-planned interim analysis at 203 DFS events. There was no significant difference in DFS per independent review committee (IRC) (HR: 0.870, 95% CI: 0.660–1.147, p = 0.3211). Overall survival data were not mature. Similar AEs (99% vs. 92%) and serious AEs (19% vs. 14%), but more grade 3/4 AEs (61% vs. 30%) were reported for axitinib vs. placebo [431].

In contrast, the S-TRAC study included 615 patients randomised to either sunitinib or placebo [433]. The results showed a benefit of sunitinib over placebo for DFS (HR: 0.76, 95% CI: 0.59–0.98, p = 0.03). Grade 3/4 toxicity in the study was 60.5% for patients receiving sunitinib, which translated into significant differences in QoL for loss of appetite and diarrhoea [432]. The study published its updated results in 2018; the results for DFS had not changed significantly (HR: 0.74, 95% CI: 0.55–0.99, p = 0.04) and median OS was not reached in either arm (HR: 0.92, 95% CI: 0.66–1.28, p = 0.6) [432].

The last trial being reported is the SORCE RCT which investigated one and three years of adjuvant sorafenib and which also included patients with non-clear cell subtypes [434]. In SORCE no differences in DFS or OS for patients with high risk of recurrence, or patients with ccRCC only was found. Median DFS was not reached for three years of sorafenib or for placebo (HR: 1.01, 95% CI: 0.83–1.23; p = 0.95), and OS was different (HR: 1.06, 95% CI: 0.82–1.38; p = 0.638). More than half of participants stopped treatment by twelve months. Adverse event rates grade ≥ 3 were 58.6% and 63.9% receiving one year or three years of sorafenib [434].

To date, the results of one RCT on the role of adjuvant everolimus (EVEREST) in patients with RCC is still unpublished.

A recent meta-analysis of phase III randomised clinical trials on adjuvant TKIs in ccRCC was published [435]. In the overall population, the pooled HR of OS and DFS was 0.89 (95% CI: 0.76–1.04) and 0.84 (95% CI: 0.76–0.93), respectively. In the low- and high-risk populations, the pooled DFS HR was 0.98 (95% CI: 0.82–1.17) and 0.85 (95% CI: 0.75–0.97), respectively. Adjuvant use of TKIs does not appear to provide a statistically significant OS benefit. However, a benefit in DFS has been observed in overall and high-risk populations, suggesting that better selection of patients might be important for the evaluation of adjuvant therapies in RCC, although these results must be balanced against significant toxicity.

In summary, there is currently a lack of proven benefits of adjuvant therapy with VEGFR-TKIs for patients with high-risk RCC after nephrectomy. The European Medicines Agency (EMA) has not approved sunitinib for adjuvant treatment of high-risk RCC in adult patients after nephrectomy.

Immune checkpoint inhibitors, designed to restore and enhance immune activity against cancer cells, have shown impressive efficacy in the metastatic setting. Several trials have tested these agents in metastatic RCC, leading to a still-ongoing revolution in the treatment pathway. The inclusion of these drugs in clinical practice has led to a third generation of adjuvant studies on ICIs. These include the programmed death receptor-1
inhibitors nivolumab (PROSPER; NCT03055013), pembrolizumab (KEYNOTE-564; NCT03142334), as well as the programmed death ligand-1 inhibitors atezolizumab (IMmotion010; NCT03024996) and durvalumab (RAMPART [Renal Adjuvant MultiPle Arm Randomised Trial]; NCT03288532). Recruitment for most of these studies is still ongoing and except for KEYNOTE-564, results are awaited as of 2022-2023.

The Keynote-564 trial is the first trial to report positive primary endpoint data on DFS [436]. Keynote-564 evaluated pembrolizumab (17 cycles of 3-weekly therapy) vs. placebo as adjuvant therapy for 994 patients with intermediate (pT2, grade 4 or sarcomatoid, N0 M0; or pT3, any grade, N0, M0) or high risk (pT4, any grade, N0 M0; or pT any stage, and grade, or N+, M0), or M1 [no evidence of disease (NED) after primary tumour plus soft tissue metastases completely resected ≤ one year from nephrectomy] disease. The median follow-up, defined as time from randomisation to data cut-off, was 24.1 months. The primary endpoint of DFS per investigator assessment was significantly improved in the pembrolizumab group vs. placebo (HR: 0.68, 95% CI: 0.53-0.87, p = 0.001). The estimated 24-month DFS rate was 77% vs. 68% for pembrolizumab and placebo, respectively. Benefit occurred across broad subgroups of patients including those with M1/NED disease post-surgery (n = 58 [6%]). Investigator assessed DFS was considered preferable to DFS by central review due to its clinical applicability. Overall survival showed a non-statistically significant trend towards a benefit in the pembrolizumab arm (HR: 0.54, 95% CI: 0.30-0.96, p = 0.0164). Follow-up was short and few OS events occurred (two-year OS rate of 97% [pembrolizumab] vs. 94% [placebo]). Grade 3-5 all-cause AEs occurred in 32% vs. 18% of patients for pembrolizumab and placebo, respectively. Quality of life assessment by FKSI-DRS and QLQ30 did not show a statistically significant or clinically meaningful deterioration in health-related QoL or symptom scores for either adjuvant pembrolizumab or placebo.

After GRADE assessment the Panel members reached consensus and issued a weak recommendation for adjuvant pembrolizumab for patients with high-risk (defined as per study) operable ccRCC until final OS data are available [437]. Although the guidelines previously did not recommend sunitinib despite positive DFS data in the absence of OS benefit [432, 433, 438], the Panel decided for adjuvant pembrolizumab for the following reasons:

- Immune checkpoint inhibitor therapy has a different mode of action than VEGFR-TKI resulting in complete responses in up to 16% of patients in PD-1 unselected populations in metastatic disease [439]. Despite immature OS data with the early OS signal potentially driven by the M1 population the Panel cannot exclude that a survival benefit will emerge. This was not the case in the adjuvant sunitinib trial (STRAC) [432, 436].
- Pembrolizumab is better tolerated than sunitinib and does not lead to a decline of QoL compared to placebo as did sunitinib [436, 440].
- A number of adjuvant VEGFR trials failed to show a DFS advantage for sunitinib or other VEGFR inhibitors resulting in a negative meta-analysis [441].

The Panel considered the following cautionary points in their decision leading to a weak recommendation:

- A high proportion of patients, cured by surgery, are receiving unnecessary, and potentially harmful treatment.
- The tolerability profile is acceptable but grade 3-5 AEs were higher with 14.7% in the pembrolizumab arm as in the placebo arm (occurring in approximately one-third of patients, all cause). Approximately 18% of patients required treatment discontinuation early for AEs which gives a broad indicator of tolerability. Endocrine AEs may require life-long therapy.
- Other ICI trials have not yet reported and are not available for meta-analysis.
- Biomarker analysis to predict outcome and AEs are not available.
- Final OS data are not yet available.

7.2.5.1 Summary of evidence and recommendations for neoadjuvant and adjuvant therapy

**Summary of evidence LE**

- Adjuvant tyrosine kinase inhibitor therapy does not improve OS after nephrectomy. 1b
- In one single RCT, in selected high-risk patients, adjuvant sunitinib improved DFS but not OS. 1b
- Adjuvant sorafenib, pazopanib, everolimus, girentuximab or axitinib does not improve DFS or OS after nephrectomy. 1b
- Adjuvant pembrolizumab after nephrectomy in patients with high-risk RCC improves disease-free survival. 1b
- In one RCT, in selected intermediate-high or high-risk patients or M1 NED, adjuvant pembrolizumab improved DFS. 1b
- Adjuvant RCTs are ongoing to evaluate the benefit of adjuvant immunotherapy after nephrectomy in high-risk patients. 1b

**Recommendations**

- Do not offer adjuvant therapy with sorafenib, pazopanib, everolimus, girentuximab or axitinib. Strong
- Do not offer adjuvant sunitinib following surgically resected high-risk clear-cell renal cell carcinoma (ccRCC). Weak
- Offer adjuvant pembrolizumab to patients with ccRCC following surgery with curative intent with a risk of recurrence as defined in the trial.* Weak

*p T2 G4 or pT3 any G; pT4 any G; pN+ Any G.

7.3 Advanced/metastatic RCC

7.3.1 Local therapy of advanced/metastatic RCC

7.3.1.1 Cytoreductive nephrectomy

Tumour resection is potentially curative only if all tumour deposits are excised. This includes patients with the primary tumour in place and single- or oligometastatic resectable disease. For most patients with metastatic disease, cytoreductive nephrectomy (CN) is palliative and systemic treatments are necessary. In a combined analysis of two RCTs comparing CN+ IFN-based immunotherapy vs. IFN-based immunotherapy only, increased long-term survival was found in patients treated with CN [442]. However, IFN-based immunotherapy is no longer relevant in contemporary clinical practice. In order to investigate the role and sequence of CN in the era of targeted therapy, a structured literature assessment was performed to identify relevant RCTs and systematic reviews published between July 1st - June 30th 2019.
Two RCTs [400, 443] and a narrative systematic review were identified [444]. The narrative systematic review included both RCTs and ten non-randomised studies. CARMENA, a phase III non-inferiority RCT investigating immediate CN followed by sunitinib vs. sunitinib alone, showed that sunitinib alone was not inferior to CN followed by sunitinib with regard to OS [445]. The trial included 450 patients with metastatic ccRCC of intermediate- and MSKCC poor-risk of whom 226 were randomised to immediate CN followed by sunitinib and 224 to sunitinib alone. Patients in both arms had a median of two metastatic sites. Patients in both arms had a tumour burden of a median/mean of 140 mL of measurable disease by Response Evaluation Criteria In Solid Tumours (RECIST) 1.1, of which 80 mL accounted for the primary tumour. The study did not reach the full accrual of 576 patients and the Independent Data Monitoring Commission (IDMC) advised the trial steering committee to close the study. In an ITT analysis after a median follow-up of 50.9 months, median OS with CN was 13.9 months vs. 18.4 months with sunitinib alone (HR: 0.89, 95% CI: 0.71–1.10). This was found in both risk groups. For MSKCC intermediate-risk patients (n = 256) median OS was 19.0 months with CN and 23.4 months with sunitinib alone (HR: 0.92, 95% CI: 0.60–1.24) and for MSKCC poor risk (n = 193) 10.2 months and 13.3 months, respectively (HR: 0.86, 95% CI: 0.62–1.17). Non-inferiority was also found in two per-protocol analyses accounting for patients in the CN arm who either did not undergo surgery (n = 16) or did not receive sunitinib (n = 40), and patients in the sunitinib-only arm who did not receive the study drug (n = 11). Median PFS in the ITT population was 7.2 months with CN and 8.3 months with sunitinib alone (HR: 0.82, 95% CI: 0.67–1.00). The clinical benefit rate, defined as disease control beyond twelve weeks was 36.6% with CN and 47.9% with sunitinib alone (p = 0.022). Of note, 38 patients in the sunitinib-only arm required secondary CN due to acute symptoms or for complete or near-complete response. The median time from randomisation to secondary CN was 11.1 months.

The randomised EORTC SURTIME study revealed that the sequence of CN and sunitinib did not affect PFS (HR: 0.88, 95% CI: 0.59–1.37, p = 0.569). The trial accrued poorly and therefore results are mainly exploratory. However, in secondary endpoint analysis a strong OS benefit was observed in favour of the deferred CN approach in the ITT population with a median OS of 32.4 (range 14.5–65.3) months in the deferred CN arm vs. 15.0 (9.3–29.5) months in the immediate CN arm (HR: 0.57, 95% CI: 0.34–0.95, p = 0.032). The deferred CN approach appears to select out patients with inherent resistance to systemic therapy [446]. This confirms previous findings from single-arm phase II studies [444, 447]. Moreover, deferred CN and surgery appear safe after sunitinib which supports the findings, with some caution, of the only available RCT. In patients with poor PS or IMDC poor risk, small primaries and high metastatic volume and/or a sarcomatoid tumour, CN is not recommended [448]. These data are confirmed by CARMENA [445] and upfront pre-surgical VEGFR-targeted therapy followed by CN seems to be beneficial [449].

Meanwhile first-line therapy recommendations for patients with their primary tumour in place have changed to ICI combination therapy (see Section 7.4.2.4) with sunitinib and other VEGFR-TKI monotherapies reserved for those who cannot tolerate ICI combination or have no access to these drugs. High-level evidence regarding CN is not available for ICI combinations but up to 30% of patients with primary metastatic disease, treated with their tumour in place, were included in the pivotal ICI combination trials (Table 7.2). The subgroup HRs, where available, suggest better outcomes for the ICI combination compared to sunitinib monotherapy. In mRCC patients without a need for immediate drug treatment, a recent systematic review evaluating effects of CN demonstrated an OS advantage of CN [444]. These data were supported by a nation-wide registry study showing that patients selected for primary CN had a significant OS advantage across all age groups [450].

The results of CARMENA and SURTIME demonstrated that patients who require systemic therapy benefit from immediate drug treatment. While randomised trials to investigate deferred vs. no cytoreductive nephrectomy with ICI and ICI combinations are ongoing, the exploratory results from the ICI combination trials demonstrate that the respective IO+IO or TKI+IO combinations have a superior effect on the primary tumour and metastatic sites when compared to sunitinib alone (Table 7.2). In accordance with the CARMENA and SURTIME data this suggests that mRCC patients and IMDC intermediate- and poor-risk groups with their primary tumour in place should be treated with upfront IO-based combinations. In patients with a clinical response to IO-based combinations, a subsequent CN may be considered.

7.3.1.1 Embolisation of the primary tumour
In patients unfit for surgery or with non-resectable disease, embolisation can control symptoms including visible haematuria or flank pain [291, 292, 401] (see recommendations Section 7.1.2.2.4).

7.3.2 Local therapy of metastases in metastatic RCC
A systematic review of the local treatment of metastases from RCC in any organ was undertaken [456]. Interventions included metastasectomy, various radiotherapy modalities, and no local treatment. The outcomes assessed were OS, CSS and PFS, local symptom control and AEs. A risk-of-bias assessment was conducted [457]. Of the 2,235 studies identified only sixteen non-randomised comparative studies were included.

Eight studies reported on local therapies of RCC-metastases in various organs [458-465]. This included metastases to any single organ or multiple organs. Three studies reported on local therapies of RCC metastases in bone, including the spine [466-468], two in the brain [469, 470] and one each in the liver [471], lung [472] and pancreas [473]. Three studies were published as abstracts only [461, 463, 472]. Data were too
heterogeneous to meta-analyse. There was considerable variation in the type and distribution of systemic therapies (cytokines and VEGF-inhibitors) and in reporting the results.

7.3.2.1 Complete versus no/incomplete metastasectomy
A systematic review, including only eight studies, compared complete vs. no and/or incomplete metastasectomy of RCC metastases in various organs [458-465]. In one study complete resection was achieved in only 45% of the metastasectomy cohort, which was compared with no metastasectomy [465]. Non-surgical modalities were not applied. Six studies [459-461, 463-465] reported a significantly longer median OS or CSS following complete metastasectomy (the median value for OS or CSS was 40.75 months, range 23–122 months) compared with incomplete and/or no metastasectomy (the median value for OS or CSS was 14.8 months, range 8.4–55.5 months). Of the two remaining studies, one [458] showed no significant difference in CSS between complete and no metastasectomy, and one [462] reported a longer median OS for metastasectomy albeit no p-value was provided.

Three studies reported on treatment of RCC metastases in the lung [472], liver [471], and pancreas [473], respectively. The lung study reported a significantly higher median OS for metastasectomy vs. medical therapy only for both targeted therapy and immunotherapy. Similarly, the liver and pancreas study reported a significantly higher median OS and five-year OS for metastasectomy vs. no metastasectomy.

7.3.2.2 Local therapies for RCC bone metastases
Of the three studies identified, one compared single-dose image-guided radiotherapy (IGRT) with hypofractionated IGRT in patients with RCC bone metastases [468]. Single-dose IGRT (≥ 24 Gy) had a significantly better three-year actuarial local PFS rate, also shown by Cox regression analysis. Another study compared metastasectomy/curettage and local stabilisation with no surgery of solitary RCC bone metastases in various locations [466]. A significantly higher five-year CSS rate was observed in the intervention group. After adjusting for prior nephrectomy, gender and age, multi-variable analysis still favoured metastasectomy/curettage and stabilisation. A third study compared the efficacy and durability of pain relief between single-dose stereotactic body radiotherapy (SBRT) and conventional radiotherapy in patients with RCC bone metastases to the spine [467]. Pain, ORR, time-to-pain relief and duration of pain relief were similar.

7.3.2.3 Local therapies for RCC brain metastases
Two studies on RCC brain metastases were included. A three-armed study compared stereotactic radiosurgery (SRS) vs. whole brain radiotherapy (WBRT) vs. SRS and WBRT [469]. Each group was further subdivided into recursive partitioning analysis (RPA) classes I to III (I favourable, II moderate and III poor patient status). Two-year OS and intra-cerebral control were equivalent in patients treated with SRS alone and SRS plus WBRT.

Both treatments were superior to WBRT alone in the general study population and in the RPA subgroup analyses. A comparison of SRS vs. SRS and WBRT in a subgroup analysis of RPA class I showed significantly better two-year OS and intra-cerebral control for SRS plus WBRT based on only three participants. The other study compared fractionated stereotactic radiotherapy (FSRT) with metastasectomy and conventional radiotherapy or conventional radiotherapy alone [470]. Several patients in all groups underwent alternative surgical and non-surgical treatments after initial treatment. One-, two- and three-year survival rates were higher but not significantly so for FSRT as for metastasectomy and conventional radiotherapy, or conventional radiotherapy alone. Fractionated stereotactic radiotherapy did not result in a significantly better two-year local control rate compared with metastasectomy plus conventional radiotherapy.

7.3.2.4 Embolisation of metastases
Embolisation prior to resection of hypervascular bone or spinal metastases can reduce intra-operative blood loss [166]. In selected patients with painful bone or paravertebral metastases, embolisation can relieve symptoms [167] (see recommendation Section 7.1.2.2.4).

7.3.2.5 Adjuvant treatment in cM0 patients after metastasectomy
Patients after metastasectomy and no evidence of disease (cM0) have a high risk of relapse. Recent attempts to reduce RFS by offering adjuvant TKI treatment after metastasectomy did not demonstrate an improvement in RFS. In a recent phase II trial 129 patients were randomised to either pazopanib 800 mg daily vs. placebo for 52 weeks. The primary study endpoint of a 42% DFS improvement from 25% to 45% at three years was not met. Hazard ratio for DFS in pazopanib vs. placebo-treated patients was 0.85 (0.55–1.31), p = 0.47 [168]. A second phase II trial randomised 69 ccRCC patients after metastasectomy and no evidence of disease to either sorafenib (400 mg twice daily) or observation. The study was terminated early due to slow accrual and the availability of new agents and multimodal treatment options, including surgery or a locoregional approach. The primary endpoint of RFS was not reached with a RFS of 21 months in the sorafenib arms vs. 37 months in the observation arm (p = 0.404) [169].
KEYNOTE-564 included a small percentage of patients who were treated by nephrectomy and complete metastasectomy within one year after primary diagnosis (6% in the experimental arm and 6% in the placebo arm) [436]. A metachronous interval of < 1 year for recurrences following surgery with curative intent is a poor prognostic factor by IMDC classification [249, 474]. Systemic therapy based on immune combinations has stronger levels of evidence than surgery in this intermediate/advanced disease setting [475]. Also, TKI-driven adjuvant trials after metastasectomy have shown no DFS or OS benefit [168, 169].

Results for single-agent pembrolizumab post-surgery for metastatic disease are therefore difficult to interpret due to the small subgroup. Nevertheless, the DFS HR of 0.29 (95% CI: 0.12-0.69) in favour of resection of M1 to NED plus pembrolizumab shows that patients with subclinical, but progressive disease who were subjected to metastasectomy had a benefit of adjuvant systemic therapy with pembrolizumab. Based on the current data it cannot be concluded that for patients with oligo-progressive disease, metastasectomy within the first year of initial diagnosis of the primary and subsequent adjuvant pembrolizumab is superior to a period of observation and dual IO based combination first-line therapy upon progression. Data from the TKI era suggest that patients with oligometastatic disease recurrence can be observed for up to a median of sixteen months before systemic therapy is required and that this practice is common in real-world settings (30%) [476, 477].

In addition, it is possible that metastatectomy may lead to poorer outcomes compared to systemic therapy approaches as a relapse within the first twelve months and presentation with synchronous (oligo-) metastatic disease is attributed to the IMDC intermediate risk-group. The Panel therefore does not encourage metastasectomy and adjuvant pembrolizumab in this advanced population with recurrent disease within one year after primary surgery. A careful reassessment of disease status to rule out rapid progressive disease should be performed. Data from other adjuvant ICI studies including M1 NED subgroups may clarify this issue further (IMmotion010, NCT03024996).

7.4.2 Targeted therapies
In sporadic ccRCC, hypoxia-inducible factor (HIF) accumulation due to VHL-inactivation results in overexpression of VEGF and platelet-derived growth factor (PDGF), which promote neo-angiogenesis [478-480]. This process substantially contributes to the development and progression of RCC. Several targeting drugs for the treatment of mRCC are approved in both the USA and Europe.

Most published trials have selected for clear-cell carcinoma subtypes, thus no robust evidence-based recommendations can be given for non-ccRCC subtypes.

In major trials leading to registration of the approved targeted agents, patients were stratified according to the IMDC risk model (Table 7.3) [251].

7.4.2.1 Tyrosine kinase inhibitors

7.4.2.1.1 Sorafenib
Sorafenib is an oral multi-kinase inhibitor. A trial compared sorafenib and placebo after failure of prior systemic immunotherapy or in patients unfit for immunotherapy. Sorafenib improved PFS (HR: 0.44, 95% CI: 0.35–0.55, p < 0.01) [481]. Overall survival improved in patients initially assigned to placebo who were censored at crossover [482].

In patients with previously untreated mRCC sorafenib was not superior to IFN-α (phase II study). A number of studies have used sorafenib as the control arm in sunitinib-refractory disease vs. axitinib, dovitinib or temsirolimus. None showed superior survival for the study drug compared to sorafenib.

7.4.2.1.2 Sunitinib
Sunitinib is an oral TKI inhibitor and has anti-tumour and anti-angiogenic activity. First-line monotherapy with sunitinib demonstrated significantly longer PFS compared with IFN-α. Overall survival was greater in patients treated with sunitinib (26.4 months) vs. IFN-α (21.8 months) despite crossover [483].

In the EFFECT trial, sunitinib 50 mg/day (four weeks on/two weeks off) was compared with continuous uninterrupted sunitinib 37.5 mg/day in patients with cc-mRCC [484]. No significant differences in OS were seen (23.1 vs. 23.5 months, p = 0.615). Toxicity was comparable in both arms. Because of the non-significant, but numerically longer time to progression with the standard 50 mg dosage, the authors recommended using this regimen. Alternate scheduling of sunitinib (two weeks on/one week off) is being used to manage toxicity, but robust data to support its use is lacking [485, 486].

7.4.2.1.3 Pazopanib
Pazopanib is an oral angiogenesis inhibitor. In a trial of pazopanib vs. placebo in treatment-naïve mRCC patients and cytokine-treated patients, a significant improvement in PFS and tumour response was observed [487].

A non-inferiority trial comparing pazopanib with sunitinib (COMPARZ) established pazopanib as
an alternative to sunitinib. It showed that pazopanib was not associated with significantly worse PFS or OS compared to sunitinib. The two drugs had different toxicity profiles, and QoL was better with pazopanib [488]. In another patient-preference study (PISCES), patients preferred pazopanib to sunitinib (70% vs. 22%, p < 0.05) due to symptomatic toxicity [489]. Both studies were limited in that intermittent therapy (sunitinib) was compared with continuous therapy (pazopanib).

7.4.2.1.4 Axitinib
Axitinib is an oral selective second-generation inhibitor of VEGFR-1, -2, and -3. Axitinib was first evaluated as second-line treatment. In the AXIS trial, axitinib was compared to sorafenib in patients who had previously failed cytokine treatment or targeted agents (mainly sunitinib) [490].

The overall median PFS was greater for axitinib than sorafenib. Axitinib was associated with a greater PFS than sorafenib (4.8 vs. 3.4 months) after progression on sunitinib. Axitinib showed grade 3 diarrhoea in 11%, hypertension in 16%, and fatigue in 11% of patients. Final analysis of OS showed no significant differences between axitinib or sorafenib [491, 492]. In a randomised phase III trial of axitinib vs. sorafenib in first-line treatment-naïve cc-mRCC, a significant difference in median PFS between the treatment groups was not demonstrated, although the study was underpowered, raising the possibility of a type II error [493]. As a result of this study, axitinib is not approved for first-line therapy.

7.4.2.1.5 Cabozantinib
Cabozantinib is an oral inhibitor of tyrosine kinase, including MET, VEGF and AXL. Cabozantinib was investigated in a phase I study in patients resistant to VEGFR and mTOR inhibitors demonstrating objective responses and disease control [221]. Based on these results an RCT investigated cabozantinib vs. everolimus in patients with ccRCC failing one or more VEGF-targeted therapies (METEOR) [494, 495]. Cabozantinib delayed PFS compared to everolimus in VEGF-targeted therapy refractory disease (HR: 0.58, 95% CI: 0.45–0.75) [494] (LE: 1b). The median OS was 21.4 months (95% CI: 18.7 to not estimable) with cabozantinib and 16.5 months (95% CI: 14.7–18.8) with everolimus in VEGF-resistant RCC. The HR for death was 0.66 (95% CI: 0.53–0.83, p = 0.0003) [495]. Grade 3 or 4 AEs were reported in 74% with cabozantinib and 65% with everolimus. Adverse events were managed with dose reductions; doses were reduced in 60% of the patients who received cabozantinib.

The Alliance A031203 CABOSUN randomised phase II trial comparing cabozantinib and sunitinib in first-line in 157 intermediate- and poor-risk patients favoured cabozantinib for RR and PFS, but not OS [496, 497]. Cabozantinib significantly increased median PFS (8.2 vs. 5.6 months, adjusted HR: 0.66, 95% CI: 0.46 to 0.95; one-sided p = 0.012). Objective response rate was 46% (95% CI: 34–57) for cabozantinib vs. 18% (95% CI: 10–28) for sunitinib. No difference in OS was seen. Due to limitations of the statistical analyses within this trial, the evidence is inferior over existing choices.

7.4.2.1.6 Lenvatinib
Lenvatinib is an oral multi-target TKI of VEGFR1, VEGFR2, and VEGFR3, with inhibitory activity against fibroblast growth factor receptors (FGFR1, FGFR2, FGFR3, and FGFR4), platelet growth factor receptor (PDGFR-α), re-arranged during transfection (RET) and receptor for stem cell factor (KIT). It has recently been investigated in a randomised phase II study in combination with everolimus vs. lenvatinib or everolimus alone (see Section 7.4.4.1.1 for discussion of results) [498].

7.4.2.1.7 Tivozanib
Tivozanib is a potent and selective TKI of VEGFR1, VEGFR2, and VEGFR3 and was compared in two phase III trials with sorafenib in patients with mRCC [499, 500]. Tivozanib was approved by the EMA in front-line mRCC. While it was associated with a PFS advantage in both studies, no OS advantage was seen. In view of the choice of sorafenib as the control arm in the front-line trial, the Panel considers there is too much uncertainty, and too many attractive alternatives, to support its use in this front-line setting.

7.4.2.2 Monoclonal VEGF antibody
Bevacizumab is a humanised monoclonal antibody. The double-blind AVOREN study compared bevacizumab plus IFN-α with IFN-α monotherapy in mRCC. Overall response was higher in the bevacizumab plus IFN-α group. Median PFS increased from 5.4 months with IFN-α to 10.2 months with bevacizumab plus IFN-α. No benefit was seen in MSKCC poor-risk patients. Median OS in this trial, which allowed crossover after progression, was not greater in the bevacizumab/IFN-α group (23.3 vs. 21.3 months) [501].

An open-label trial (CALGB 90206) of bevacizumab plus IFN-α vs. IFN-α showed a higher median PFS for the combination group [502, 503]. Objective response rate was also higher in the combination group. Overall toxicity was greater for bevacizumab plus IFN-α, with significantly more grade 3 hypertension, anorexia,
fatigue, and proteinuria. Bevacizumab, alone, or in combinations, is not widely recommended or used in mRCC due to more attractive alternatives.

7.4.2.3 **mTOR inhibitors**

7.4.2.3.1 **Temsirolimus**
Temsirolimus is a specific inhibitor of mTOR [504]. Its use has been superseded as front-line treatment option.

7.4.2.3.2 **Everolimus**
Everolimus is an oral mTOR inhibitor, which is established in the treatment of VEGF-refractory disease. The RECORD-1 study compared everolimus plus best supportive care (BSC) vs. placebo plus BSC in patients with previously failed anti-VEGFR treatment (or previously intolerant of VEGF-targeted therapy) [505]. The data showed a median PFS of 4 vs. 1.9 months for everolimus and placebo, respectively [505].

The Panel consider, even in the absence of conclusive data, that everolimus may present a therapeutic option in patients who were intolerant to, or previously failed, immune- and VEGFR-targeted therapies (LE: 4). Recent phase II data suggest adding lenvatinib is attractive.

7.4.2.4 **Summary of evidence and recommendations for targeted therapy in metastatic clear-cell RCC**

7.4.3 **Immunotherapy**

7.4.3.1 **Immune checkpoint inhibitors**

7.4.3.1.1 **Immuno-oncology monotherapy**
Immune checkpoint inhibitor with monoclonal antibodies targets and blocks the inhibitory T-cell receptor PD-1 or cytotoxic T-lymphocyte-associated antigen 4 (CTLA-4)-signalling to restore tumour-specific T-cell immunity [506]. Immune checkpoint inhibitor monotherapy has been investigated as second- and third-line therapy. A phase III trial of nivolumab vs. everolimus after one or two lines of VEGF-targeted therapy for mRCC with a
clear cell component (CheckMate 025, NCT01668784) reported a longer OS, better QoL and fewer grade 3 or 4 AEs with nivolumab than with everolimus [507]. Nivolumab has superior OS to everolimus (HR: 0.73, 95% CI: 0.57–0.93, p < 0.002) in VEGF-refractory RCC with a median OS of 25 months for nivolumab and 19.6 months for everolimus with a five-year OS probability of 26% vs. 18% [508] (LE: 1b). Patients who had failed multiple lines of VEGF-targeted therapy were included in this trial making the results broadly applicable. The trial included 15% MSKCC poor-risk patients. There was no PFS advantage with nivolumab despite the OS advantage. Progression-free survival does not appear to be a reliable surrogate of outcome for PD-1 therapy in RCC. Currently PD-L1 biomarkers are not used to select patients for this therapy.

There are no RCTs supporting the use of single-agent ICI in treatment-naïve patients. Randomised phase II data for atezolizumab vs. sunitinib showed a HR of 1.19 (95% CI: 0.82–1.71) which did not justify further assessment of atezolizumab as single agent as first-line treatment option in this group of patients, despite high complete response rates in the biomarker-positive population [509]. Single-arm phase II data for pembrolizumab from the KEYNOTE-427 trial show high response rates of 38% (up to 50% in PD-L1+ patients), but a PFS of 8.7 months (95% CI: 6.7–12.2) [509]. Based on these results and in the absence of randomised phase III data, single-agent checkpoint inhibitor therapy is not recommended as an alternative in a first-line therapy setting.

7.4.3.2 Immunotherapy/combination therapy
The phase III trial CheckMate 214 (NCT 02231749) showed a superiority of nivolumab and ipilimumab over sunitinib. The primary endpoint population focused on the IMDC intermediate- and poor-risk population where the combination demonstrated an OS benefit (HR: 0.63, 95% CI: 0.44–0.89) which led to regulatory approval [409] and a paradigm shift in the treatment of mRCC [1]. Results from CheckMate 214 further established that the combination of ipilimumab and nivolumab was associated with higher response rates (RR) (39% in the ITT population), complete response rates (8% in the ITT population [central radiology review]) and duration of response compared to sunitinib. Progression-free survival did not achieve the pre-defined endpoint. The exploratory analysis of OS data in the PD-L1-positive population was 0.45 (95% CI: 0.29–0.41).

A recent update with 60-month data shows ongoing benefits for the immune combination with independently assessed complete response rates of 11% and a HR for OS in the IMDC intermediate- and poor-risk group of 0.68 (0.58–0.81). The 60-months OS probability was 43% for ipilimumab plus nivolumab vs. 31% for sunitinib, respectively [510]. In this update the IMDC good-risk group did not continue to perform better with sunitinib although this effect occurs due to a late overlap of the KM-curves (HR for OS: 0.94 [95% CI: 0.65–1.37]) [511].

Nivolumab plus ipilimumab was associated with 15% grade 3-5 toxicity including 1.5% treatment-related deaths. It should therefore be administered in centres with experience of immune combination therapy and appropriate supportive care within the context of a multidisciplinary team (LE: 4). PD-L1 biomarker is currently not used to select patients for therapy.

The frequency of steroid use has generated controversy and further analysis, as well as real world data, are required. For these reasons the Panel continues to recommend ipilimumab and nivolumab in the intermediate- and poor-risk population.

The KEYNOTE-426 trial (NCT02853331 reported results for the combination of axitinib plus pembrolizumab vs. sunitinib in 861 treatment-naïve cc-mRCC patients [512]. Overall survival and PFS assessed by central independent review in the ITT population were the co-primary endpoints. Response rates and assessment in the PD-L1-positive patient population were secondary endpoints. With a median follow-up of 12.8 months, at first interim analysis both primary endpoints were reached. The median PFS in the pembrolizumab plus axitinib arm was 15.1 months vs. 11.1 in the sunitinib arm (HR: 0.69, 95% CI: 0.57–0.84, p < 0.001). Median OS has not been reached initially in either arm, but the risk of death was 47% lower in the axitinib plus pembrolizumab arm when compared to the sunitinib arm (OS HR: 0.53, 95% CI: 0.38–0.74, p < 0.0001). Response rates were also higher in the experimental arm (59.3% vs. 35.7%). Efficacy occurred irrespective of IMDC group and PD-L1 status. Treatment-related AEs (≥ grade 3) occurred in 63% of patients receiving axitinib and pembrolizumab vs. 58% of patients receiving sunitinib. Treatment-related deaths occurred in approximately 1% in both arms.

A recent update of KEYNOTE-426 with a minimum follow-up of 35.6 months (median 42.8 months) demonstrated an ongoing OS benefit for axitinib plus pembrolizumab in the ITT population (HR: 0.73, 95% CI: 0.60–0.88, p < 0.001). Median OS for axitinib plus pembrolizumab was 45.7 months (95% CI: 43.6 – NR) vs. 40.1 month (95% CI: 34.3 – 44.2) for sunitinib with a PFS benefit (HR: 0.68, 95% CI: 0.58–0.80, p < 0.0001) which was across all IMDC subgroups for PFS, while OS was similar between axitinib plus pembrolizumab...
vs. sunitinib in the favourable subgroup with an OS benefit in the IMDC intermediate- and poor-risk groups. The complete response rate by independent review was 10% in the pembrolizumab plus axitinib arm and 4% in the sunitinib arm [513].

The phase III CheckMate 9ER trial randomised 651 patients to nivolumab plus cabozantinib (n = 323) or vs. sunitinib (n = 328) in treatment-naïve cc-mRCC patients. The primary endpoint of PFS assessed by central independent review in the ITT population was significantly prolonged for nivolumab plus cabozantinib (16.6 months) vs. sunitinib (8.3 months, HR: 0.51, 95% CI: 0.41–0.64, p < 0.0001). The nivolumab/cabozantinib combination also demonstrated a significant OS benefit in the secondary endpoint compared with sunitinib (HR: 0.60, CI: 0.40–0.89, p = 0.0010) after a median follow-up of 18.1 months. The independently assessed ORR was 55.7% vs. 27.1% with a complete response rate of 8% for nivolumab plus cabozantinib vs. 4.6% with sunitinib. The efficacy was observed independent of IMDC group and PD-L1 status. Treatment-related AEs (> grade 3) occurred in 61% of patients receiving cabozantinib and nivolumab vs. 51% of patients receiving sunitinib. Treatment-related deaths occurred in one patient in the nivolumab/cabozantinib arm and in two patients in the sunitinib arm.

Recently, the randomised phase III trial CLEAR (Lenvatinib/Everolimus or Lenvatinib/Pembrolizumab Versus Sunitinib Alone as Treatment of Advanced Renal Cell Carcinoma) was published [439]. CLEAR randomised a total of 1,069 patients (in a 1:1:1 ratio) to lenvatinib plus pembrolizumab (n = 355) vs. lenvatinib plus everolimus (n = 357) vs. sunitinib (n = 357). The trial reached its primary endpoint of independently assessed PFS at a median of 23.9 vs. 9.2 months, for lenvatinib plus pembrolizumab vs. sunitinib, respectively (HR: 0.39, 95% CI: 0.32–0.49, p < 0.001). Overall survival significantly improved with lenvatinib plus pembrolizumab vs. sunitinib (HR: 0.66, 95% CI: 0.49–0.88, p = 0.005). Objective response for lenvatinib plus pembrolizumab was 71% with 16% of the patients having a complete remission. Efficacy was observed across all IMDC risk groups, independently of PD-L1 status. Treatment-related AEs of grade 3 and higher with lenvatinib plus pembrolizumab were 72%. Treatment-related death occurred in four patients in the lenvatinib plus pembrolizumab arm and in one patient in the sunitinib arm.

The JAVELIN trial investigated 886 patients in a phase III RCT of avelumab plus axitinib vs. sunitinib [453]. The trial met one of its co-primary endpoints (PFS in the PD-L1-positive population at first interim analysis [median follow up 11.5 months]). Hazard ratios for PFS and OS in the ITT population were 0.69 (95% CI: 0.56–0.84) and 0.78 (95% CI: 0.55–1.08), respectively. The same applies to the atezolizumab/bevacizumab combination which also achieved a PFS advantage over sunitinib in the PD-L1-positive population at interim analysis and ITT (HR: 0.74, 95% CI: 0.57–0.96), but has not yet shown a significant OS advantage (HR: 0.81, 95% CI: 0.63–1.03) [514]. Final OS results are awaited and the combination cannot currently be recommended.

Patients who stop nivolumab plus ipilimumab because of toxicity require expert guidance and support from a multi-disciplinary team before re-challenge can occur (LE: 1). Patients who do not receive the full four doses of ipilimumab due to toxicity should continue on single-agent nivolumab, where safe and feasible (LE: 4).

Treatment past progression with nivolumab plus ipilimumab can be justified but requires close scrutiny and the support of an expert multi-disciplinary team [514, 518] (LE: 1).

Patients who stop TKI and IO due to immune-related toxicity can receive single-agent TKI once the adverse event has resolved (LE: 1). Adverse event management, including transaminitis and diarrhoea, require particular attention as both agents may be causative. Expert advice should be sought on re-challenge of ICIs after significant toxicity (LE: 4). Treatment past progression on axitinib plus pembrolizumab or nivolumab plus cabozantinib requires careful consideration as it is biologically distinct from treatment past progression on ipilimumab and nivolumab.

Generally, the Panel is of the opinion that nivolumab plus ipilimumab, pembrolizumab plus axitinib and nivolumab plus cabozantinib should be administered in centres with experience of immune combination therapy and appropriate supportive care within the context of a multi-disciplinary team (LE: 4).

7.4.4 Therapeutic strategies

7.4.4.1 Treatment-naïve patients with clear-cell metastatic RCC

The combination of pembrolizumab plus axitinib as well as nivolumab plus cabozantinib and lenvatinib plus pembrolizumab is the standard of care in all IMDC-risk patients and ipilimumab plus nivolumab in IMDC intermediate- and poor-risk patients (Figure 7.1). Therefore, the role of VEGFR-TKIs alone in front-line mRCC has been superseded. Sunitinib, pazopanib, and cabozantinib (IMDC intermediate- and poor-risk disease), remain alternative treatment options for patients who cannot receive or tolerate immune checkpoint inhibition in this setting (Figure 7.1).

7.4.4.1.1 Sequencing systemic therapy in clear-cell metastatic RCC

The sequencing of targeted therapies is established in mRCC and maximises outcomes [498, 507]. Pembrolizumab plus axitinib, nivolumab plus cabozantinib, lenvatinib plus pembrolizumab and nivolumab plus ipilimumab are the new standard of care in front-line therapy. The impact of front-line immune checkpoint inhibition on subsequent therapies is unclear. Randomised data on patients with disease refractory to either nivolumab plus ipilimumab or TKI plus IO in a first-line setting are lacking, and available cohorts are limited [519]. Prospective data on tivozanib, cabozantinib and axitinib are available for patients progressing on immunotherapy, but these studies do not focus solely on the front-line setting, involve subset analyses, and are too small for definitive conclusions [507, 520].

Retrospective data on VEGFR-TKI therapy after progression on front-line immune combinations exist but have significant limitations. When considering this data in totality, there is some activity but it is still too early to recommend one VEGFR-TKI over another after immunotherapy/immunotherapy or immunotherapy/VEGFR combination (Figure 7.2). After the axitinib plus pembrolizumab combination, changing the VEGFR-TKI at progression to cabozantinib or any other TKI not previously used is recommended.

The Panel do not support the use of mTOR inhibitors unless VEGF-targeted therapy is contraindicated as they have been outperformed by other VEGF-targeted therapies in mRCC [521]. Drug choice in the third-line setting, after ICI combinations and subsequent VEGF-targeted therapy, is unknown. The Panel recommends a subsequent agent which is approved in VEGF-refractory disease, with the exception of re-challenge with immune checkpoint blockade. Cabozantinib is the only agent in VEGF-refractory disease with RCT data showing a survival advantage and should be used preferentially [468]. Axitinib has positive PFS data in VEGF-refractory disease. Both sorafenib and everolimus have been outperformed by other agents in VEGF-refractory disease and are therefore less attractive [521]. The lenvatinib plus everolimus combination appears superior to everolimus alone and has been granted EMA regulatory approval based on randomised phase II data. This is an alternative despite the availability of phase II data only [498]. As shown in a study which also included patients on ICIs tivozanib provides PFS superiority over sorafenib in VEGF-refractory disease [522].

Patients who do not receive the full four doses of ipilimumab due to toxicity should continue on single-agent nivolumab, where safe and feasible. Re-challenge with combination therapy requires expert support.

Treatment past progression can be justified but requires close scrutiny and the support of an expert multi-disciplinary team.

Nivolumab plus ipilimumab was associated with 15% grade 3-5 toxicity and 1.5% treatment-related deaths. Tyrosine kinase inhibitor-based IO combination therapies were associated with grade 3-5 toxicity ranging between 61-72% and 1% of treatment-related deaths.

7.4.4.1.3 Renal tumours with sarcomatoid features
Subset analyses have shown improved results for PD-L1 inhibitors combined with CTLA4 or VEGF-targeted therapy in renal tumours with sarcomatoid features. Bevacizumab/atezolizumab, ipilimumab/nivolumab, axitinib/pembrolizumab and avelumab/axitinib can all be recommended instead of VEGF-targeted therapy alone. These options have OS advantages over sunitinib and superseded VEGF-targeted therapy.

Recommendation Strength rating
Offer immune checkpoint inhibitor combination therapy for advanced cc-mRCC with sarcomatoid features. Weak

7.4.4.2 Treatment of patients with non-clear-cell metastatic RCC
No phase III trials of patients with non-cc-mRCC have been reported. Expanded access programmes and subset analyses from RCC studies suggest the outcome of these patients with targeted therapy is poorer than for ccRCC. Targeted treatment in non-cc-mRCC has focused on temsirolimus, everolimus, sorafenib, sunitinib and pembrolizumab [528-531].

</tr>
</tbody>
</table>

Recommendation Strength rating
Offer sunitinib to patients with other non-cc RCC subtypes than papillary RCC. Weak

7.4.4.3 Papillary metastatic RCC
The most common non-cc subtypes are type I and non-type I pRCCs. There are small single-arm trials for sunitinib and everolimus [9, 531-534]. A trial of both types of pRCC treated with everolimus (RAPTOR), showed a median PFS of 3.7 months per central review in the ITT population with a median OS of 21.0 months [534]. In a non-randomised phase II trial, type 2 pRCC associated with HLRCC, a familial cancer syndrome caused by germline mutations in the fumarate hydratase enzyme gene, the combination of bevacizumab 10 mg/kg IV every two weeks and erlotinib 150 mg orally daily has been evaluated [535]. The combination regimen reports interesting activity with an ORR of 64% (27/42, 95% CI: 49–77) in the HLRCC cohort, with a median PFS of 21.1 months (95% CI: 15.6–26.6). Grade ≥ 3 treatment-related AEs occurred in 47% of patients, including hypertension (34%) and proteinuria (13%).

For pRCC new evidence is available from the SWOG PAPMET randomised phase II trial which compared sunitinib to cabozantinib, crizotinib and savolitinib in 152 patients with papillary mRCC [536]. Progression-free survival was longer in patients in the cobozantinib group (median 3.0 months, 95% CI: 6–12) than in the sunitinib group (5.6 months, CI: 3–7; HR for progression or death 0.60 [0.37–0.97, one-sided p = 0.019]). Response rate for cabozantinib was 23% vs. 4% for sunitinib (two-sided p = 0.010). Savolitinib and crizotinib did not improve PFS compared with sunitinib. Grade 3 or 4 AEs occurred in 69% (31/45) of patients receiving sunitinib, 74% (32/43) of patients receiving cobozantinib, 37% (10/27) receiving crizotinib, and 39% (11/28) receiving savolitinib; one grade 5 thromboembolic event was recorded in the cobozantinib group. These results support adding cobozantinib as an option for patients with papillary mRCC based on superior PFS results compared to sunitinib.

In addition, savolitinib was investigated in the SAVIOR trial [537] as first-line treatment for MET-driven tumours defined as chromosome 7 gain, MET amplification, MET kinase domain variations or hepatocyte growth factor amplification by DNA alteration analysis (~30% of screened patients were MET positive). In a limited patient group, savolitinib (n = 27) was compared with sunitinib (n = 33). The trial was stopped early, largely due to poor accrual. The efficacy data appeared to favour savolitinib (median PFS 7.0 months, 95% CI: 2.8 months-NR vs. 5.6 months, 95% CI: 4.1–6.9 months, PFS HR: 0.71, 95% CI: 0.37–1.36, OS HR: 0.51,94% CI: 0.21–1.17, RR: 27% vs. 7%, for savolitinib and sunitinib, respectively). The median OS for savolitinib was NR. Savolitinib was better tolerated compared with sunitinib with 42% grade ≥ 3 AEs compared to 81% with sunitinib.

Efficacy for pembrolizumab in the pRCC subset (118/165) was; RR: 29%, PFS: 5.5 months (95% CI: 3.9–6.1 months) and OS: 31.5 months (95% CI: 25.5 months-NR), but these results are based on a single-arm phase II study [509]. Pembrolizumab can be conceded in this setting due to the high unmet need.

Patients with non-cc-mRCC should be referred to a clinical trial, where appropriate.

Patients with non-cc-mRCC should be referred to a clinical trial, where appropriate.

Treatment of patients with rare tumours

Renal medullary carcinoma

Renal medullary carcinoma is one of the most aggressive RCCs [26, 27] and most patients (~67%) will present with metastatic disease [26, 28]. Even patients who present with seemingly localised disease may develop macrometastases shortly thereafter, often within a few weeks.

Despite treatment, median OS is thirteen months in the most recent series [33]. Due to the infiltrative nature and medullary epicentre of RMC, RN is favoured over PN even in very early-stage disease. Retrospective data indicate that nephrectomy in localised disease results in superior OS (16.4 vs. 7 months) compared with systemic chemotherapy alone, but longer survival was noted in patients who achieved an objective response to first-line chemotherapy [33, 538]. There is currently no established role for distant metastasectomy or nephrectomy in the presence of metastases.

Palliative radiation therapy is an option and may achieve regression in the targeted areas but it will not prevent progression outside the radiation field [539, 540]. Renal medullary carcinoma is refractory to monotherapies with targeted anti-angiogenic regimens including TKIs and mTOR inhibitors [33, 165]. The mainstay systemic treatments for RMC are cytotoxic combination regimens which produce partial or complete responses in ~29% of patients [165]. There are no prospective comparisons between different chemotherapy regimens but most published series used various combinations of platinum agents, taxanes, gemcitabine, and/or anthracyclines [33, 34]. High-dose-intensity combination of MVAC has also shown efficacy against RMC [541] although a retrospective comparison did not show superiority of MVAC over cisplatin, paclitaxel, and gemcitabine [34]. Single-agent anti-PD-1 immune checkpoint therapy has produced responses in a few case reports, although, as yet, insufficient data are available to determine the response rate to this approach [539, 540]. Whenever possible, patients should be enrolled in clinical trials of novel therapeutic approaches, particularly after failing first-line cytotoxic chemotherapy.

Treatment of hereditary RCC

von-Hippel-Lindau-disease-associated RCC

Patients with VHL disease often develop RCC and tumours in other organs including CNS, retinal haemangioblastomas, and pancreatic tumours, and commonly undergo several surgical resections in their lifetime. In VHL disease, belzutifan, a hypoxia-inducible factor 2α (HIF-2α) inhibitor, has been approved by the US Food and Drug Administration (FDA) for the treatment of ccRCC and other neoplasms associated with VHL for the treatment of tumours that do not require immediate surgery. Approval was based on the results from a phase II, open-label, single-arm trial in patients with tumours not larger than 3 cm [542]. Belzutifan induced partial responses with an RCC ORR of 49%, and a disease control rate of 98.4% after 21.8 months treatment. All patients with pancreatic lesions had an ORR of 77%, and those with CNS haemangioblastoma had a 30% response rate. In total, 33% of patients reported ≥ grade 3 AEs, and seven patients (11.5%) discontinued the treatment. In the treatment with pazopanib for VHL only 52% continued with the treatment after 24 weeks [543].

With favourable efficacy results and with relatively low-grade side effects, belzutifan seems to be a valuable contribution to the treatment of patients with the VHL disease, and it is currently under review by the EMA.

Locally recurrent RCC after treatment of localised disease

Most studies reporting on local recurrent disease after removal of the kidney have not considered the true definition of local recurrence after RN, PN and thermal ablation, which are: local recurrence in the tumour-bearing kidney, tumour growth exclusively confined to the true renal fossa, recurrences within the renal vein,
the ipsilateral adrenal gland or the regional LNs. In the existing literature the topic is weakly investigated and often regarded as local recurrent disease.

7.5.1  **Locally recurrent RCC after nephron-sparing approaches**
Locally recurrent disease can affect the tumour-bearing kidney after PN or focal ablative therapy such as RFA and cryotherapy. Local relapse may be due to the incomplete resection of the primary tumour, in a minority of the cases to the local spread of the tumour by microvascular embolisation, or true multifocality [203, 544].

The prognosis of recurrent disease not due to multifocality is poor, despite salvage nephrectomy [544]. Recurrent tumour growth in the regional LNs or ipsilateral adrenal gland may reflect metachronous metastatic spread (see Section 7.3). After treatment solely for localised disease, systemic progression is common [545, 546].

Following thermal ablation or cryotherapy generally intra-renal, but also peri-renal, recurrences have been reported in up to 14% of cases [547]. Whereas repeat ablation is still recommended as the preferred therapeutic option after treatment failure, the most effective salvage procedure as an alternative to complete nephrectomy has not yet been defined.

7.5.2  **Locally recurrent RCC after radical nephrectomy**
Isolated local fossa recurrence is rare and occurs in about 1-3% after radical nephrectomy. More commonly in pT3-4 than pT1-2 and grade 3-4. Most patients with local recurrence of RCC are diagnosed by either CT/MRI scans as part of the post-operative follow-up [548]. The median time to recurrence after RN was 19-36 months in isolated local recurrence or 14.5 months in group including metastatic cases as well [548-550]. Isolated local recurrence is associated with worse survival [203, 551]. Based on retrospective and non-comparative data only, several approaches such as surgical excision, radiotherapy, systemic treatment and observation have been suggested for the treatment of isolated local recurrence [552-554]. Among these alternatives, surgical resection with negative margins remains the only therapeutic option shown to be associated with improved survival [551]. Open surgery has been successfully reported in studies [555, 556]. One of the largest series including 2,945 patients treated with RN reported on 54 patients with recurrent disease localised in the renal fossa, the ipsilateral adrenal gland or the regional LNs as sole metastatic sites [552]. Another recent series identified 33 patients with isolated local recurrences and 30 local recurrences with synchronous metastases within a cohort of 2,502 surgically treated patients, confirming the efficacy of locally directed treatment vs. conservative approaches (observation, systemic therapy) [557].

A five-year OS with isolated local recurrence was 60% (95% CI: 0.44–0.73) and ten-year OS was 32% (95% CI: 0.15–0.51). Overall survival differed significantly by the time period between primary surgery and occurrence of recurrence (< two years vs. ≥ two years: ten-year OS rate 31% (95% CI: 10.2–55.0) vs. 45% (95% CI: 21.5–65.8; HR: 0.26; p = 0.0034) [548]. Metastatic progression was observed in 60 patients (58.8%) after surgery [549]. Patient survival can be linked to the type of treatment received, as shown by Marchioni, et al. In a cohort of 96 patients, 45.8% were metastatic at the time of recurrence; three-year CSS rates after local recurrence were 92.3% (± 7.4%) for those who were treated with surgery and systemic therapy, 63.2% (± 13.2%) for those who only underwent surgery, 22.7% (± 0.9%) for those who only received systemic therapy and 20.5% (± 10.4%) for those who received no treatment (p < 0.001).

However, minimally invasive approaches, including standard and hand-assisted laparoscopic and robotic approaches for the resection of isolated RCC recurrences have been occasionally reported. Recently, Martini et al., published the largest surgical cohort of robotic surgery in this setting (n = 35) providing a standardisation of the nomenclature, describing the surgical technique for each scenario and reporting on complications, renal function, and oncologic outcomes [558]. Ablative therapies including cryoablation, radiofrequency and microwave ablation, may also have a role in managing recurrent RCC patients, but further validation will be needed [559, 560].

In summary, the limited available evidence suggests that in selected patients surgical removal of locally recurrent disease with negative margins can induce durable tumour control, although with expected high risk of complications. Johnson et al. published on 51 planned repeat PNs in 47 patients with locally recurrent disease, reporting a total of 40 peri-operative complications, with temporary urinary extravasation being the most prevalent [561]. Since local recurrences develop early, with a median time interval of 10–20 months after treatment of the primary tumour [562], a guideline-adapted follow-up scheme for early detection is recommended (see Chapter 8 - Follow-up) even though benefit in terms of cancer control has not yet been demonstrated [563].

Adverse prognostic parameters are a short time interval since treatment of the primary tumour (< 3–12 months) [564], sarcomatoid differentiation of the recurrent lesion and incomplete surgical resection [552]. In case
complete surgical removal is unlikely to be performed or when significant comorbidities are present (especially when combined with poor prognostic tumour features), palliative therapeutic approaches including radiation therapy aimed at symptom control and prevention of local complications should be considered (see Sections 7.3 and 7.4).

Following metastasectomy of local recurrence after nephrectomy, adjuvant therapy can be considered (see Section 7.2.5. Neoadjuvant and adjuvant therapy). Local recurrence combined with other metastases is treated as a metastatic RCC.

8. FOLLOW-UP IN RCC

8.1 Introduction

Surveillance after treatment for RCC allows the urologist to monitor or identify:

• post-operative complications;
• renal function;
• local recurrence;
• recurrence in the contralateral kidney;
• distant metastases;
• cardiovascular events.

There is no consensus on follow-up strategies after RCC treatment, with limited evidence suggesting that more frequent post-operative imaging intervals do not provide any improvement for early detection of recurrence that would lead to improved survival [563]. As such, intensive radiological surveillance may not be necessary for all patients. Follow-up is also important to assess functional outcomes and to limit long-term sequelae such as renal function impairment, end-stage renal disease and cardiovascular events [565].

Currently, the key question is whether any recurrence detection during follow-up and subsequent treatment will lead to any meaningful change in survival outcome for these patients.

In contrast to high-grade and/or locally advanced disease, the outcome after surgery for T1a low-grade tumours is almost always excellent. It is therefore reasonable to stratify follow-up, taking into account the risk of each different RCC to develop a local or distant recurrence. Although there is no randomised evidence, large studies have examined prognostic factors with long follow-up [188, 566, 567] (LE: 4). One study has shown a survival benefit in patients who were followed within a structured surveillance protocol vs. patients who were not [568]; patients undergoing follow-up seem to have a longer OS when compared to patients not undergoing routine follow-up [568].

Furthermore, an individualised and risk-based approach to RCC follow-up has recently been proposed. The authors used competing risk models, incorporating patient age, pathologic stage, relapse location and comorbidities, to calculate when the risk of non-RCC death exceeds the risk of RCC recurrence [569]. For patients with low-stage disease but with a Charlson comorbidity index ≥ 2, the risk of non-RCC death exceeded that of abdominal recurrence risk already one month after surgery, regardless of patient age.
Recurrence after PN is rare, but early diagnosis is relevant, as the most effective treatment is surgery [555, 571]. Recurrence in the contralateral kidney is rare (1–2%) and can occur late (median 5–6 years) [572] (LE: 3). Follow-up can identify local recurrences or metastases at an early stage. In metastatic disease, extended tumour growth can limit the opportunity for surgical resection, which is considered the standard therapy in cases of resectable and preferably solitary lesions. In addition, early diagnosis of tumour recurrence may enhance the efficacy of systemic treatment if the tumour burden is low.

8.2 Which imaging investigations for which patients, and when?

- The sensitivity of chest radiography and US for detection of small RCC metastases is poor. The sensitivity of chest radiography is significantly lower than CT-scans, as proven in comparative studies including histological evaluation [573-575]. Therefore, follow-up for recurrence detection with chest radiography and US are less sensitive [576].
- Positron-emission tomography and PET-CT as well as bone scintigraphy should not be used routinely in RCC follow-up, due to their limited specificity and sensitivity [6, 127].
- Surveillance should also include evaluation of renal function and cardiovascular risk factors [565].
- Outside the scope of regular follow-up imaging of the chest and abdomen, targeted imaging should be considered in patients with organ-specific symptoms, e.g., CT or MRI imaging of the brain in patients experiencing neurological symptoms [577].

Controversy exists on the optimal duration of follow-up. Some authors argue that follow-up with imaging is not cost-effective after five years; however, late metastases are more likely to be solitary and justify more aggressive therapy with curative intent. In addition, patients with tumours that develop in the contralateral kidney can be treated with NSS if the tumours are detected early. Several authors have designed scoring systems and nomograms to quantify the likelihood of patients to develop tumour recurrences, metastases, and subsequent death [238, 240, 578, 579]. These models, of which the most utilised are summarised in Chapter 6 - Prognosis, have been compared and validated [580] (LE: 2). Using prognostic variables, several stage-based follow-up regimens have been proposed, although, none propose follow-up strategies after ablative therapies [581, 582]. A post-operative nomogram is available to estimate the likelihood of freedom from recurrence at five years [235]. Recently, a pre-operative prognostic model based on age, symptoms and TNM staging has been published and validated [583] (LE: 3).

A follow-up algorithm for monitoring patients after treatment for RCC is needed, recognising not only the patient’s risk of recurrence profile, but also the efficacy of the treatment given (Table 8.1). These prognostic systems can be used to adapt the follow-up schedule according to predicted risk of recurrence. Ancillary to the above, life-expectancy calculations based on comorbidity and age at diagnosis may be useful in counselling patients on duration of follow-up [584].

Table 8.1: Proposed follow-up schedule following treatment for localised RCC, taking into account patient risk of recurrence profile and treatment efficacy (based on expert opinion [LE: 4])

<table>
<thead>
<tr>

<th>CT once every two yrs</th>
</tr>
</thead>
</table>

ccRCC = clear cell renal cell carcinoma; CT = computed tomography; mo = months; non-ccRCC = non clear cell renal cell carcinoma; yr = years.

The table above provides recommendations on follow-up strategies for low, intermediate and high risk of recurrence in patients curatively treated for localised RCC either with NSS or RN. Computed tomography in the table refers to imaging of both chest and abdomen. Alternatively, MRI of the abdomen can be performed instead of a CT-scan.

* Risk of recurrence profiles should be based on validated prognostic models. The EAU RCC Guidelines Panel recommends the 2003 Leibovich model for ccRCC [238]. However, other validated models can be used by physicians based on their own national/regional recommendations. In a similar fashion, for curatively treated localised non-ccRCC, the Panel recommends the use of the University of California Los Angeles integrated staging system (UISS) to determine risk of recurrence [239].

** For all risk of recurrence profiles, functional follow-up, mainly monitoring renal and cardiovascular function, may continue according to specific clinical needs irrespective of the length of the oncological follow-up.

*** For low-risk profiles at > 3 years and intermediate-risk at > 5 years of follow-up respectively, consider counselling patients about terminating oncological follow-up imaging based on assessment of comorbidities, age, life expectancy and/or patient wishes.

### 8.3 Summary of evidence and recommendations for surveillance following RN or PN or ablative therapies in RCC

</tr>
<tr>
<td>Patients undergoing follow-up have a better OS than patients not undergoing surveillance.</td>
<td>3</td>
</tr>
<tr>
<td>Prognostic models provide stratification of RCC risk of recurrence based on TNM and histological features.</td>
<td>3</td>
</tr>
<tr>
<td>In competing-risk models, risk of non-RCC-related death exceeds that of RCC recurrence or related death in low-risk patients.</td>
<td>3</td>
</tr>
<tr>
<td>Life expectancy estimation is feasible and may support counselling of patients on duration of follow-up.</td>
<td>4</td>
</tr>
</tbody>
</table>
Recommendations | Strength rating
--- | ---
Base follow-up after treatment of localised RCC on the risk of recurrence. | Strong
Perform functional follow-up (renal function assessment and prevention of cardiovascular events) both in nephron-sparing (NSS) and radical nephrectomy patients. | Weak
Intensify follow-up in patients after NSS for tumours > 7 cm or in patients with a positive surgical margin. | Weak
Consider curtailing follow-up when the risk of dying from other causes is double that of the RCC recurrence risk. | Weak
Base risk of recurrence stratification on validated subtype-specific models such as the Leibovich Score for ccRCC or the University of California Los Angeles integrated staging system for non-ccRCC. | Weak

8.4 Research priorities
There is a clear need for future research to determine whether follow-up can optimise patient survival. Data evaluating at which time point follow-up has the highest chance to detect recurrence will be most valuable for clinical practice. Novel prognostic markers at surgery should be investigated to determine the risk of relapse over time.

10. CONFLICT OF INTEREST

All members of the Renal Cell Cancer Guidelines Panel have provided disclosure statements of all relationships that they have that might be perceived as a potential source of a conflict of interest. This information is publically accessible through the European Association of Urology website: https://uroweb.org/guideline/renal-cell-carcinoma/?type=panel/.

This guidelines document was developed with the financial support of the European Association of Urology. No external sources of funding and support have been involved. The EAU is a non-profit organisation and funding is limited to administrative assistance and travel and meeting expenses. No honoraria or other reimbursements have been provided.

11. CITATION INFORMATION

The format in which to cite the EAU Guidelines will vary depending on the style guide of the journal in which the citation appears. Accordingly, the number of authors or whether, for instance, to include the publisher, location, or an ISBN number may vary.

The compilation of the complete Guidelines should be referenced as:

If a publisher and/or location is required, include:

References to individual guidelines should be structured in the following way:
Contributors’ names. Title of resource. Publication type. ISBN. Publisher and publisher location, year.

11. CONFLICT OF INTEREST  65

12. CITATION INFORMATION  65
1. INTRODUCTION

1.1 Aim and objectives
The aim of these guidelines is to present the current evidence for the diagnosis and treatment of patients with cancer of the testis. Testicular cancer (TC) represents 5% of urological tumours affecting mostly younger males. This document addresses post-pubertal testicular germ-cell tumours (TGCTs) in the male including spermatocytic tumour and sex cord/gonadal stromal tumours.

It must be emphasised that clinical guidelines present the best evidence available to the experts but following guideline recommendations will not necessarily result in the best outcome. Guidelines can never replace clinical expertise when making treatment decisions for individual patients, but rather help to focus decisions which should also take personal values and references/individual circumstances of patients into account. Guidelines are not mandates and do not purport to be a legal standard of care.

1.2 Panel composition
The European Association of Urology (EAU) Guidelines Panel on TC consists of a multidisciplinary group of clinicians including, urologists, medical oncologists, a radiation-oncologist, and a pathologist. When necessary, consultants from other specialties provide input. Members of this Panel have been selected, based on their expertise, to represent the professionals treating patients with TC. All experts involved in the production of this document have submitted potential conflict of interest statements which can be viewed on the EAU website: http://www.uroweb.org/guideline/testicular-cancer/.

1.3 Available publications
A quick reference document (Pocket guidelines) is available, in print and as an app for iOS and Android devices. These are abridged versions which may require consultation together with the full text version. Several scientific publications are available, as are a number of translations of all versions of the EAU Testicular Cancer Guidelines. All documents are accessible through the EAU website: http://www.uroweb.org/guideline/testicularcancer/.

1.4 Publication history and summary of changes

1.4.1 Publication history
The EAU published the first guidelines on TC in 2001. Since 2008, the TC Guidelines contains a separate chapter on testicular stromal tumours. This document presents a limited update of the 2021 publication. Review papers have been published in the society's scientific journal European Urology, the latest version dating to 2015 [1].

1.4.2 Summary of changes
For the 2022 Testicular Cancer Guidelines, new references have been added throughout the document. Key changes in this publication include:

- The chapter on stromal tumours has been re-structured and revised under a new heading: “Rare adult para- and testicular tumours”;
- All the chapters have been reviewed and supporting text and recommendations across the guideline have been rephrased and revised;
- Summaries of evidence have been added throughout the text;
- Old citations have been refreshed and replaced with newer references;
- A number of articles identified after the scope search cut-off date have been included as they contain important information pertaining to guidelines recommendations;
- The recent re-validation of the 1997 International Germ Cell Cancer Collaborative Group (IGCCCG) prognostic risk-factor based system for metastatic testicular Germ cell tumours in patients treated with cisplatin-etoposide as first-line chemotherapy has been included in the text replacing the old version with the corresponding references;
- New supporting text regarding VTE prophylaxis in males with metastatic germ cell tumours (GCTs) receiving chemotherapy has been added.

2. METHODS

New and relevant evidence has been identified, collated, and appraised through a structured assessment of the literature. The search was limited to studies representing high levels of evidence only (i.e., systematic reviews with meta-analysis, randomised controlled trials [RCTs], and prospective non-randomised comparative studies)
published in the English language. The search was restricted to articles published between April 2020 and June 2021 and included testicular stromal tumours. Databases covered by the search included PubMed, Ovid, EMBASE and the Cochrane Central Register of Controlled Trials and the Cochrane Database of Systematic Reviews. After deduplication, a total of 1,959 unique records were identified, retrieved and screened for relevance. Fifty-eight new and updated references have been included in the 2022 Guidelines. A detailed search strategy is available online: http://uroweb.org/guideline/testicular-cancer/?type=appendices-publications.

For each recommendation within the guidelines there is an accompanying online strength rating form, the basis of which is a modified GRADE methodology [2, 3]. Each strength rating form addresses a number of key elements namely:

1. the overall quality of the evidence which exists for the recommendation, references used in this text are graded according to a classification system modified from the Oxford Centre for Evidence-Based Medicine Levels of Evidence [4];
2. the magnitude of the effect (individual or combined effects);
3. the certainty of the results (precision, consistency, heterogeneity and other statistical or study related factors);
4. the balance between desirable and undesirable outcomes;
5. the impact of patient values and preferences on the intervention;
6. the certainty of those patient values and preferences.

These key elements are the basis which panels use to define the strength rating of each recommendation. The strength of each recommendation is determined by the balance between desirable and undesirable consequences of alternative management strategies, the quality of the evidence (including certainty of estimates), and nature and variability of patient values and preferences.

Additional information can be found in the general Methodology section of this print, and online at the EAU website: www.uroweb.org/guidelines.

A list of associations endorsing the EAU Guidelines can also be viewed online at the above address.

2.1 Review
The 2020 Guidelines document was subjected to peer-review following publication.

2.2 Future goals
• A systematic review on diagnostic accuracy on value of the ultrasound (US) in the diagnostic of small testicular masses in collaboration with the Sexual and Reproductive Health has been produced and is under peer-review.
• A review and discussion of the recommendations with patient associations is ongoing.
• The development of a TC survivorship plan in collaboration with patient associations is planned.
• An Individual Patient Data (IPD) prognostic factor study on the value of pathological factors in clinical stage I seminoma testis patients under active surveillance approved by the Guidelines Office Methods Committee and including data from with five international centres is presently in the analysis phase.
• Care Pathways on diagnostic, treatment CS I, and treatment of metastatic disease and Cheat Sheets on TC are being prepared in collaboration with the EAU GO.

3. EPIDEMIOLOGY, AETIOLOGY & PATHOLOGY

3.1 Epidemiology and Aetiology
Testicular cancer represents 1% of adult neoplasms and 5% of urological tumours, with three to ten new cases per 100,000 males/per year in Western societies [6]. Its incidence has increased during recent decades, particularly in industrialised countries [7, 8], and continues to rise. At diagnosis, 1-2% of cases are bilateral and the predominant histology is germ cell tumours (GCT) (90-95% of cases) [6]. The peak incidence is in the third decade of life for non-seminoma testis (NST) and mixed GCT patients, and in the fourth decade for seminoma testis (ST) patients. In 5% of TGCT patients the primary site is at an extragonadal location [9].

There are two fundamental categories of TGCTs based on their development and epigenetic features. Most malignant post-pubertal TGCTs (or type II GCT) originate from the germ cell neoplasia “in situ” (GCNIS). They
are clinically and histologically subdivided into seminomas and non-seminomas, the later encompassing somatic and extra-embryonal elements of embryonal carcinoma, yolk sac, choriocarcinoma and teratoma [10].

Non-related GCNIS tumours include pre-pubertal type teratoma and yolk sac (Type I), diagnosed at early paediatric age, and spermatocytic tumours (Type III), diagnosed in the elderly. Although there is overlapping histology between the pre-pubertal teratoma/yolk sac and the teratoma and yolk sac elements in the GCNIS-related non-seminomas, they have a separate and independent pathogenesis [10].

Overall, type II TGCT have a low mutational burden and few somatic changes. A specific recurrent genetic marker – an isochromosome of the short arm of chromosome 12 – (i12p) – is over-represented in most invasive GCNIS-related TGCTs [10, 11] but not found in GCNIS [12]. However, some type II TGCTs, mostly seminomas, appear to lack a gain of 12p and present preferential cKIT mutations. Without occurrence of these mutations GCNIS will not progress to invasive GCTs [10]. Other significant chromosomal aberrations in type II TGCTs are gain of 7, 8, 21 and loss of chromosomes 1p, 11, 13 and 18 [13].

Epidemiological risk factors for the development of TC are components of the testicular dysgenesis syndrome (which encompasses cryptorchidism), hypospadias, decreased spermatogenesis and impaired fertility [14-16] or disorders/differences of sex development [17]. Additional risk factors include family history of TC among first-degree relatives and the presence of a contralateral testicular tumour or GCNIS [14, 18-24]. Recent genome-wide association studies revealed detectable susceptibility loci leading to an increased relative risk to develop TC [25].

3.2 Histological classification

General:
The recommended pathological classification shown below is based on the 2016 update of the World Health Organization (WHO) pathological classification [26].

1. Germ cell tumours
   - Germ cell neoplasia in situ (GCNIS)

2. Derived from GCNIS
   - Seminoma
   - Embryonal carcinoma
   - Yolk sac tumour, post-pubertal type
   - Trophoblastic tumours
   - Teratoma, post-pubertal type
   - Teratoma with somatic malignant components
   - Mixed germ cell tumours

3. Germ cell tumours unrelated to GCNIS
   - Spermatocytic tumour
   - Yolk sac tumour, pre-pubertal type
   - Mixed germ cell tumour, pre-pubertal type

4. Sex cord/stromal tumours
   - Leydig cell tumour
     - Malignant Leydig cell tumour
   - Sertoli cell tumour
     - Malignant Sertoli cell tumour
     - Large cell calcifying Sertoli cell tumour
     - Intratubular large cell hyalinising Sertoli cell neoplasia
   - Granulosa cell tumour
     - Adult type
     - Juvenile type
   - Thecoma/fibroma group of tumours
   - Other sex cord/gonadal stromal tumours
     - Mixed
     - Unclassified
   - Tumours containing both germ cell and sex cord/gonadal stromal
     - Gonadoblastoma
5. **Miscellaneous non-specific stromal tumours**
   - Ovarian epithelial tumours
   - Tumours of the collecting ducts and rete testis
     - Adenoma
     - Carcinoma
   - Tumours of paratesticular structures
     - Adenomatoid tumour
     - Mesothelioma (epithelioid, biphasic)
     - Epididymal tumours
   - Cystadenoma of the epididymis
   - Papillary cystadenoma
   - Adenocarcinoma of the epididymis
   - Mesenchymal tumours of the spermatic cord and testicular adnexae

4. **STAGING & CLASSIFICATION SYSTEMS**

4.1 **Staging**

The 2016 Tumour, Node, Metastasis (TNM) classification of the International Union Against Cancer (UICC) is recommended to assess the anatomical extent of the disease (Table 4.1) [27].

Table 4.1: TNM classification for testicular cancer (adapted from UICC, 2016, 8th edn.) [27]

Stage IA: Patients have primary tumours limited to the testis and epididymis, with no evidence of microscopic vascular or lymphatic invasion by tumour cells on microscopy, no sign of metastases on clinical examination or imaging, and post-orchidectomy serum tumour marker levels within normal limits. Marker decline in patients with CS I disease should be assessed until normalisation.

Stage IB: Patients have a more locally invasive primary tumour, but no sign of metastatic disease.

Stage IS: Patients have persistently elevated (and usually increasing) serum tumour marker levels after orchidectomy, indicating subclinical metastatic disease (or possibly a second GCT in the remaining testis).

In population-based patient series from developed countries, 75-80% of seminoma patients, and about 55%-64% of non-seminomatous germ cell tumour (NSGCT) patients have stage I disease at diagnosis [29, 30]. True stage IS (persistently elevated or increasing serum tumour marker levels after orchidectomy) is found in about 5% of non-seminoma patients [29].
### 4.3 The International Germ Cell Cancer Collaborative classification for the prognostic-risk groups of metastatic testicular cancer

The 1997 IGCCCG defined a prognostic risk-factor system for metastatic GCT based on identification of clinically independent adverse factors. The classification has been revalidated on a contemporary cohort of metastatic testicular GCT treated with cisplatin/etoposide based first-line chemotherapy.

Compared to the 1997 figures, the five-year progression-free survival (PFS) of non-seminoma patients was unchanged for good- and intermediate-risk, but significantly improved for poor-risk patients (from 41% to 54%). The five-year overall survival (OS) was substantially better for all groups. In addition to the traditional components of the IGCCCG risk-prognostic groups previously described, older age (linear association) and lung metastasis were confirmed as negative factors for PFS [31].

In seminoma, the five-year PFS increased to 89% and 79% in good- and intermediate-risk patients with the corresponding OS rates of 95% and 88%. Lactate dehydrogenase (LDH) proved to be an additional adverse prognostic factor. Good-prognosis patients with LDH above 2.5 times the upper limit of normal (ULN) had a three-year PFS of 80% and a three-year OS of 92%, vs. 92% and 97% (in the group with lower LDH) [32].

*Pre-chemotherapy serum tumour markers should be assessed immediately prior to the administration of chemotherapy (same day).*

5. DIAGNOSTIC EVALUATION

5.1 Physical examination
Testicular cancer usually presents as a unilateral scrotal testicular mass detected by the patient, or as an incidental finding on US. Scrotal pain may be present in 27% of patients [33, 34] and a potential reason for delayed diagnosis in 10% of cases [33]. Around 1% of patients presenting with gynaecomastia have a germ cell or sex cord/gonadal tumour of the testes [35] and 11% present with back and flank pain [34]. As such, when there is suspicion of TC, physical examination must include abdominal, chest and supraclavicular exploration.

5.2 Imaging
5.2.1 Ultrasonography of the testes
High-frequency (>10 MHz) testicular US should be used to confirm a testicular tumour even in the presence of a clinically evident testicular lesion [34, 36].

The use of testicular US can:
1. determine whether a mass is intra- or extra-testicular;
2. determine the volume and anatomical location of the testicular lesion;
3. be used to characterise the contralateral testicle – to exclude other lesions and identify risk factors for GCNIS (see section 5.4.4).

Testicular US is also recommended for all men with retroperitoneal or visceral masses and/or without elevated serum human chorionic gonadotropin (hCG) or alpha-fetoprotein (AFP) in the absence of a palpable testicular mass; and for fertility work-up evaluation [34, 36-38].

A range of modalities of US have been investigated (B-mode, dynamic contrast enhanced, real-time elastography, and shear wave elastography) in small cohorts to determine if these can distinguish between benign and malignant testicular lesions [39-42]. So far, the results are not reliable enough to replace the mandatory histopathological tissue diagnosis.

5.2.2 Computerised tomography
Contrast enhanced computerised tomography (CECT) is the most sensitive means to evaluate the thorax, abdomen, and pelvis for TC staging [43]. Contrast enhanced computerised tomography is recommended in all patients for staging before orchidectomy but may be postponed until histopathological confirmation of malignancy.

The size of metastases should be described in three dimensions, or at least by the greatest axial diameter. For abdominal staging, a recent systematic review reports a median sensitivity, specificity, positive predictive value (PPV), negative predictive value (NPV) and accuracy with CECT of 67% (range 37-100%), 92% (range 58-100%), 87% (60-100%), 73% (67-100%) and 83% (range 71-100%), respectively [43].

Sensitivity decreases and specificity increases with increasing lymph node cut-off size. With nodes ≥ 4 mm pooled sensitivity and specificity are 93% and 58% respectively, whereas for nodes ≥ 10 mm sensitivity is 37% and specificity increases to 100% [43]. Using a 10 mm short-axis lymph node diameter as a cut-off yielded a high specificity (97%), a moderate sensitivity (59%) and false-negative rate of 20% in the retroperitoneum [44]. The expected patterns of nodal spread in TC should be considered when evaluating small and borderline nodes.

Chest CT was evaluated in three studies in a systematic review by Pierorazio et al., [43]. This presents a median sensitivity, specificity, PPV, NPV and accuracy of 100% (range 95-100%), 93% (range 89-97%), 68% (range 25-84%), 100% (range 99-100%) and 93% (range 91-97%), respectively. Computerised tomography of the chest is more sensitive but less specific than chest X-ray (CXR) in thoracic staging. Nevertheless, potential harms of chest CT imaging in low-stage seminoma should be taken into consideration [43].

In patients with masses (< 2 cm) in the retroperitoneum or chest and negative tumour markers, restaging after six to eight weeks rather than treatment initiation is advisable (See sections 7.2.2.1 and 7.2.2.2).

Cerebral imaging by CECT is recommended in patients with NSGCT, multiple lung metastases and poor-prognosis IGCCCG risk group (for patients with hCG values > 5,000 UI/L), or if clinical symptoms are present [45].
5.2.3 Magnetic resonance imaging

Magnetic resonance imaging (MRI) of the scrotum provides higher sensitivity and specificity than scrotal US in the diagnosis of TC, but its high cost does not justify its routine use for this purpose [46-48]. It should only be considered when US is inconclusive, as local staging for testis-sparing surgery (TSS) planning, to differentiate between paratesticular and intratesticular lesions and/or to characterise intratesticular masses (e.g., distinctive features of Leydig tumours) [46, 47, 49].

Magnetic resonance imaging of the abdomen may be used for staging in case of allergy to iodine-based contrast media with similar accuracy to CECT in the detection of retroperitoneal nodal enlargement [43].

There is no literature regarding the comparative accuracy of CECT and MRI for the detection and evaluation of cerebral metastases in CGTs. Data from cerebral metastasis detection in other malignancies suggest that MRI is far more sensitive than CECT but requires specific expertise [42, 50, 51]. Therefore, when available, MRI should be preferentially used in the evaluation of cerebral metastases in GCTs [51]. Magnetic resonance imaging of the spine is also advisable in patients with symptoms suggesting metastatic disease or if there is equivocal staging on CECT [50].

5.2.4 Fluorodeoxyglucose-positron emission tomography

There is no evidence to support the use of Fluorodeoxyglucose-positron emission tomography (FDG-PET) for initial staging and follow-up of TC [43, 50, 52, 53]. Fluorodeoxyglucose-positron emission tomography is only recommended for seminoma patients with post-chemotherapy residual masses > 3 cm (largest diameter) to assess FDG activity [54]. Fluorodeoxyglucose-positron emission tomography should not be performed until at least two months after completion of the last cycle of chemotherapy, as inflammation and the desmoplastic reaction induced by chemotherapy may result in FDG avidity and a false positive result [53]. Whilst the NPV for active disease is > 90% [55, 56], the PPV ranges from 23% to 69% [55-57]. False positives are common and may occur in up to 80% of lesions [55, 57], indicating that necrosis, fibrosis, and the consequent inflammation are also associated with FDG activity. Caution is advised on initiating active therapy driven only by positive findings on FDG-PET-CT [57].

5.2.5 Bone scan

There is no evidence to support the use of bone scan for staging of TC.

5.3 Serum tumour markers

5.3.1 Pre-operative serum tumour markers

Alphafetoprotein beta subunit of human Chorionic Gonadotropin (β-hCG) and LDH should be determined before and after orchidectomy as they support the diagnosis of TC, may be indicative of GCT histology and are used for disease staging and risk stratification (Table 4.3), as well as to monitor treatment response and detect disease relapse [58, 59].

In a recently reported cohort, the three markers (AFP, β-hCG and LDH) are simultaneously elevated in 7.1% of patients. The elevation of any of these three markers is seen in up to 60% of patients at diagnosis [50.2% (44-56%) in CS I and 93% in CS III (75.8-98.8%)] [59].

Both alphafetoprotein and β-hCG increase is detected in 39% of patients with NSGCT [59], and up to 90% of NSGCTs present with a rise in either AFP or β-hCG at diagnosis [33, 59, 60]. Pure seminomas may also have modestly elevated β-hCG level at diagnosis in up to 30% (9-32%) of cases [58, 59].

Tumour markers have limitations due to their low sensitivity as normal levels do not exclude the presence of disease [60].

5.3.2 Serum tumour markers after orchidectomy

Serum levels of AFP, β-hCG and LDH following orchidectomy provide staging and prognostic information [61]. As the serum half-life of AFP and β-hCG are five to seven days and one to three days respectively, it may take several weeks until normalisation occurs [58, 60]. The persistence of, or increase in, serum tumour marker elevation following orchidectomy indicates the likely presence of metastatic disease [59]. Whilst normalisation of marker levels after orchidectomy is a favourable indicator, it does not exclude the possibility of metastatic disease. With metastatic TC, risk stratification is based on serum tumour marker levels immediately before initiation of systemic treatment [61]. Before chemotherapy AFP and LDH levels may act as prognostic factors for OS in non-seminoma intermediate risk group [62].
At relapse, only 25% of patients have elevated AFP and β-hCG, and LDH may remain persistently elevated in 50% of patients despite cure [59]. Tumour markers should be routinely used for follow-up as indicators of recurrence, although the precise frequency of testing is not well defined [63].

### 5.3.3 Other tumour markers
Micro RNAs (miRNAs) are emerging as potential new biomarkers for TC. A number of studies suggest higher discriminatory accuracy for miRNAs (particularly miR-371a-3p) compared to conventional GCT markers in diagnosis, treatment monitoring, and predicting of residual or recurrent viable disease [64-71]. Furthermore, they may differentiate between GCT and other (stromal/non-germ cell originated) tumours [71]. However, before miRNAs can be considered for use in routine clinical practice, several issues including laboratory standardisation, availability of the test and, importantly, prognostic validation [70] need to be resolved.

### 5.4 Inguinal exploration and initial management

#### 5.4.1 Orchidectomy
Orchidectomy including division of the spermatic cord at the internal inguinal ring represents the standard of care in patients with TC. Scrotal approach should be avoided when TC is suspected as it results in a higher local recurrence rate [72].

#### 5.4.2 Testis-sparing surgery
Testis-sparing surgery is a valid treatment option in men with interstitial cell or benign testicular tumours and may prevent hypogonadism, lifelong testosterone supplementation and infertility in young men.

In men with TGCTs orchidectomy represents the standard of care as pathological studies describe multifocal and/or adjacent GCNIS in 20-30% of patients [73, 74]. However, TSS when feasible, is indicated in synchronous bilateral tumours or in tumours in solitary tests [75]. Importantly, when indicated in this setting, besides enucleation of the testicular lesion, at least two additional testicular biopsies should be taken to exclude GCNIS [76].

Testis-sparing surgery can also be offered in cases of small or indeterminate testicular masses with negative tumour markers in the presence of a normal contralateral testis in order to avoid the over-treatment of potentially benign lesions and to preserve testicular function [75, 77]. Patients should be informed that cancer can be present even in small (i.e., < 1 cm) masses [75, 78, 79], thus obtaining histology is mandatory.

In both settings, TSS should only be offered together with frozen section examination (FSE). Frozen section examination has shown to be reliable and highly concordant with final histopathology, with a 99% and 96% of sensitivity and specificity respectively and 98% and 97% of PPV and NPV, respectively [77, 80, 81]. In cases of discordance between FSE and final pathology delayed orchidectomy might be needed.

Whether history of GCT or indeterminate small testicular lesion, patients should be made aware on the following issues regarding TSS practice: that limited data exists regarding oncological safety of TSS; that local recurrence rates have been reported (overall 0-26.9%), when TC is present in the specimen [75, 79, 82] and that TSS has implications for ongoing surveillance of the testis. Similarly, patients should be informed about the role and impact of adjuvant radiotherapy when GCNIS is present, on the potential infertility, the need for hormonal supplementation despite parenchyma preservation [75, 79, 83], and that possible discordance between FSE and final pathology may drive the need for a delayed orchidectomy.

#### 5.4.3 Insertion of testicular prosthesis
Testicular prosthesis should be offered to all patients receiving unilateral or bilateral orchidectomy [83]. The prosthesis can be inserted at orchidectomy or subsequently without adverse consequences, including infection [84].

#### 5.4.4 Contralateral biopsy
Contralateral biopsy has been advocated to exclude the presence of GCNIS [85]. Whilst routine policy in some countries [86], the low incidence of GCNIS and metachronous contralateral testicular tumours (up to 9% and approximately 2.5%, respectively) [87, 88], the morbidity of GCNIS treatment (see section 7.1.1), and the fact that most metachronous tumours are low stage at presentation, makes it controversial to recommend routine contralateral biopsy in all patients [89, 90]. Nevertheless, the risks and benefits of biopsy of the contralateral testis should be discussed with TC patients at high risk for contralateral GCNIS, i.e., testicular volume < 12 mL,
and/or a history of cryptorchidism. Contralateral biopsy is not necessary in patients older than 40 years without risk factors [76, 91, 92]. Patients should be informed that a subsequent TGCT may arise despite a negative biopsy [93]. When indicated, a two-site surgical testicular biopsy is the technical procedure recommended [76].

5.5 Pathological examination of the testis
The recommendations for reporting and handling the pathological examination of a testis neoplasm are based on the recommendations of the International Society of Urological Pathology (ISUP) [94-97].

Mandatory pathological requirements:
• **Macroscopic features**: It must indicate radical or partial orchidectomy, side, testis size, number of tumours, and macroscopic features of the epididymis, cord length, and tunica vaginalis.
• **Sampling**: At least a 1 cm$^2$ section for every centimetre of maximum tumour diameter including normal macroscopic parenchyma (if present), tunica albuginea and epididymis, with selection of suspicious areas. If the tumour is < 20 mm it should be completely sampled.
• At least one proximal (base of the cord) and one distal section of spermatic cord plus any suspicious area. Cord blocks should preferably be taken prior to tumour sections to avoid contamination.
• **Microscopic features and diagnosis**: histological types (specify individual components and estimate amount as percentage) according to WHO 2016 [94]:
  - Presence or absence of peri-tumoural lymph vessels and/or blood vessels invasion. In case of doubt, the use of endothelial markers, such as CD31, are recommended.
  - Presence or absence of GCNIS in non-tumour parenchyma.
  - In case of rete testis invasion attention should be paid to distinguishing between pagetoid involvement and stromal invasion [95].
• If microscopic findings are not concordant with serum markers further block samples should be taken.
• **pT category according to TNM 2016** [27]. In a multifocal seminoma the largest nodule should be used to determine pT category.

Immune-histochemical markers in cases of doubt are:
• **Seminoma**: CD-117 (c-KIT), OCT 3/4, Sall4, PLAP
• **GCNIS**: CD-117 (c-KIT), OCT 3 / 4, Sall4, PLAP
• **Syncytiotrophoblast**: $\beta$-hCG
• **Embryonal carcinoma**: CD30
• **Yolk sac tumour**: Glypican 3
• **Sex cord gonadal tumours**: Inhibin, calretinin

The search for i12p (FISH or PCR) or gain in Ch9 (spermatocytic tumour) are additional immuno-chemistry techniques, utility confirmation of other molecular markers such as PS3, MDM2, KRAS AND HRAS is awaited [98].

In order to facilitate consistent and accurate data collection, promote research, and improve patient care, the International Collaboration on Cancer Reporting has constructed a dataset for the reporting of urological neoplasms. The dataset for testicular tumours encompasses the updated 2016 WHO classification of urological tumours, the ISUP consultation and staging with the 8th edition of the American Joint Cancer Committee (AJCC) [97].

The dataset includes those elements unanimously agreed by the expert panel as “required” (mandatory) and those “recommended” (non-mandatory) that would ideally be included but are either non-validated or not regularly used in patient management [97]. The dataset for handling pathological assessment of TC is shown in Table 5.5.
Table 5.5: Recommended dataset for reporting of neoplasia of the testis (modified from the International Collaboration on Cancer Reporting) [97].

### 5.6 Screening

There are no high-level evidence studies supporting screening programs. It has not been shown that screening asymptomatic patients has benefit in terms of detecting TC at a more curable stage, despite the fact that stage and prognosis have been shown to be directly related to early diagnosis [99, 100].

Until clinical data supporting or refuting self-examination in the general population becomes available, TC patients and their family members should be informed about the importance of physical self-examination, particularly in the presence of clinical risk factors including family history of TC [101].

### 5.7 Impact on fertility and fertility-associated issues

Sperm abnormalities and Leydig cell dysfunction are frequently found in patients with TCs prior to orchidectomy [102, 103]. Up to 24% of TC patients are azoospermic and almost 50% have abnormal sperm counts (oligozoospermic) before treatment [103].

Treatment for TC, including orchidectomy, may have a negative impact on reproductive function [104]. Chemotherapy and radiation treatment (RT) can both impair fertility; although, long-term infertility is rare after radiation therapy and is dose-cumulative-dependent after chemotherapy [105-107]. Spermatogenesis usually recovers one to four years after chemotherapy [108]. In CS I, adjuvant treatment (BEP [cisplatin, etoposide, bleomycin] x1; Carbo x1) does not appear to significantly affect testicular function compared to surveillance, with full recovery after one year [109].

All patients should be offered semen preservation as the most cost-effective strategy for fertility preservation, and pre-treatment fertility assessment (testosterone, luteinising hormone [LH] and follicle stimulating hormone [FSH] levels) is advised [110].

If cryopreservation is desired, sperm banking should be offered before orchidectomy, maximizing the chances of fertilisation, and avoiding the risk of a non-functioning remaining testicle after surgery. If not arranged before orchidectomy, it should be undertaken prior to chemotherapy or RT [105-107, 110, 111].
Long-term testosterone supplementation is necessary in patients who have had bilateral orchidectomy or have low testosterone levels after treatment of GCNIS [112].

Chemotherapy and RT are both teratogenic. Therefore, contraception must be used during treatment and for at least six months after its completion [113].

For more detailed information, the reader is referred to the EAU Guidelines on Sexual Reproductive Health [114].

6. PROGNOSIS

6.1 Risk factors for metastatic relapse in clinical stage I testicular cancer

With stage I seminoma, primary testicular tumour size and stromal invasion of the rete testis have been identified as predictors for relapse in a pooled analysis of retrospective data [115]. Absence of both factors indicates a low risk of recurrence (6%) [116]. Whilst the original analysis was not supported by a further retrospective report [117], some prospective series [118-120] support the prognostic significance of tumour size and stromal invasion of the rete testis. Two systematic reviews have assessed the prognostic value of these risk factors [121, 122]. While tumour size (continuous or dichotomised) and rete testis invasion are associated with a higher risk of relapse, both systematic reviews highlighted the low quality of the studies included and that the level of evidence is too low to recommend the use of these pathological risk factors to drive adjuvant treatment decisions [121, 122].

For non-seminoma stage I, invasion of the primary tumour into blood or lymphatic vessels, lymphovascular invasion (LVI), is the most reliable single predictor of occult metastatic disease [96, 123, 124]; while interobserver agreement is limited, immunohistochemistry might improve detection [125]. The percentage of embryonal carcinoma within a tumour may enhance the PPV and NPV of LVI [123], but there is no definitive prognostic cut-off for percentage [123]. Risk of relapse at five years with LVI is 50% compared to 15% without LVI. The significant prognostic pathological risk factors for stage I TC are listed in Table 6.1.

7. DISEASE MANAGEMENT

The availability of cis-platin based chemotherapy to which TC is exquisitely sensitive, in combination with surgery and in highly selected cases, radiotherapy, has resulted in the high cure rates seen with this disease [126]. Careful staging at diagnosis, adequate early treatment based on a multidisciplinary approach, rigorous follow-up and adequate initiation of salvage therapies are critical to successful outcomes.

Whilst early stages can be successfully treated in a non-specialist centre, relapse rates are higher than in specialist centres [127, 128]. In clinical trials on poor-prognosis patients, OS relates to the number of patients treated at the participating centre (worse if < 5 patients enrolled) [129]. Treatment at high-volume specialist centres is thus strongly encouraged. Establishment of second-opinion clinics for TC patients as well as collaboratively working with specialist centres may also help prevent over- and under-treatment [130]. This will ensure that patients are neither subjected to unnecessary or inappropriate treatment and associated toxicities or denied early management options which may subsequently compromise their long-term quality of life or survival.

Initiation of treatment before histopathological confirmation:
In cases of life-threatening disseminated disease, chemotherapy should commence immediately, particularly when the clinical picture strongly supports TC, and/or tumour markers are increased. Orchidectomy in these circumstances can be delayed until clinical stabilisation occurs or subsequently be performed in combination with resection of residual lesions.

7.1 Stage I germ cell tumours

7.1.1 Germ cell neoplasia “in situ” (GCNIS)
If GCNIS is diagnosed in a patient with a solitary testis, local radiotherapy (18-20 Gy in fractions of 2 Gy) should be considered [107, 131-133]. Chemotherapy is significantly less effective, and the cure rates are dose-dependent [131]. Radiotherapy to a solitary testis will result in infertility and increased long-term risk of Leydig cell insufficiency [107]. Fertile patients who wish to father children may delay radiation therapy and be monitored with regular testicular US [76].
If GCNIS is diagnosed and the contralateral testis is normal, management options include orchidectomy or close observation, as the five-year risk of developing TC is 50% [134].

7.1.2  **Seminoma germ cell tumour clinical stage I (SGCT CS I)**

Approximately 15% of clinical stage I SGCT patients have subclinical metastatic disease, usually in the retroperitoneum, and will relapse after orchidectomy alone [117, 120, 135, 136]. Adjuvant treatment decisions should be based on thorough discussions with the patient, incorporating potential advantages and disadvantages, as well as individual patient circumstances.

7.1.2.1  **Surveillance**

Several prospective non-randomised surveillance studies have been conducted over the past decade. These have shown an overall risk of relapse in unselected CS I patients of 12-20% at five years with 17% in the largest series of over 1,500 patients [137]. Most occur in the retroperitoneal lymph nodes during the first two years [138-140].

Risk of relapse is 12% with small size (tumours < 3 cm) as a single parameter [119, 139]. With both small tumour size (< 4 cm) and absence of stromal rete testis invasion even lower recurrence rates of 6% have been described.

The cancer-specific survival (CSS) rate reported with surveillance for CS I seminoma performed by specialist centres is over 99% [137, 138, 140, 141]. Whilst cost effective compared to other management strategies [142], surveillance can represent a burden to the patient due to the need for repeated imaging of the retroperitoneum and clinic visits. These may impact patient compliance which is crucial to an active surveillance strategy.

7.1.2.2  **Adjuvant chemotherapy**

A trial compared one cycle of carboplatin reaching area under curve of 7 mg/mL/min (AUC 7) with adjuvant RT. This showed no difference in relapse free rates (95% and 96%), time to recurrence and survival after a median follow-up of four years [143-145]. Non-randomised risk-adapted population-based studies using one cycle of carboplatin reported a lower five-year relapse rate of 3%-4% compared to 14-16% with active surveillance [138, 140]. Adjuvant carboplatin (AUC 7) is therefore an alternative to RT or surveillance in CS I seminoma [138, 143, 144]. Retrospective data shows a median time to relapse after Carboplatin of nineteen months, with 15% of relapses occurring beyond three years. Time to relapse after Carboplatin is longer than with active surveillance. Most patients relapsing after adjuvant carboplatin can be successfully treated with a standard cisplatin-based chemotherapy regimen appropriate to their disease stage [146].

7.1.2.3  **Adjuvant radiotherapy**

Seminomas are extremely radiosensitive tumours. Adjuvant RT to a para-aortic (PA) field or a PA and ipsilateral field (PA and ipsilateral iliac nodes), with a total dose of 20-24 Gy, reduces the relapse rate between 1-3% [147-149]. A large MRC RCT of 20 Gy vs. 30 Gy PA radiation in CS I seminoma showed non-inferiority in terms of recurrence rates [148]. A scrotal shield should be considered during adjuvant RT in order to prevent scattered radiation toxicity in the contralateral testis [150]. Adjuvant irradiation of supra-diaphragmatic lymph nodes is not indicated.

Whilst moderate acute gastrointestinal side effects occur in up to 60% of patients, moderate chronic gastrointestinal side-effects are present in about 5% of patients. Severe radiation induced long-term toxicity is seen in less than 2% of patients.

The main concern with adjuvant RT is the long-term risk of radiation-induced non-germ cell malignancies [150-153]. This has limited its role in CS I seminoma to elderly patients and those unfit for chemotherapy.

7.1.2.4  **Risk-adapted treatment**

Tumour size > 4 cm and stromal rete testis invasion may stratify patients into low- and high-risk groups. These risk factors were introduced based on an analysis of retrospective trials [102], and then confirmed in subsequent prospective studies [119, 120]. Patients with both risk factors have a 32% of relapse compared to 6% with neither. Prospective trials based on these risk factors have demonstrated the feasibility of a risk-adapted approach to CS I seminoma.

A large study in 744 patients with CS I seminoma managed with a risk-adapted policy (low risk [0-1 factors] receiving active surveillance and high risk [1-2 factors] treated with two adjuvant courses of carboplatin, AUC 7) with a median follow-up of 67 months showed 12% of low-risk cases relapsed on active surveillance.
whilst 3% of those with one or both risk factors relapsed with adjuvant chemotherapy. The patterns and outcome of relapse was similar in the two groups [119, 154].

A trial of 897 patients offered surveillance to patients with no or one risk factor whilst patients with both risk factors were offered one dose of carboplatin, AUC 7 [120]. The decision regarding adjuvant treatment was made by the individual patient. At a median follow-up of 5.6 years, patients without risk factors had a relapse rate of 4% with surveillance compared to 2% with adjuvant carboplatin. When one or both risk factors were present, 15.5% of surveillance patients relapsed whereas 9% receiving adjuvant carboplatin relapsed. Thirty-three per cent of relapses who received adjuvant carboplatin occurred more than three years after orchidectomy with 3% occurring after five years [120].

7.1.3 **Non-seminomatous germ cell tumours clinical stage I (CS I-NSGCT)**

Management options for CS I-NSGCTs comprise surveillance, adjuvant chemotherapy or retroperitoneal lymph node dissection. Overall, approximately 70% of CS I-NSGCTs are cured with orchectomy alone. In those with the high-risk feature of LVI, relapse occurs in 50% compared to 15% in those without LVI. A thorough discussion should be undertaken with the patient outlining the potential advantages and disadvantages of treatment options, as well as individual co-morbidities, disease features, risk factors, specific circumstances, and personal preferences, to guide their treatment decision.

7.1.3.1 **Surveillance**

Surveillance for CS I-NSGCT entails a strict protocol of repeated cross-sectional imaging, monitoring of serum tumour markers and clinical assessment for the early identification of the subset of patients experiencing relapse who must receive salvage treatment.

The largest reports of surveillance indicate a cumulative relapse risk in about 30% of CS I-NSGCT (five-year conditional risk of relapse 42% and 17% for high- and low-risk CS I-NSGCT, respectively) [136, 137]. Of these, 92% present within the first two years [136, 137].
Serum tumour markers alone are an unreliable indicator of relapse. In a systematic review of CS I-NSGCT patients undergoing surveillance, the rate of marker elevation at time of relapse varied between 28 and 75% [155]. Approximately 60% of relapses occur in the retroperitoneum and 11% have large volume metastatic recurrent disease reinforcing the need for cross-sectional imaging [136, 156].

Surveillance studies have reported lower relapse rates compared to some series of patients undergoing primary Retroperitoneal lymph node dissection (RPLND) [157]. This is likely related to both selection bias with both exclusion of high-risk cases and very early marker relapse precipitating treatment prior to surveillance re-imaging. Based on the overall CSS data, surveillance within a rigorous protocol can safely be offered to patients with non-risk stratified CS I-NSGCT who are compliant and informed about the expected recurrence rate and need for salvage treatment [156, 158, 159].

7.1.3.2 Retroperitoneal lymph node dissection (RPLND)

Prior to the availability of effective systemic therapy for relapsed disease primary RPLND for CS I-NSGCT evolved as a strategy which improved survival following orchidectomy [160]. A large series of 464 unselected cases of CS I-NSGCT commencing within this era reported an overall relapse rate of 14%. Of PS (pathological stage) II cases 36% relapsed. With PS I cases 11% relapsed – which is consistent with more contemporary series reporting approximately 10% of patients with no evidence of nodal involvement at RPLND (i.e., PS I) relapsing at distant sites [123, 160, 161]. More recent series report lower relapse rates possibly reflecting case selection [162].

Since the introduction of platin based chemotherapy the role of adjuvant primary RPLND in men with stage I GCT has decreased. The few indications in stage I disease include men with Teratoma with somatic malignant transformation, interstitial cell tumours with an increased risk of metastases or patients who are not willing or suitable to undergo chemotherapy in case of a later recurrence.

With RPLND 18-30% of patients have active nodal malignancy (i.e., PS II), [161, 163]. Without further treatment approximately 30% of these will recur [161]. The presence of LVI, predominant embryonal carcinoma and pT stage of the primary as well as histologically extranodal tumour extension all appear associated with an increased risk of recurrence. The use of these further parameters has yet to be clearly defined in clinical practice [161, 164]. However, following RPLND, presence and extent of lymph-node involvement (specifically lymph-node ratio), may represent stronger predictive factors of recurrence and could be adopted for subsequent decision making [161, 162].

Strategies to reduce the morbidity of primary RPLND include nerve-sparing and minimally invasive approaches. In a multicentre setting, higher rates of in-field recurrences and complications have been reported with nerve-sparing RPLND [163, 165]. This suggests that primary RPLND, when indicated or chosen, should be performed by an experienced surgeon in a specialist centre. Minimally invasive (laparoscopic or robot-assisted) primary RPLND, appears feasible and safe (e.g., low-complication rate) in experienced hands. However, most of the series have only a short follow-up precluding definitive conclusions regarding oncological outcomes when compared to open primary RPLND. At present, it cannot be recommended outside of a high-volume RPLND centres with appropriate minimally-invasive expertise [166-173].

Follow-up after RPLND is less demanding and costly than other options due to the reduced need for cross-sectional imaging [174]. Nevertheless, in view of the high CSS rates of surveillance with salvage treatment in cases of relapse, the low relapse rates with adjuvant chemotherapy, and the lower reproducibility of primary RPLND on a large scale, its role for CS I-NSGCT has diminished.

7.1.3.3 Adjuvant chemotherapy

Adjuvant chemotherapy has been evaluated with both one and two cycles of BEP in CS I-NSGCT. A prospective trial from 1996, as well as subsequent studies, used two cycles of BEP in high-risk patients (LVI present) [175-177]. In these series, including 200 patients, some with a median follow-up of nearly 7.9 years [175], a relapse rate of only 2.7% was reported, with minimal long-term toxicity. Two cycles of cisplatin-based adjuvant chemotherapy also do not seem to adversely affect fertility or sexual activity [178].

More studies have shown one cycle of adjuvant BEP results in similar very low recurrence rates (2-3%) [179, 180]. Reduction from two to one cycle of BEP improves the risk-benefit ratio of adjuvant chemotherapy considerably. A randomised phase III trial has also compared two-year recurrence free survival with adjuvant BEP x 1 to RPLND. Results favoured chemotherapy with recurrence free survival of 99.5% vs. 91% [165]. The hazard ratio to experience a tumour recurrence with surgery compared to BEP x 1 was 8 [165]. No clinically relevant differences in quality of life (QoL) were detected [181].
A community based prospective study of 490 unselected patients with CS I-NSGCT that received adjuvant single cycle BEP had five-year relapse rates of 3% and 2% for LVI+ and LV- patients, respectively. After a median follow-up of eight years these rates were sustained, no relapses were observed beyond 3.3 years [179, 180]. These numbers imply that > 90% of relapses are prevented by single cycle BEP which is now the recommended strategy if adjuvant chemotherapy is considered [179, 180]. The very-long term (> 20 years) side effects of adjuvant chemotherapy, particularly cardiovascular, are yet to be fully defined which should be considered with decision-making [182, 183].

Limited data are available on outcomes with relapse after adjuvant BEP. A retrospective analysis indicated that about one third of these relapses were late and that the outcome may be slightly worse compared to those presenting with de novo metastatic disease [184].

7.1.3.4 Risk-adapted treatment

A risk-adapted strategy is an alternative to any single approach for patients with CS I-NSGCT. The advantages and disadvantages of treatment options must be discussed with patients in the context of their specific circumstances including disease risk factors, co-morbidities, and personal preference, as well as clinician recommendation in reaching a treatment decision. Lymphovascular invasion appears as the strongest predictive risk factor for relapse and should be carefully outlined to the patient in order to assist in their decision-making.

Patients without LVI should be guided to consider surveillance, although some patients with significant co-morbidities or concerns regarding salvage chemotherapy with multicyle cisplatin-based chemotherapy may opt for adjuvant therapy. Those with LVI should have their high risk of relapse (up to 50%) highlighted and be guided to consider adjuvant management, and chemotherapy with BEP X 1 as the “preferred” option.

Some patients may wish to consider primary RPLND although they need to be aware of the potential additional requirement of adjuvant chemotherapy if nodes contain active disease (pN1), as well as the 10% risk of systemic relapse, even if pN0, requiring subsequent chemotherapy treatment (BEP X 3).

7.1.3.5 Post Pubertal Teratoma with somatic malignant component

According to a multi-institutional study analysing retrospective datasets of CS I patients with post-pubertal teratoma with somatic malignant component (TSMC), these patients had inferior five-year OS of approximately 10% compared to other CS I-GCT patients. Furthermore, CS I TSMC cases undergoing primary RPPLND had a much higher proportion of nodal metastases (PS II) than expected (37.5%). Despite its limitations this study provides the strongest evidence on this issue and supports primary RPLND in CS I-NSGCT with TSMC [185].

For patients presenting with CS I pure post-pubertal teratoma without a somatic malignant component, surveillance provides comparable survival outcomes to primary RPLND [186]. However, subtype discrepancies in primary diagnostic of post-pubertal teratoma are not infrequent. When present they consist in addition of subtype and involve secondary somatic type of malignancy in 83% of cases. As such, central review by expert genitourinary pathologist is recommended when teratoma is diagnosed in the orchidectomy specimen [187].

# Primary retroperitoneal lymph node dissection should be advised in men with post-pubertal teratoma with somatic malignant component.

BEP = cisplatin, etoposide, bleomycin; CS = clinical stage; IGCCCG = International Germ Cell Cancer Collaborative Group; NS = nerve-sparing; RPLND = retroperitoneal lymph node dissection; VIP = etoposide, cisplatin, ifosfamide.
7.2 Metastatic germ cell tumours
The first-line treatment of metastatic GCTs depends on:
• the histology of the primary tumour;
• prognostic groups as defined by the IGCCCG (Table 4.3) [61];
• serum tumour marker decline during the first cycle of chemotherapy in poor-prognosis patients.
In relapsed patients, a prognostic score has been developed including response to first-line therapy which can be used to estimate patient outcome following salvage chemotherapy [189].

7.2.1 Clinical stage I with (persistently) elevated serum tumour markers
If AFP or β-hCG increase or fail to normalise following orchidectomy, US examination of the contralateral testicle must be performed. If a contralateral tumour is excluded, repeat staging four weeks after orchidectomy is required [188].

Some patients may have stable but slightly elevated AFP or β-HCG and can be initially monitored. Treatment should be commenced if markers rise or when follow-up imaging demonstrates metastatic disease [188].

The treatment of true CS IS-NSGT should be the same as other good-prognosis metastatic non-seminoma (stage IIA/B). With this, five- and ten-year disease-free survival of 87% and 85%, respectively, have been recently reported [190].

7.2.2 Metastatic disease (stage IIA/B)
7.2.2.1 Stage IIA/B seminoma
Patients with enlarged retroperitoneal lymph nodes < 2 cm and normal markers may be observed for six to eight weeks with repeat-staging imaging as these may be non-metastatic. Treatment should not be initiated unless metastatic disease is unequivocal based on biopsy, increasing nodal size/number, or subsequent marker rise [188, 190]. A special case are those patients who can undergo primary RPLND within a trial or institutional study (see below for further details).

Standard historical treatment of stage II A/B seminoma has been radiotherapy, with reported relapse rates of 9-24% [191, 192]. Most reports describe large target fields and high doses. Further studies using more limited fields report similar rates of relapse [193]. The radiation dose recommended in stage IIA and IIB is 30 Gy and 36 Gy, respectively, with the standard field encompassing the PA and ipsilateral iliac nodes. With these, five-year relapse-free survival rates in stage IIA and IIB are 92% and 90%, respectively [191, 192]. Further dose reduction in stage IIA to 27 Gy is associated with a higher relapse rate of 11% [140, 193].

Accumulating data on long-term morbidity, such as an increased risk of cardiovascular events and second malignancies following radiotherapy has raised concerns. One study with a follow-up of nineteen years reported a sevenfold higher all-cause mortality rate than mortality due to seminoma [194].

Currently, chemotherapy is the preferred alternative to radiotherapy for stage II seminoma. This entails three cycles of BEP as a preferred strategy, or four cycles of etoposide and cisplatin (EP) as an alternative in case of contraindications to bleomycin, or for older patients [195]. There are no randomised studies comparing radiotherapy and chemotherapy. A recent meta-analysis of thirteen high-quality studies, comparing efficacy and toxicity of radiotherapy and chemotherapy in stage IIA/IIB patients [196], showed that radiotherapy and chemotherapy appeared to be similarly effective in both stages, with a non-significant trend towards greater efficacy for chemotherapy (HR: 2.17) in stage IIB seminoma [196]. Acute toxicity was almost exclusively reported following chemotherapy, while long-term toxicity was more frequent following radiotherapy, mainly comprising bowel toxicity and secondary cancers, generally in the irradiated field [196]. Radiation therapy may be considered in highly selected patients who are either elderly or have contraindications or difficulties tolerating systemic chemotherapy.

Single agent carboplatin, using three to four cycles at AUC 7 is not an alternative to standard EP or BEP chemotherapy for metastatic disease, due to the risk of failure (19%) or subsequent relapse (13%) at the site of initial nodal disease [197]. The same strategy utilising a higher dose of carboplatin, AUC 10, has also been reported in a trial [198] and a subsequent multi-institutional analysis [199]. The latter study comprised 216 patients and reported three-year PFS of 96.5% and five-year DSS of 98.3% comparable to standard regimens. Myelosuppression was the principal toxicity with 37% and 27% experiencing grade 3 or higher neutropenia and thrombocytopenia, respectively.
Primary RPLND has also been reported for CS II seminoma [200, 201]. Data from the National Cancer Data Base identified 155 men who underwent primary RPLND for CS II A/B reporting five-year OS of 92%. Specific trials are addressing the role of primary RPLND compared to standard options.

Figure 2: Treatment options in patients with seminoma clinical stage IIA and B*

*When enlarged retroperitoneal lymph nodes are < 2 cm and with normal markers, treatment should not be initiated unless metastatic disease is unequivocal based on biopsy, increasing nodal size/number, or subsequent marker rise.

BEP = cisplatin, etoposide, bleomycin; EP = etoposide, cisplatin.

7.2.2.2 Stage II A/B non-seminoma (NSGCT)

Management of CS II A/B NSGCTs encompasses patients in which retroperitoneal nodal disease is present at diagnosis, or appears with relapse following initial surveillance for stage I disease, or marker negative patients with equivocal radiological findings.

All cases of CS II A/B NSGCT with elevated tumour markers at presentation, as well as those in whom nodal disease evolves with a concomitant increase in the tumour marker AFP or ß-hCG, require primary chemotherapy according to the treatment algorithm for patients with metastatic disease and according to IGCCCG risk-group (See section 7.2.3).

In CS IIA NSGCT disease without elevated tumour markers, nerve-sparing RPLND when performed by an experienced surgeon in a specialised centre is the recommended initial treatment [202, 203]. Initial surveillance may be considered, in patients with normal markers and lymph nodes < 2 cm of greatest axial diameter, or non-nodular shape with early re-evaluation at six weeks. A shrinking lesion may be observed further. If the lesion progresses further or fails to adequately resolve it should be regarded as CS II and be managed with chemotherapy or primary RPLND based on marker status as outlined in Figure 3.

Patients down-staged to PS I require no further treatment even with LVI in the primary tumour site. With PS II disease RPLND alone may be curative. A recent study from Indiana found that 81% of patients with confirmed PS II disease were cured with RPLND alone without additional adjuvant chemotherapy [204]. A further retrospective report on selected patients with stage II relapse after surveillance for stage I NSGCT confirmed a long-lasting remission in 73% of cases following RPLND alone [156]. Relapse, usually outside the retroperitoneum, occurs in 30% of patients with PS II treated with RPLND alone, requiring systemic treatment according to risk-group.
However, adjuvant chemotherapy to reduce the risk of relapse in PS II may be discussed with the patient. Key issues include the risk of overtreatment in about 70% of cases, the need of adequate follow-up to monitor the usually predictable pattern of relapse with minimal but not absent risk of late relapses, the higher relative risk of more intensive therapy in case of relapse, and the possibility of considering quality of surgery and extent of disease (positive lymph node-ratio) as a predictive factor to orient decision. When the choice is for adjuvant chemotherapy, standard treatment is BEP for a maximum of two cycles, but a recent single-centre study of 150 patients undergoing two cycles EP following RPLND and PS II disease reported excellent outcomes with a ten-year relapse-free survival of 98% [205].

Primary RPLND for CS IIA/B disease with elevated markers is not recommended outside a specific study in a referral centre [202, 203].

When a marker negative stage II A/B relapse is diagnosed two or more years after initial diagnosis, a CT- or US-guided biopsy should be advised to confirm the diagnosis of GCT relapse before initiating treatment. A RPLND may be an alternative option and should be performed if biopsy is not feasible or does not provide confirmation of active disease. There is insufficient published data on PET scans in this situation to provide recommendations.

**Figure 3: Treatment options in patients with non-seminoma clinical stage IIA**

* Most of the patients will be good prognostic group (BEP x3 or PE x4).

** In case of PS II A/B patient can be followed-up or receive adjuvant chemotherapy (maximum of 2 cycles).

BEP = cisplatin, etoposide, bleomycin; NS = nerve-sparing; RPLND = retroperitoneal lymph node dissection; PS = pathological stage; PD = progressive disease; NC = no change.

7.2.3 Metastatic disease (stage II C and III)

7.2.3.1 Primary chemotherapy

7.2.3.1.1 Good-prognosis risk group - seminomatous germ cell tumour

For metastatic seminoma, studies available suggest that a cisplatin-based regimen should be preferred to carboplatin chemotherapy [206].

As data from the GETUG S99 trial indicates that EP x 4 results in cure in almost all cases of good-prognosis SGCTs [207], this regime can also be used; therefore, standard treatment in good-prognosis seminoma should be, BEP x 3 or EP x 4. In the case of contraindications to bleomycin, EP x 4 should be given [208].

Post-chemotherapy masses should be managed as described in Section 7.5.2.
7.2.3.1.2 Intermediate-prognosis risk group - seminomatous germ cell tumour
For patients with intermediate-risk seminoma, BEP x 4 or etoposide, cisplatin, ifosfamide (VIP) when contraindications to bleomycin, are the recommended options, although no RCT has focused specifically on this rare group of patients (see Table 4.3).

7.2.3.1.3 Good-prognosis risk group - non-seminomatous germ cell tumour
For non-seminoma, the primary treatment of choice for metastatic disease in patients with good-prognosis disease, according to the IGCCCG risk classification (Table 4.3.), is BEP x 3 (Table 7.1) [61]. This regimen is superior to cisplatin, vinblastine, and bleomycin (PVB) in patients with advanced disease [208].

The available randomised controlled data support the equivalence of three or four cycles of BEP on a three- or five-day regime for projected two-years PFS. However, the group of patients on the three-days regime experienced increased GI toxicity at three months and increased two-years risk of tinnitus (see section 8.2.6). The difference in toxicity between the three- and five-day regimes reached clinical relevance when BEP x 4 was given [209, 210]. Based on these data the BEP x 3 and a five-day regimen is strongly recommended in the good-prognosis risk group.

</tr>
</tbody>
</table>

*Plus, hydration.

Patients with a clear contraindication to bleomycin may receive EP x 4 [209]. In all other cases omission of bleomycin is not recommended.

Two RCTs support the superiority of 3 x BEP over other regimes or schedule intensities [195, 211]. Additionally, a RCT has suggested that when EP is used the mortality rate is twice that as when BEP is used, although the difference did not reach statistical significance [195]. Furthermore, the incidence of residual active cancer in the post-chemotherapy RPLND group was significantly higher in patients who received EP x 4 compared to BEP x 3 (32% vs. 8%, p < 0.0.01) [212]. The risk of requiring post-RPLND adjuvant chemotherapy could be higher after EP x 4 which could thereby offset the anticipated advantage of reduced toxicity.

Therapy should be given without reduction of the doses at 21-day intervals. Cytopenias on day fifteen of BEP are common; however, Bleomycin on day fifteen should be given irrespective of neutropenia or thrombocytopenia. Delaying a chemotherapy cycle is justified only in the presence of severe granulocytopenia <500/mm³ or thrombocytopenia <50,000/IU. Mild neutropenia without fever alone is not a reason to delay the next cycle. As Granulocyte colony-stimulating factor (GCS-F) lowers the risk of neutropenic sepsis, one may consider up-front administration. Granulocyte colony-stimulating factor must be given if infectious complications have occurred during or after chemotherapy, or when a treatment interval is delayed due to myelotoxicity [213].

7.2.3.1.4 Intermediate-prognosis risk group - non-seminomatous germ cell tumour
With this group the available data support BEP x 4 as standard treatment [214].

7.2.3.1.5 Poor-prognosis risk group - non-seminomatous germ cell tumour
For patients with a poor-prognosis non-seminoma as defined by the IGCCCG, one standard treatment consists of BEP x 4. Four cycles of cisplatin, etoposide and ifosfamide (PEI) has similar efficacy, but is more myelotoxic [215]. Several RCTs have shown no advantage in OS for upfront high-dose chemotherapy (HDCT) in the overall poor-prognosis patient group [216, 217].

Patients with a slow tumour marker decline after the first or second cycle represent a prognostically inferior subgroup [217, 218]. There are several ways to calculate slow tumour marker decline with an example available at: https://www.gustaveroussy.fr/calculation-tumor/NSGCT.html.

A trial in poor prognosis NSGCT demonstrated that intensifying treatment with dose-dense chemotherapy improves PFS in patients with an early unfavourable tumour marker decline [219]. The trial was not powered...
to estimate overall survival. Based on the results from this trial, patients with an unfavourable tumour marker decline after BEP x 1 can be switched to a more intensive (dose-dense) chemotherapy regimen [219]. Further prospective trials/registries are planned to validate this approach. Additional patient groups with an unfavourable prognosis on standard treatment are mediastinal primary non-seminoma and patients with brain metastases at initial diagnosis [220, 221]. These may also be candidates for upfront intensified treatment, preferably in a prospective study.

As a matched-pair analysis comparing high-dose to conventional treatment resulted in a better survival rate [222], poor-prognosis patients should still be treated in ongoing prospective trials or registries, whenever possible. Patients meeting poor-prognosis criteria should be transferred to a specialist centre, as better outcomes are reported for intermediate and poor-prognosis patients treated within a clinical trial at high-volume centres [129, 223]. There are no general recommendations for treatment modifications for patients with poor performance status (Karnofsky < 50%) or extended liver infiltration (> 50%), although two small reports indicate that an initial cycle of dose-reduced therapy may reduce acute mortality without compromising long-term outcome. The number of subsequent cycles of full-dose therapy should, however, not be reduced after an initial low-dose induction cycle [223, 224].

Patients with extended pulmonary infiltration are at risk for acute respiratory distress syndrome (ARDS). They should receive only two to three days of EP, followed by standard chemotherapy when the risk of ARDS has passed (typically after ten days). Management of patients with advanced disease in high-volume centres is associated with improved survival and is consequently recommended [225].

7.2.3.1.6 Prevention of thromboembolism events during chemotherapy

Thromboembolic events (TEE) occur more frequently in patients with GCT receiving chemotherapy than in young males under chemotherapy for other cancers [226]. In Denmark, comparison of TEE incidence between 5,185 GCT patients and 51,850 men without GCT revealed that GCT patients undergoing BEP chemotherapy had significantly more TEE within the first year: with hazard ratios (HRs) of 6.3, 6.0, and 24.7 for myocardial infarction, cerebrovascular accident, and venous thromboembolism, respectively [227]. Indwelling venous access devices (VADs) have been identified as TEE risk factors [228].

Recent RCTs have assessed the risks and benefits of thromboprophylaxis in ambulatory cancer patients receiving chemotherapy and report a relative risk reduction of 30-60% in venous thromboembolic events (VTE) but a doubling of bleeding risk [229-232]. Based on these results, the most recent ASCO Clinical Practice Guideline Update recommends thromboprophylaxis with apixaban, rivaroxaban, or low molecular weight heparin (LMWH) to cancer patients with a high risk of VTE and low risk of bleeding [233]. Metastatic germ cell tumour (mGCT) patients were under-represented in all trials and; thus, it is not clear whether this recommendation applies to this group although retrospective data suggests a similar efficacy of VTE prophylaxis [234].

Several retrospective cohort studies published mGCT specific VTE and bleeding risks as well as potential VTE risk factors. In the largest multi-centre cohort study, men with mGCT showed a cumulative VTE incidence of 11% and < 1% were fatal [235]. Nearly all VTEs occurred shortly prior to or during the first 90 days of commencing chemotherapy [235]. Bleeding was observed in 0.5% (95% CI: 0.02–1%) of men not on thromboprophylaxis, 2.5% (95% CI: 0.3–8.8%) of men on thromboprophylaxis and 3.6% (95% CI: 1.2–8.3%) of patients fully anticoagulated because of VTE [235]. A cumulative VTE incidence of 5% during or after chemotherapy occurred in men without any risk factors for VTE. This would translate to a number needed to treat of 32-55 depending on the assumed efficacy of thromboprophylaxis [228]. If thromboprophylaxis resulted in a similar VTE risk reduction and bleeding risk increase observed in other cancers [229-232], VTE may decrease by a relative risk of 30-60%. This would translate to an absolute risk reduction from 5-10% to 2-5% with the absolute risk of bleeding increasing from <1% to approximately 2-3% [228].
Critics of thromboprophylaxis in mGCT argue that the interobserver reliability of detecting incidental asymptomatic VTEs on staging scans is poor and some asymptomatic VTEs may only represent artifact. Nevertheless only <1% mGCT have asymptomatic VTEs detected on staging scans [228]. Furthermore, incidental VTEs may not truly be asymptomatic as affected patients may have mild symptoms such as cough and fatigue which may be misinterpreted because of the underlying cancer or its associated treatment.

Advocates of thromboprophylaxis contend that reduction of VTE risk may improve outcomes as VTE can be fatal directly or indirectly in <1% of cases. An immediate initial consequence of VTE is the need for therapeutic anticoagulation which is associated with a higher risk of clinically significant bleeding [228, 236] including critical areas particularly intracerebral and complicate post chemotherapy surgery. Venous thromboembolic events may also result in long term complications including post-thrombotic syndromes leading to venous leg ulceration and chronic pain. Similarly, pulmonary embolism can impair right ventricular function and pulmonary arterial pressure that does not resolve in 10-30% of patients, with up to 4% ultimately developing chronic symptomatic pulmonary hypertension [237]. These complications all reduce QoL and increase lifetime healthcare costs.

Based on disease specific VTE risk assessments in numerous retrospective cohort studies and the long life-expectancy of mGCT patients, the European Association of Urology Testis Cancer Guideline panel has discussed a recommendation regarding thromboprophylaxis. All members agreed that men with mGCTs undergoing chemotherapy are at high-risk for VTE and low-risk of bleeding. Although several mGCT specific VTE risk factors have been described in the literature [238] only data from retrospective cohorts is available, VTE outcome definitions are heterogeneous and, in most of the studies, only univariable analyses without external validation were performed. Given the apparent high VTE incidence and only non-validated VTE risk factors, the panel preferences were divided between those panel members that favoured thromboprophylaxis in all men and those panel members that restricted thromboprophylaxis to men with certain risk factors. For the final guideline recommendation, the panel agreed that based on the current literature only a generic statement about the use of thromboprophylaxis should be given until stronger evidence is available. Therefore, RCTs or well conducted prospective cohort studies with an adequate sample size allowing adjusting for potential confounders and numerous risk factors are needed to clarify the indication for thromboprophylaxis.

However, no randomised trials are underway to answer those questions and the only two retrospective studies analysed the risk benefits of thromboprophylaxis reported contradictory results [234, 239]. Both studies only had a limited number of men with VTE limiting the ability to account for known confounders which limits the conclusion from both studies.

A generic statement in the TC Guideline should remind clinicians about the high VTE incidence and to prescribe thromboprophylaxis after balancing the risk and benefits. Additionally, the majority of the panel agreed that a central venous-access device should be avoided whenever possible as this represents the only modifiable risk factor which remained significantly associated with VTE in a multivariable risk-prediction model [228].

Thromboprophylaxis includes either LMWH or oral thromboprophylaxis (apixaban 2.5 mg bid or rivaroxaban 10 mg qd) starting before chemotherapy and continued for at least 90 days. Thromboprophylaxis should only be prescribed if no drug interactions or significant risk factors for bleeding are present. Although GCT patients specific risk factors for bleeding are ill-defined the personal experience of panel members and case reports suggest that men with organ infiltration, cerebral metastases and/or significantly elevated β-hCG levels suggestive of choriocarcinoma are at a higher risk of bleeding.

7.3 Treatment evaluation and further treatment

7.3.1 Treatment evaluation
Response to treatment should be assessed after the initial induction cycle by repeat imaging and/or re-evaluation of tumour markers. With marker decline and/or radiologically regressing or stable tumour features, the planned chemotherapy, based on prognostic group, should be completed [240, 241]. If markers decline, but metastases progress on imaging, induction therapy must be completed followed by early resection [242].

With initial disease progression following induction (primary cisplatin refractory), patients should be switched to experimental drug trials [243]. Slow marker decline with the initial one to two cycles of chemotherapy warrants consideration for dose intensification (see section 7.2.3.1.5).

Following completion of treatment, cases with a low-level $\beta$-hCG plateau should be observed to determine whether complete normalisation subsequently occurs. In patients with a low plateau serum AFP level after chemotherapy, removal of residual masses should be undertaken, with subsequent AFP monitoring. Salvage chemotherapy is only indicated for documented marker progression [244, 245].

7.3.2 Residual tumour resection

7.3.2.1 Seminoma
A residual mass of seminoma should be monitored with imaging and tumour markers and not primarily resected, irrespective of size [246-249]. Those with AFP elevation should be regarded as mixed GCTs, be managed as NSGCTs and considered for surgical resection. False-positive AFP elevation (e.g., due to liver toxicity after chemotherapy) has to be excluded.

Fluorodeoxyglucose-positron emission tomography has a high NPV in patients with residual masses after treatment of seminoma. False positive results are less frequent when scans are scheduled more than two months after chemotherapy. In patients with residual masses > 3 cm, FDG-PET should be performed in order to provide more information on disease viability. In patients with residual masses < 3 cm, the use of FDG-PET may be useful, but it is optional [55, 56].

When a post-chemotherapy mass remains positive at reclassification with FDG-PET with no volume increase, repeat FDG-PET should be performed six weeks later. A recent publication shows a low PPV for vital tumours in residual lesions (generally > 3 cm) after chemotherapy in metastatic seminoma (11% to 38% depending on sub-group). Therefore, caution is recommended with FDG-PET as a single parameter to drive clinical decisions in a persistent mass [57]. In patients with progressive disease on radiological criteria (i.e., a growing mass which enhances with CECT or is FDG-PET avid), salvage therapy is indicated (usually chemotherapy or radiotherapy) [250-252]. Surgery may be an option in patients with a residual nodular mass and contraindications to further chemotherapy or irradiation.

Patients with persistently high and/or progressing $\beta$-hCG elevation after first-line chemotherapy should proceed to salvage chemotherapy. Progressing patients without $\beta$-hCG progression should undergo histological verification (e.g., by percutaneous or surgical biopsy) before salvage chemotherapy is given. When RPLND is indicated, this should be performed in referral centres, as residual seminoma masses may be extremely difficult to remove due to intense fibrosis [251]. Ejaculation may be preserved in some of these cases [253].

7.3.2.2 Non-seminoma
Following first-line BEP chemotherapy, only 6-10% of residual masses contain active cancer, 50% have post-pubertal teratoma, and 40% comprise of necrotic-fibrotic tissue only [254]. Fluorodeoxyglucose-positron emission tomography is not indicated to re-stage patients following chemotherapy [50, 52, 53]. With complete radiological remission, RPLND is not indicated [255, 256].

Usual timing for restaging is three to four weeks after the beginning of the last cycle. No diagnostic or risk calculator can accurately predict histology of the residual masses. Thus, resection is mandatory in all patients with a residual mass > 1 cm in greatest axial diameter at cross-sectional CECT imaging until novel predictive models are externally validated [257-260]. Surgery when indicated should be performed within six to eight weeks after the last chemotherapy cycle.

There is uncertainty regarding the role of surgery with residual retroperitoneal lesions < 1 cm. It is difficult to distinguish between a true residual node below 10 mm and a complete remission, and many authors consider these situations as equivalent. Residuals containing cancer or teratoma are possible, but the vast majority of patients have fibro-necrotic tissue only [261]. So far, post-chemotherapy RPLND in case of residuals < 10 mm
or complete remission is an option [262], but the alternative option is an observation protocol with recurrence risk of 6-9% depending on the follow-up duration [255, 256]. In the series with the longest follow-up of 15.5 years, twelve (9%) of 141 patients relapsed despite a complete response following primary treatment [256]. Eight of the twelve relapsing patients were cured with subsequent treatment. These cases should be discussed on individual basis taking into account the orientation and expectations of the patient.

Patients after salvage chemotherapy or HDCT in first or subsequent salvage situations harbour vital tumour at a much higher rate [263]. Surgery is therefore indicated in salvage patients even with residual masses < 1 cm [255, 256].

When resection is indicated bilateral nerve-sparing RPLND is the standard option. Ipsilateral template resection avoids contralateral nerve dissection and leads to improved functional results together with favourable clinical results although mapping studies describe the risk of missed contralateral disease [264].

In men with post-chemotherapy residuals with a residual diameter < 5 cm [265], as well as unilateral lymph node metastases on pre- and post-chemotherapy CT scans, left-sided tumours only require para-aortic resection whereas right-side tumours need paracaval and interaortocaval resection down to the iliac arteries [266, 267].

Indications for ipsilateral template resection after first-line chemotherapy represent men with a residual tumour volume < 5 cm and ipsilateral metastatic disease on pre- and post-chemotherapy scans. The mere resection of the residual tumour (so called lumpectomy) should not be performed [256, 260, 261, 263, 265, 267, 268].

Laparoscopic or robotic RPLND may yield comparable outcomes to open procedures in selected cases with low-volume residual disease and when undertaken by very-experienced surgeons. This should only be considered in specialist TC centres with expertise in open RPLND and minimally invasive surgery to ensure appropriate case selection. In this setting, up to 30% of post-Chemotherapy RPLND have been reported via a laparoscopic approach [269-271]. Experience with robot-assisted laparoscopic RPLND remains limited [272] and atypical recurrences have been reported, and occur more often, with this approach [167].

7.3.3 Sequencing of surgery in the case of multiple sites
In general, surgery should commence at the site with the highest volume of residual disease. The histology of the mass diverges in different organ sites [257]. In cases of residual retroperitoneal and lung masses, the presence of fibro-necrotic tissue in the retroperitoneum is associated with a probability as high as 90% that lung masses contain the same histology [273]. Resection of contralateral pulmonary lesions is not mandatory when pathologic examination of the lesions from the initial side show complete necrosis. Discordant histology between lung sites, however, may occur in up to 20% of cases [274, 275].

7.3.3.1 Quality and intensity of surgery
Post-chemotherapy surgery is always demanding. Whilst most post-chemotherapy RPLNDs do not require resection of major vessels or organs, a proportion of patients may require an intervention in which organs affected by the disease are removed in order to achieve radical resection (e.g., kidney, psoas muscle or gross vessels), and may potentially also require ad hoc reconstructive surgery (e.g., vascular interventions such as vena cava or aortic prostheses). Patients undergoing adjunctive complex surgery benefit from disease control but have a greater risk of complications [276, 277]. In patients with intermediate- or poor-risk and residual disease > 5 cm, the probability of vascular procedures is as high as 20% [278]. This “maximal” surgery must therefore be referred to specialised centres capable of interdisciplinary surgery (hepatic resections, vessel replacement, spinal neurosurgery, thoracic surgery). Even with centralisation of treatment, the median number of RPLNDs performed per surgeon/year in the U.K. is six [279]. Nevertheless, patients treated within such centres benefit from a significant reduction in peri-operative mortality from 6-0.8% [280]. In addition, specialised urologic surgeons are capable of reducing the local recurrence rate from 16-3% with a higher rate of complete resections [281].

7.3.3.2 Salvage and desperation surgery
Surgery of resectable disease after salvage treatment remains a potentially curative option in patients with any residual mass following salvage chemotherapy. Survival after surgery and first salvage chemotherapy improved by 70% at ten years, following taxane-containing regimens [282]. Also, even with extensive salvage chemotherapy, surgery remains a fundamental tool to achieve durable complete remissions in up to 20% of patients [283, 284].
Desperation surgery refers to resection of non-responsive or progressive (e.g., rising markers) disease following salvage chemotherapy. When the disease is resectable, a significant proportion of these patients can be rendered disease-free in the long term [285].

7.3.3.3 Consolidation chemotherapy after secondary surgery
After resection of necrosis or post-pubertal teratoma, no further treatment is required. In cases of incomplete resection of viable cancer, two adjuvant cycles of conventionally dosed cisplatin-based chemotherapy may be given in certain subgroups (e.g., poor-prognosis patients) [268]. However, caution is required with cumulative doses of bleomycin. After complete resection of ‘vital’ tumour < 10% of the total volume, particularly in patients who initially had a good-prognosis based on IGCCCG criteria, the relapse rate is very low and adjuvant chemotherapy is not beneficial in preventing further relapse [286]. The prognosis is worse if malignant disease is present in masses resected after second- and third-line chemotherapy. In this latter situation, post-operative chemotherapy is not indicated [287].

7.3.4 Systemic salvage treatment for relapse or refractory disease
Cisplatin-based combination salvage chemotherapy will result in long-term remissions in approximately 50% of patients who relapse after first-line chemotherapy. These results are highly dependent on several prognostic factors [288]. The regimens of choice are four cycles of a three-agent regimen including cisplatin and ifosfamide plus a third drug: etoposide (PEI/VIP), paclitaxel (TIP), or potentially gemcitabine (GIP) (Table 7.3) [289, 290]. No RCT has compared these regimens. Due to their potential risk of lethal haematological toxicity, these regimens should be used with G-CSF support and by well-trained oncologists.

A retrospective analysis by the International Prognostic Factors Study Group (IPFSG) evaluated the risk of relapse in patients in whom this occurred after at least three cisplatin-based cycles and subsequent cisplatin-based conventional-dose or carboplatin-based high-dose salvage chemotherapy [189]. Seven variables - histology, primary tumour location, response, progression-free interval after first-line treatment and level of AFP, hCG and the presence of liver, bone or brain metastasis at salvage treatment were identified as independent prognostic variables of relapse after initial cisplatinum-based chemotherapy [189]. Using these factors, five risk-groups: very low-risk = -1 points; low-risk = 0 points; intermediate-risk = 1-2 points; high-risk = 3-4 points; and very high-risk > 5 points; were identified with significant differences in PFS and OS. Table 7.4 illustrates these five risk groups and the corresponding two-year PFS and three-year OS rates [189]. Several recent trials have validated this scoring system [292-295]. As in first-line therapy, the prognostic impact of tumour marker decline applies in the salvage setting [296]. While progression to induction chemotherapy was negative for OS, prior use of paclitaxel was not significantly associated with a negative outcome [297].
A secondary analysis of the IPFSG cohort (n = 1,600 patients) showed an improvement of about 10-15% in OS in all prognostic subgroups when treated with high-dose salvage therapy compared to standard dose therapy. To prospectively confirm this finding, an RCT of high-dose vs. conventional dose chemotherapy in patients with first-line relapse is underway (Tiger trial). When HDCT is used as a salvage treatment, sequential treatment cycles of high-dose carboplatin and etoposide (HD-CE) should be preferred to a single high-dose regimen as the former is associated with less toxicity-related deaths [292]. A recent systematic review confirmed the superiority of using at least two high-dose cycles in the salvage setting over a single high-dose cycle [298]. It is clearly of the utmost importance that these rare patients with relapse are treated within clinical trials and at specialised centres.

HR = hazard ratio; PFS – progression-free survival; n = number of patients; OS = overall survival.

7.3.5 Second relapse

No RCTs have been reported for patients with second relapse and overall conventional therapy does not appear effective. For patients who have received two series of conventionally dosed therapy (first-line and first-salvage), high-dose chemotherapy with autologous stem cell support should be used [293]. With this the prospect of cure is only 20% to 25%.

Patients relapsing within four to eight weeks after platinum-based therapy, or who are progressing despite platinum-based therapy, as well as those relapsing shortly after high-dose chemotherapy, are considered as cisplatin refractory. Combinations of gemcitabine and oxaliplatin or the triple combination of gemcitabine, oxaliplatin and paclitaxel have resulted in response rates of 25-45% in this setting. Cisplatin re-challenge in association with gemcitabine and paclitaxel may be considered in patients with adequate renal function [299]. For patients with a second relapse not responding to the combination of oxaliplatin and gemcitabine or the triple combination, inclusion in clinical trials is encouraged.

Patients with a good response undergoing subsequent resection of residual tumour lesions may still have a 15-20% chance of long-term cure [283, 300].

Various targeted agents have generally failed in refractory disease, including immune checkpoint inhibitors [292-298, 301]. Trials combining PD1/PDL-1 and CTLA4 inhibitors are ongoing; however, even for those combinations early results are not encouraging.
7.3.5.1 Late relapse (more than two years after end of first-line treatment)

Late relapse is defined as recurrence more than two years after completion of successful primary treatment of metastatic TC [54]. According to a pooled analysis, this occurs in 1.4% and 3.2% of seminoma and non-seminoma patients, respectively [302]. Interestingly, in a population-based study all late-relapsing seminoma patients had viable GCT [303]. These can be treated with chemotherapy and radiotherapy.

In contrast, patients with late-relapsing NSGCT should undergo surgical resection when feasible, alone or in combination with chemotherapy. Some patients, including those with rapidly rising β-hCG, may benefit from induction salvage chemotherapy with subsequent reconsideration of surgery for resection of persisting residual masses [202]. In general, however, surgery represents the mainstay of treatment, and it should be performed in most patients when feasible irrespective of the level of their tumour markers in order to completely resect all viable GCT post-pubertal teratoma or TSTC [202, 304]. Survival strongly relates to the histology of the recurrent lesions rather than that of the initial disease. If not completely resectable, biopsies should be obtained for histological evaluation to direct salvage chemotherapy based on the tumour phenotype. Review by an experienced pathologist is critical to avoid misinterpretation of the therapeutic morphological changes that occur with the treatment of GCT [305]. If the patient responds to salvage chemotherapy, secondary surgery should then be undertaken if feasible. With unresectable, but localised refractory disease, stereotactic or conventional radiotherapy may be considered. To avoid excess mortality, late relapses should be treated only at centres experienced in managing such patients [306].

7.3.6 Treatment of brain metastases

Brain metastases occur in the context of initial metastatic disease, systemic relapse and rarely as an isolated site of relapse. Long-term survival of patients presenting with brain metastases at diagnosis is poor (30-50%) and even poorer when a site of recurrent disease (five-year survival-rate is 2-5%) [307, 308]. A large international database comprising 523 patients reported 48% three-year OS rates in patients with brain metastases at initial diagnosis and 27% three-year OS rates for patients with brain metastases at relapse [45].

Chemotherapy as initial treatment proved effective in a first-line setting (potentially even as dose-intensified therapy upfront) with data also supporting the use of multimodal treatment particularly in relapsed disease [45]. Consolidation RT, even with total response after chemotherapy, should therefore be used in patients with brain metastases at relapse, but must be carefully discussed in a first-line setting [309]. Surgery may be considered in cases with a persistent solitary metastasis, depending on the systemic disease status, histology of the primary tumour and the location of the metastasis.

### 8. FOLLOW-UP AFTER CURATIVE THERAPY

#### 8.1 Minimal recommendations for follow-up

Based on different risks of relapse depending on diagnosis and initial treatment, three major follow-up groups can be defined:

1. patients with seminoma stage I;
2. patients with non-seminoma stage I on active surveillance;
3. all patients having received either adjuvant treatment or curative chemotherapy for “good”- and intermediate-prognosis metastatic disease (according to the IGCCCG) achieving a complete remission with, or without, surgery (for seminoma this includes residual lesions < 3 cm, or residual lesions > 3 cm that are PET-negative).

It is important to note that patients not achieving a complete remission or presenting with poor-prognosis disease should be followed up individually by specialised centres. Tables 8.1-8.3 show the minimal recommendations for follow-up of the three different groups based on recommendations developed at a European Society for Medical Oncology (ESMO) consensus conference [310].

Both CT and MRI can be used to evaluate the retroperitoneum, pelvis and inguinal regions for sites of metastatic disease from TC [311]. Magnetic resonance imaging benefits from an absence of ionising radiation but is more time consuming and less readily available than CT [312]. Given the frequency of follow-up, over a number of years some studies have estimated a risk of up to 1 in 300 of second malignancy related to CT imaging follow-up alone [51], although more recent dose saving protocols and limitations on field of view will have mitigated this somewhat. Nevertheless, this risk could be excluded by the use of MRI for follow-up.

Both CT and MRI rely predominantly on size cut-offs for evaluation given the excellent spatial resolution of both modalities, with morphological assessment for features such as necrosis and irregular shape an adjunct. Sensitivity and specificity vary according to the size cut-off used [311]. However, studies have shown comparable excellent results between CT and MRI with up to 98% sensitivity on MRI for the detection of retroperitoneal nodal metastases in TGCT [313]. It has, however, been demonstrated that reader experience is important when interpreting images [314]. In the setting of TGCT, one study demonstrated decreased sensitivity for detection of retroperitoneal nodal disease on MRI when reported by a trainee radiologist with sensitivity of detection of 80% [51]. However, experienced radiologists in the same study again achieved sensitivity for detection of nodal disease of 97% with good interobserver agreement. It was therefore suggested that if MRI is
to be used instead of CT for follow-up this be done in centres/units with oncological radiologists who routinely report CT and MRI in patients with TGCT rather than general radiologists who may only occasionally see such imaging. Consequently, MRI of the abdomen can be used as an alternative to CECT in experienced centres [315].

Regarding the use of US examination of the contralateral testis, the majority of the consensus meeting participants did not support repeat US investigation, either with negative biopsy or if no contralateral biopsy has been performed [310].

A very late relapse (VLR) after five years is a rare event occurring in approximately 0.5% of patients based on a population-based analysis [303]. The aim of follow-up beyond five years therefore shifts to detection of late side effects of treatment, and imaging tests are not routinely recommended.

Most patients with VLR are diagnosed due to symptoms, although up to 50% elevated tumour markers are present in both seminoma and NSGCTs [303, 316]. Patient education regarding relapse symptoms and clinician awareness are important elements of survivorship management. Early use of imaging and tumour markers with suspicion of relapse is encouraged.

8.2 Quality of life and long-term toxicities after cure of testicular cancer

The vast majority of patients will be cured with five-year relative survival rates of approximately 95% in Western Europe. Testicular cancer patients are usually between 18 and 40 years of age at diagnosis and life expectancy after cure extends over several decades [317]. Patients should be informed before treatment of common long-term toxicities, which are avoided or minimised by adherence to international guidelines.

Treatment of stage I TC is controversial, with some experts advocating surveillance for all, thereby avoiding unnecessary adjuvant chemotherapy [159], whereas others highlight the importance of patient autonomy and consider the prospect of avoiding salvage treatment with long-term toxicities appealing [318]. Unfortunately, it is not known which treatment spares most patients from long-term toxicities, which so far seem to be absent or mild after adjuvant chemotherapy. This observation is confirmed by the absence of excess mortality or late toxicities between stage I non-seminoma patients randomised to either primary RPLND or one cycle of adjuvant BEP [319].

During follow-up, patients should be screened and treated for known risk factors such as hypertension, hyperlipidaemia, and testosterone deficiency. Adverse health outcomes (AHOs) are more commonly found in TC patients who received chemotherapy than those cured by surgery alone. Further, modifiable risk factors do contribute to AHOs like hypertension and noise exposure to hearing impairment or smoking to Raynaud phenomenon [320]. Therefore, a healthy lifestyle should be promoted during the follow-up consultations. Adverse health outcomes are associated with unemployment, which is found clearly increased in TCSs as compared to a male normative population [321]. When follow-up by the TC clinician is terminated, a written cancer survivorship plan addressing late toxic effects, lifestyle recommendations, recurrence risk, and cancer-specific follow-up may be helpful [54, 322].

8.2.1 Second malignant neoplasms (SMN)

Metachronous contralateral TC represents a particular SMN as it consists of a GCT. Further, cisplatin-based chemotherapy approximately reduces the risk of a subsequent contralateral TC as compared to surgery only [323, 324]. Second malignant neoplasms of different histologic origin usually occur after the first ten years and are considered to be induced by chemo- and/or radiotherapy [322]. Testicular cancer is commonly diagnosed in adolescents and young adults (AYA), which have a higher absolute risk of developing a subsequent primary neoplasm than survivors of childhood or adult cancer [325]. In a comprehensive study on second cancers in AYA cancer survivors (aged 15-39 years at AYA cancer diagnosis), 24,309 TC survivors with 1,435 second cancers were registered as opposed to 808 expected second cancers, yielding a standardised incidence ratio of 1.8. The second cancer incidence increased with time resulting in remarkably high and accelerating 35-year cumulative incidence rate of 20% (95% CI: 18·9–21·5) [325].

The risk for solid SMN increases with younger age at radio- or chemotherapy [322]. Radiotherapy-related SMN are primarily localised within, or close to, the radiotherapy field (colon, stomach, pancreas, bladder, and the urinary tract) [322]. A remarkably clear radiation-dose relationship to gastric- and pancreatic cancer has been demonstrated [326].

Modern cisplatin-based chemotherapy has been found to be associated with a 40% increased risk of a solid SMN [327]. A relationship between cumulative dose of cisplatin and second SMN, especially in the GI tract, has been noted [328]. As few studies have observation times beyond 25 years, the cumulative incidence of SMN may be underestimated. An increase from 6.5% after 25 years to 20% after 35 years has been
reported [325]. Second malignant neoplasms were identified in 9.4% of Swedish TC survivors, with half these cancers considered uncommon in men in their 40s [329]. Survival was 40% in TC survivors with a SMN as opposed to 80% in those without [329].

The European Society for Blood and Marrow Transplantation (EBMT) reported SMN in 59 of the 5,295 TC patients registered after receiving HDCT within a median follow-up of 3.8 years. Of them, 39% developed a hematologic SMN and 58% a solid SMN. Twenty-year cumulative incidence of solid and hematologic SMN was 4.2% and 1.4% respectively, with median OS shorter after diagnosis of hematologic vs. solid SMN (8.6 vs. 34.4 months). Age ≥ 40 years at the time of HDCT was significantly associated with hematologic, but not with solid SMNs [330]. Among 24,900 US TCSs, one out of six (16.9%) developed a solid SMN after 30 years of observation time [331].

8.2.2 Leukaemia
In a series of 40,576 TC survivors, the observed ratio for developing leukaemia, mostly acute myeloid (AML) and lymphoblastic leukaemia was 2.6 [332]. Among 24,900 US TCSs, the risk of developing leukaemia, mostly AML, after chemotherapy was 2.7 fold increased [331]. The risk of AML seems to be related to both the dose of cisplatin and etoposide. Doses of etoposide exceeding 2 g/m² have been shown to increase the subsequent risk of AML [333]. The majority of TC patients receive much lower doses of etoposide than this so that the absolute risk of AML after three to four courses of BEP is very low. In patients requiring HDCT with cumulative etoposide doses exceeding this threshold, fewer than 1.5% have been reported to develop AML. There is a cumulative dose disease risk relationship with cisplatin and AML. Chemotherapy-induced leukaemia is usually diagnosed within the first ten years after treatment for TC and has a poor-prognosis [334].

8.2.3 Infections
Chemotherapy-treated TC survivors (TCSs) have a higher risk of dying from infections than the general population (standard mortality ratio 2.48, 95%; CI: 1.70-3.5) [335]. This is possibly due to long-term bone marrow suppression, as well as complications of subsequent salvage treatment (which was not reliably registered). Alternatively, extensive or subsequent surgical treatment may be contributory. Furthermore, asymptomatic pulmonary fibrosis by mediastinal radiotherapy and/or bleomycin may render TCSs vulnerable to respiratory infections long after treatment.

8.2.4 Pulmonary complications
Chemotherapy exposed TCSs have a nearly three-fold increased risk of dying of pulmonary diseases than the normal population [335]. Bleomycin-induced lung toxicity may affect 7-21% of patients in the long term, resulting in death in 1-3% [336]. Testicular cancer survivors who received high cumulative cisplatin doses and/or pulmonary surgery, have a poorer pulmonary function than those cured with surgery alone [325]. Intriguingly, long-term pulmonary complications were associated with the cumulative cisplatin doses but not with the dose of bleomycin [337]. The data contrasts with a meta-analysis on chemotherapy for TC including 6,498 patients showing a significant effect of bleomycin administration on all-grade pulmonary toxicity [338]. In a Danish cohort of 565 TC survivors, Lauritsen et al., found pulmonary function recovered with repeated assessments over five years in almost all patients [339]. Pulmonary function was not associated with reduced renal function, age, tobacco-smoking, and cumulative chemotherapy, but rather pulmonary embolism, lung surgery, and poor IGCCCG risk group [339]. In 234 good risk TCSs patients the inclusion of bleomycin did not seem to influence pulmonary morbidity, operative difficulty, or non-pulmonary post-operative complications after post-chemotherapy RPLND [340].

A Canadian study on 212 TC patients receiving bleomycin-containing chemotherapy revealed bleomycin-induced pneumonitis (BIP) in 73 patients (34%) with the majority of these (75%) asymptomatic [341]. Granulocyte colony stimulating factor use was not associated with increased risk of BIP in multivariable analyses nor was it associated with increased severity of symptomatic BIP. There was a non-statistically significant trend towards greater risk of BIP in patients that developed renal impairment during chemotherapy treatment [341].

8.2.5 Cardiovascular toxicity
Thromboembolic events (mostly venous) occur more frequently in GCT patients receiving chemotherapy than in other young male adults treated with chemotherapy for other cancers [226]. Low-dose heparins used during the course of chemotherapy may prevent the onset of thromboembolic events [234], though level 1 evidence is lacking. Mortality from cardiovascular disease (CVD) is higher in TCSs than in the general population (OR: 5) [227, 342, 343]. Furthermore, CVD is more common in chemotherapy-treated TCSs than in those who underwent surgery only [182, 344]. Feldman et al., applied the Framingham Risk Score (FRS) on 787 TC survivors and compared the results with controls [345]: FRS did not differ by chemotherapy regimen (BEP 3 vs. EP 4) nor between control and TCSs, although the latter were three times less likely to smoke and generally
more physically active. However, less educated, and less vigorously active TCSs had higher FRS representing a high-risk subgroup for intense follow-up and counselling [345].

Most of the above studies are registry-based and thus limited. Lauritsen et al., took advantage of the comprehensive prospective registration of cancer, diagnoses and drug prescription in Denmark comparing outcomes between 5,185 GCT patients and 51,850 men without GCT [227].

Cisplatin, etoposide, bleomycin (BEP) chemotherapy, applied in 1,819 GCT patients increased the risks of hypertension and hypercholesterolemia and thus CVD within one year after initiation of BEP: with hazard ratios (HRs) of 6.3, 6.0, and 24.7 for myocardial infarction, cerebrovascular accident, and venous thromboembolism, respectively. One year after BEP treatment, the risk of CVD decreased to normal levels, but after ten years, increasing risks were found for myocardial infarction (HR: 1.4; 95% CI: 1.0 to 2.0) and cardiovascular death (HR: 1.6; 95% CI: 1.0 to 2.5) [227].

Metabolic syndrome, a strong risk factor for CVD and its components, hypertension, obesity and hypercholesterolaemia, increases with treatment intensity (OR: 9.8) [343, 346, 347]. Hypogonadism increases the risk of insulin resistance, a proxy for metabolic syndrome, and an inherent risk of CVD. Bogefors et al., showed, however, that most associations between TC treatment and metabolic parameters became statistically non-significant after adjustment for hypogonadism, indicating that hypogonadism might be the mediator of several toxicities which are usually attributed to the applied TC treatment [348]. Circulating residual serum platinum might exert endothelial stress and thereby possibly lead to hypertension [349]. Furthermore, exposure to circulating platinum is associated with paraesthesia, hypogonadism, and hypercholesterolaemia as well as major vascular events [234].

In a 30-year follow-up, chemotherapy treated TCSs used more often anti-hypertensive or lipid-lowering medications as controls. The TCSs' diastolic heart function was impaired as compared to the controls, whereas no difference was found regarding systolic- or valvular function or prevalence of arrhythmias [350]. The finding of increased vascular stiffness of TCSs more than 20 years after chemotherapy suggests accelerated vascular aging; thus, highlighting the need for intensive cardiovascular risk management [351].

Physical activity reduces the risk of metabolic syndrome and CVD. High-intensity aerobic interval training (HIIT) for twelve weeks improved cardiorespiratory fitness, multiple pathways of CVD risk, and surrogate markers of mortality in TCSs as compared to standard care, i.e., no supervised training [352]. However, HIIT during cisplatin-based chemotherapy might be harmful as a planned study on 94 patients was closed early after recruiting nineteen patients and the finding of severe CVD complications among three out of nine patients undergoing HIIT [353]. Two patients developed a pulmonary embolism (respectively at days seven and nine of BEP cycle 2) and the remainder a myocardial infarction (at day seven of BEP cycle 3). It is difficult to draw firm conclusions from such small patient numbers, but the observed CVD was well above the expected 5% risk of thromboembolic complications during or shortly after cisplatin-based chemotherapy such that the authors discourage HIIT during cisplatin-based chemotherapy for TC.

8.2.6 Raynaud-like phenomena, Neurotoxicity & Ototoxicity
Chemotherapy-related Raynaud-like phenomena were reported before the introduction of cisplatin and are usually attributed to bleomycin [354, 355]. Cisplatin is believed to contribute to cold-induced vasospasms. Vogelzang et al., reported that the incidence of Raynaud's phenomenon was higher after treatment with CVB than with vinblastine and bleomycin only, 41% vs. 21%, respectively [356].

Cisplatin induces a symmetric dose-dependent sensory, distal, length-dependent glove and stocking paraesthesia, affects 29% of TCSs who received cisplatin-based chemotherapy as opposed to 10% after orchidectomy alone [343, 357]. Treatment with five or more cycles increases the frequency of this symptom to 46%. Paclitaxel-induced acute neuropathy consists of an acute pain syndrome, which usually develops within three to seven days following its administration. Platinum is measurable in the serum of TCSs many years after its application with the intensity of paraesthesia more strongly associated with platinum serum level than with the cumulative dose of applied cisplatin [349]. Patients who experience a larger decline in circulating residual serum platinum during follow-up are at reduced risk of worsening of tinnitus or hand paraesthesia [358].

Cisplatin-induced ototoxicity comprises tinnitus and hearing impairment, particularly frequencies of 4,000 Hz and higher, and is caused by damage to the outer hair cells in the inner ear [343]. Encouragingly, hearing impairment deteriorated not considerably after the first decade after chemotherapy and quite normal speech perception tests 30 years after treatment indicated a limited clinical relevance of the high-frequency hearing
Both hearing impairment and tinnitus are considerably increased after application of 50 mg/m² cisplatin over two days as compared to 20 mg/m² over five days (OR: 5.1 and 7.3, respectively), indicating a higher impact of serum peak concentrations than cumulative doses [357]. A significant association between Glutathione S-transferases (GST) genotypes and the risk of cisplatin-induced ototoxicity has been demonstrated [361, 362].

A comprehensive clinical and genome-wide analysis of multiple severe cisplatin-induced neurotoxicities has revealed a correlation between neurotoxicity, ototoxicity, and Raynaud phenomena in TCSs [363]. Of particular interest was the observation that certain TCSs seem to be particularly vulnerable to develop multiple and serious neuro-otological toxicities. TCSs without toxicities comprised the 196 controls and TCSs with two to three severe toxicities represented the 104 cases. Only three controls (1.5%) reported fair/poor health as compared to 18 (17.5%) of the cases.

Patients with multiple severe neurotoxicities were also more likely to report symptoms of peripheral motor neuropathy. Current smoking had a clearly negative impact on severe neurotoxicities. No genome-wide significant SNPs for developing severe cisplatin-induced neurotoxicities were identified. The authors concluded that metastatic TC patients with good-risk features should preferably be treated with 3 x BEP instead of 4 x EP in order to avoid neurotoxicities by the fourth cycle of cisplatin [363].

8.2.7 Cognitive function
There are concerns that chemotherapy may reduce the cognitive function leading to “chemo-brain.” Amidi et al., could show an alteration of brain structural networks after cisplatin-based chemotherapy for TC [364]. Impaired brain networks may underlie poorer performance over time on both specific and non-specific cognitive functions in TC survivors following chemotherapy.

8.2.8 Nephrotoxicity
Cisplatin-based chemotherapy may lead to long-term renal dysfunction in 20-30% of TCSs [234, 344, 346]. In TC patients, reduced renal excretion of cisplatin and bleomycin might increase the risk of other toxicities, e.g., bleomycin-related pneumonitis [365, 366]. A comprehensive assessment of 1,206 Danish TCSs, however, did not reveal a significant association between chemotherapy-induced impaired renal function and other toxicities [342]. Renal recovery was poor after five or more cycles of BEP as compared to after BEP x 3 [347]. The estimation of glomerular filtration rate (eGFR) depends on whether creatinine or cystatin is applied, with the latter substance leading to an overestimation of eGFR in cisplatin treated TCSs, whereas this discrepancy was not found in patients with chronic kidney failure due to medical disease [367]. Genomic markers are related to the risk of cisplatin-induced nephrotoxicity [368]. How these results will impact selection and/or modification of chemotherapy remains to be seen.

8.2.9 Hypogonadism
Testicular endocrine dysfunction comprises insufficient testosterone production and/or compensatory increased LH levels. Subnormal testosterone levels have been reported in TCSs treated with chemotherapy, when compared to those treated with surgery only or the general population [343, 365, 369, 370]. Compensated Leydig cell dysfunction in TCSs (testosterone within normal limits & increased LH values) was not associated with symptoms of depression, anxiety, sexual dysfunction, fatigue or impaired overall self-evaluated QoL, such that testosterone substitution seems not to be indicated in these patients [371].

Hypogonadism increases the risk of insulin resistance and hence the risk of metabolic syndrome, which, in turn, might lead to CVD in the long term [348]. Wiechno et al., could show a decline in testosterone and an increase in LH and FSH within one year after treatment for unilateral TC [372]. Although there are clear indications of hypogonadism-related complications, and despite an established association between low testosterone and metabolic syndrome, no clear association between Leydig cell dysfunction and the risk of metabolic syndrome during a median ten-year follow-up could be established [373].

Walsh et al., reported a RCT demonstrating a benefit of testosterone replacement therapy in young male survivors of TC, lymphoma, and leukaemia aged 25–50 years who had low morning serum testosterone. Under the six months of replacement therapy, cancer survivors that received testosterone experienced a decrease in trunk fat mass and whole-body fat mass and an increase in lean-body mass, but no effect on reported physical functioning or other QoL scores when compared to those that received a placebo gel [374]. The absence of improved QoL and the issue of rendering TCSs sub- or infertile by testosterone replacement therapy is the reason why the TC panel does not recommend this strategy until more compelling endpoints are reported. An ongoing Danish RCT might yield new level 1 evidence [375].
Erectile dysfunction (OR: 4.2) has been significantly associated with chemotherapy in a recent multicentre study [343]. Of 481 North American TCSs treated with modern cisplatin-based chemotherapy, 38% were hypogonadal (defined as on testosterone substitution or serum testosterone level ≤ 3.0 ng/mL) [376]. Hypogonadism was associated with the number of adverse health outcomes and its risk increased with age and obesity [377].

8.2.10 Fatigue

Chronic fatigue (CF) is described as a subjective feeling of emotional, physical and/or cognitive tiredness that is not relieved by rest and persists for more than six months. Significantly higher levels of C-reactive protein and interleukin-1 receptor antagonist are measured in TCSs with CF [377]. Also, a significantly higher frequency of CF (16%) was reported in a cross-sectional Norwegian study of long-term TCSs at a median of twelve years after treatment for TC when compared with the age-matched Norwegian population (10%) [210]. Of note, the prevalence of CF increased from 15-27% during a ten-year period in long-term TCSs [378].

8.2.11 Quality of life

Quality of life is transiently reduced by chemotherapy, during which patients experience a loss of appetite, increased fatigue, increased dyspnoea and reduced social- and physical function [210]. When comparing three or four cycles of BEP in good-risk patients, all outcomes favour treatment with three courses [209]. After one and two years, one-third of patients reported an improvement in global QoL after chemotherapy, while one fifth of patients reported deterioration, with no difference between treatment groups. After adjuvant treatment of non-seminoma stage I patients, there was no difference in short-term or long-term (five years) QoL between RPLND, or one course of BEP [181].

Anxiety, depression, fear of cancer recurrence (FCR), and distress may impair the health-related quality of life (HRQoL) in TCSs. A recent review identified a considerable variation in both severity and prevalence of each of these issues, probably due to use of different questionnaires and also cultural variations [379]. Clinically significant anxiety is reported in approximately one out of five TCSs and distress in one out of seven; therefore, it is more frequent among TCS than in the general population. Depression was not uniformly found to be more frequent, whereas every third TCSs reported fear of recurrence. Importantly, poorer psychological outcomes were more common among single, unemployed TCSs with a low socio-economic status and co-morbidities, as well as those experiencing worse symptoms/side effects, and those using passive coping strategies.

A German study found clinically significant anxiety in 6.1% and depression present in 7.9% of TC patients, with both a higher number of physical symptoms and the prospect of having children being related to higher levels of anxiety and depression [380].

Among 2,479 Danish long-term TCSs, higher anxiety was reported by those who experienced bilateral TC as compared to unilateral TC [381]. For a subset of approximately 11% of TCSs, the diagnosis of TC was traumatic. This subset was found to suffer from post-traumatic stress disorder in the long term, which resulted in significant QoL reduction [382]. Kreiberg et al., recommend stress symptoms at follow-up visits in order to timely identify TCSs requiring support [383]. This recommendation is supported by the finding of an increased mental health service utilisation as compared to healthy controls [384]. Testicular cancer survivors who developed bilateral TC had a higher degree of anxiety compared to survivors of unilateral TC but did not report otherwise impaired QoL [385].

Erectile dysfunction was found in men who underwent radiotherapy, BEP chemotherapy with subsequent surgical resection of residual masses, or more than one line of treatment. The latter group also reported orgasmic dysfunction. After radiotherapy, significantly more men reported overall decreased sexual satisfaction, whereas all other groups reported no difference in overall satisfaction, intercourse satisfaction, and sexual desire [385].

Testicular cancer survivors were more likely to have high levels of stress compared to the reference population with a prevalence ratio of 1.56 (95% CI: 1.40 – 1.73), according to a big cohort study with 2,252 patients, with a median of nineteen years from diagnosis [383].
9. RARE ADULT PARA- AND TESTICULAR TUMOURS

Less than 5% of testicular cancers are unrelated to GCNIS and lack 12p alterations [386, 347]. These tumours are rare with available literature based on case reports and small retrospective series. Given the rarity of non-germ cell para-/testicular cancers, referral of these cases to specialist units for multidisciplinary discussion including central image and pathology review is highly recommended. As a result of publication bias related to these types of study, the risk of metastatic disease may be less than that reported in the literature.

9.1 Classification
These testicular tumours have a similar presentation as TC and are only identified after histopathologic examination. They are classified according to the WHO Classification of Tumours of the Urinary System and Male Genital Organs [387].

9.2 Spermatocytic Tumours
Spermatocytic tumours are GCTs unrelated to GCNIS. They show a unique amplification of chromosome 9 corresponding to the DMRT1 gene and are never associated with other forms of germ cell tumours [387].

Spermatocytic tumours are rare, occur exclusively in the testis and do not normally show elevated tumour markers [387]. Previously named “spermatocytic seminomas” they have been recently reclassified as spermatocytic tumours [387]. As those tumours cannot be differentiated from seminoma GCT by frozen section analysis, radical orchiectomy is the standard treatment option. Outcomes after testis-sparing surgery or adjuvant treatment is unknown and therefore not recommended [388]. Metastatic disease is very rare and typically presents at or soon after initial diagnosis with limited survival [388].

9.3 Sex cord-stromal tumours
Sex cord-stromal tumours are relatively uncommon but represent the second largest group of primary testicular tumours after GCT’s [389]. As a small subset of these tumours are clinically malignant, a thorough evaluation of those morphological features associated with malignancy should be performed to guide management. Two or more of the following features are associated with malignant potential: size > 5 cm, infiltrative borders, cytological atypia, three or more mitotic figures per ten high-power fields, vascular invasion and necrosis [389].

9.3.1 Leydig cell tumours
Leydig cell tumours comprise about 4% of adult testicular tumours. These mainly present as localised tumours with metastases occurring in only 2.5% [390]. They may present with hormonal manifestations, including gynaecomastia and more rarely are accompanied by Cushing’s Syndrome [389]. With testis-sparing surgery a local recurrence rate of 7% has been reported although no adjuvant treatment options can be recommended [391]. Several risk factors for metastatic disease have been proposed which may guide image-guided follow-up intensity [391]. Survival of men with metastatic disease is poor but occasional responses to surgical and systemic treatment have been reported [391].

9.3.2 Sertoli cell tumours
Sertoli cell tumours account for approximately 1% of testicular neoplasms [389]. The risk of metastases is unclear. With testis-sparing surgery a local recurrence rate of < 1% has been reported although no adjuvant treatment options can be recommended [392]. Several risk factors for metastatic disease have been proposed which may guide image guided follow-up intensity [392]. Survival of men with metastatic disease is poor although response to surgery has been occasionally reported [392].

9.3.3 Granulosa cell tumour
Granulosa cell tumours, which include adult and juvenile variants, are extremely rare and metastatic potential is unclear [389]. With testis-sparing surgery a local recurrence rate of 5% has been reported although no adjuvant treatment options can be recommended [393]. Whereas metastatic disease has never been reported in juvenile granulosa cell tumours, men with adult type may occasionally present with metastatic disease [393]. Survival of men with metastatic disease is poor although rare instances of response to surgical or systemic treatment has been reported [393].

9.3.4 Thecoma/fibroma group of tumours
These tumours derive from the testicular parenchymal stroma or from the tunica albuginea. They seem to be uniformly benign [389, 394].
9.3.5  **Paratesticular tumours of the epididymis or spermatic cord**

The majority of epididymal masses are benign cystic or inflammatory conditions. Solid epididymal tumours are rare and comprise numerous benign and neoplastic lesions. In the only population-based analyses [395], the majority of neoplastic lesions of the epididymis or spermatic cord were sarcomas, metastases from other organs or primary adenocarcinomas similar to proportions reported in institutional studies [396, 397]. Benign lesions, which may comprise the majority in clinical practice include lipomas, adenomatoid tumours leiomyomas and papillary cystadenomas.

Robust criteria to differentiate between neoplastic benign lesions have not been defined although ultrasonography with or without fine needle aspiration [398] MRI [49, 399] or surgical exploration with frozen section analyses or histopathological confirmation can be considered. No clear recommendation can be provided regarding surgical approach, extent of resection and neo- or adjuvant treatment can be given.

9.4  **Mesothelioma of the tunica vaginalis testis**

Mesothelioma of the tunica vaginalis testis is a rare but aggressive disease [400]. Beside older age, larger tumour size, presence of necrosis, angiolympathic invasion or a high mitotic index the only modifiable risk factors represents local recurrence. Therefore, aggressive local treatment with hemiscrotectomy is recommended. No clear recommendation can be given regarding adjuvant treatment. In case of metastatic disease, the median overall survival is a few months only and multimodal treatment could be considered.

9. CITATION INFORMATION
1. **INTRODUCTION**

1.1 **Aim and objectives**
Lower urinary tract symptoms (LUTS) are a common complaint in adult men with a major impact on quality of life (QoL), and have a substantial economic burden. The present Guidelines offer practical evidence-based guidance on the assessment and treatment of men aged 40 years or older with various non-neurogenic benign forms of LUTS. The understanding of the LUT as a functional unit, and the multifactorial aetiology of associated symptoms, means that LUTS now constitute the main focus, rather than the former emphasis on Benign Prostatic Hyperplasia (BPH). The term BPH is now regarded as inappropriate as it is Benign Prostatic Obstruction (BPO) that is treated if the obstruction is a significant cause of a man's LUTS. It must be emphasised that clinical guidelines present the best evidence available to the experts. However, following guideline recommendations will not necessarily result in the best outcome. Guidelines can never replace clinical expertise when making treatment decisions for individual patients, but rather help to focus decisions - also taking personal values and preferences/individual circumstances of patients into account. Guidelines are not mandates and do not purport to be a legal standard of care.

1.2 **Panel composition**
The EAU Non-neurogenic Male LUTS Guidelines Panel consists of an international group of experts with urological and clinical epidemiological backgrounds. All experts involved in the production of this document have submitted potential conflict of interest statements which can be viewed on the EAU website Uroweb: http://uroweb.org/guideline/treatment-of-non-neurogenic-male-luts/.

1.3 **Available publications**
A quick reference document, the Pocket Guidelines, is available in print and as an app for iOS and Android devices. These are abridged versions which may require consultation together with the full text version. All documents are accessible through the EAU website Uroweb: http://www.uroweb.org/guideline/treatment-of-non-neurogenic-male-luts/.

1.4 **Publication history**
The Non-neurogenic Male LUTS Guidelines was first published in 2000. Standard procedure for EAU Guidelines includes an annual assessment of newly published literature in the field to guide future updates. All sections of the 2022 Male LUTS Guidelines have been fully updated.

2. **METHODS**

2.1 **Introduction**
For the 2022 Management of Non-Neurogenic Male LUTS Guidelines, new and relevant evidence was identified, collated, and appraised through a structured assessment of the literature. A broad and comprehensive literature search, covering all sections of the Non-Neurogenic Male LUTS Guidelines was performed. The search was limited to studies representing high levels of evidence, i.e., systematic reviews (SRs) with meta-analysis, Randomised Controlled Trials (RCTs), and prospective non-randomised comparative studies, published in the English language. Databases searched included Medline, EMBASE, and the Cochrane Libraries, covering a time frame between May 1st 2019 and May 1st, 2021. A total of 2,853 unique records were identified, retrieved, and screened for relevance.

In addition, a new section, 5.6 Management of male urinary incontinence, has been added to the Guidelines. This topic was originally addressed in the now discontinued EAU Guidelines on Urinary Incontinence in Adults [1]. As with the overall Guidelines a broad and comprehensive literature search, limited to studies representing high levels of evidence and published in the English language was performed for this section. Databases searched included Medline, EMBASE, and the Cochrane Libraries, covering a time frame from May 2017, the previous update cut-off of the EAU Urinary Incontinence Guidelines and June 24th, 2021. A total of 1,054 unique records were identified, retrieved, and screened for relevance. Detailed search strategies are available online: http://www.uroweb.org/guideline/treatment-of-non-neurogenic-male-luts/supplementary-material.
For each recommendation within the guidelines there is an accompanying online strength rating form, the bases of which is a modified GRADE methodology [2, 3]. Each strength rating form addresses a number of key elements namely:

1. the overall quality of the evidence which exists for the recommendation, references used in this text are graded according to a classification system modified from the Oxford Centre for Evidence-Based Medicine Levels of Evidence [4];
2. the magnitude of the effect (individual or combined effects);
3. the certainty of the results (precision, consistency, heterogeneity and other statistical or study related factors);
4. the balance between desirable and undesirable outcomes;
5. the impact of patient values and preferences on the intervention;
6. the certainty of those patient values and preferences.

These key elements are the basis which panels use to define the strength rating of each recommendation. The strength of each recommendation is represented by the words ‘strong’ or ‘weak’ [5]. The strength of each recommendation is determined by the balance between desirable and undesirable consequences of alternative management strategies, the quality of the evidence (including certainty of estimates), and nature and variability of patient values and preferences.

Additional information can be found in the general Methodology section of this print, and online at the EAU website; http://www.uroweb.org/guideline/. A list of associations endorsing the EAU Guidelines can also be viewed online at the above address.

2.2 Review
The Non-Neurogenic Male LUTS Guidelines were peer reviewed prior to publication in 2016. The newly added section on management of urinary incontinence in males was peer reviewed prior to the publication in 2022.

2.3 Patients to whom the guidelines apply
Recommendations apply to men aged 40 years or older who seek professional help for LUTS in various non-neurogenic and non-malignant conditions such as BPO, detrusor overactivity (DO)/overactive bladder (OAB), or nocturnal polyuria. Men with other associated factors relevant to LUT disease (e.g., concomitant neurological diseases, young age, prior LUT disease or surgery) usually require a more extensive work-up, which is not covered in these Guidelines, but may include several tests mentioned in the following sections. EAU Guidelines on Neuro-Urology, Urological Infections, Urolithiasis, or malignant diseases of the LUT have been developed by other EAU Guidelines Panels and are available online: www.uroweb.org/guidelines/.

3. EPIDEMIOLOGY, AETIOLOGY AND PATHOPHYSIOLOGY
Lower urinary tract symptoms can be divided into storage, voiding and post-micturition symptoms [6], they are prevalent, cause bother and impair QoL [7-10]. An increasing awareness of LUTS and storage symptoms in particular, is warranted to discuss management options that could increase QoL [11]. Lower urinary tract symptoms are strongly associated with ageing [7, 8], associated costs and burden are therefore likely to increase with future demographic changes [8, 12]. Lower urinary tract symptoms are also associated with a number of modifiable risk factors, suggesting potential targets for prevention (e.g. metabolic syndrome) [13]. In addition, men with moderate-to-severe LUTS may have an increased risk of major adverse cardiac events [14].

Most elderly men have at least one LUTS [8]; however, symptoms are often mild or not very bothersome [10, 11, 15]. Lower urinary tract symptoms can progress dynamically: for some individuals LUTS persist and progress over long time periods, and for others they remit [8]. Lower urinary tract symptoms have traditionally been related to bladder outlet obstruction (BOO), most frequently when histological BPH progresses through benign prostatic enlargement (BPE) to BPO [6, 9]. However, increasing numbers of studies have shown that LUTS are often unrelated to the prostate [8, 16]. Bladder dysfunction may also cause LUTS, including detrusor overactivity/OAB, detrusor underactivity (DU)/underactive bladder (UAB), as well as other structural or functional abnormalities of the urinary tract and its surrounding tissues [16]. Prostatic inflammation also appears to play a role in BPH pathogenesis and progression [17, 18]. In addition, many non-urological conditions also contribute to urinary symptoms, especially nocturia [8].
The definitions of the most common conditions related to male LUTS are presented below:

- **Acute retention of urine** is defined as a painful, palpable or percussible bladder, when the patient is unable to pass any urine [6].
- **Chronic retention of urine** is defined as a non-painful bladder, which remains palpable or percussible after the patient has passed urine. Such patients may be incontinent [6].
- **Bladder outlet obstruction** is the generic term for obstruction during voiding and is characterised by increasing detrusor pressure and reduced urine flow rate. It is usually diagnosed by studying the synchronous values of flow-rate and detrusor pressure [6].
- **Benign prostatic obstruction** is a form of BOO and may be diagnosed when the cause of outlet obstruction is known to be BPE [6]. In the Guidelines the term BPO or BOO is used as reported by the original studies.
- **Benign prostatic hyperplasia** is a term used (and reserved) for the typical histological pattern, which defines the disease.
- **Detrusor overactivity** is a urodynamic observation characterised by involuntary detrusor contractions during the filling phase which may be spontaneous or provoked [6]. Detrusor overactivity is usually associated with OAB syndrome characterised by urinary urgency, with or without urgency urinary incontinence (UUI), usually with increased daytime frequency and nocturia, if there is no proven infection or other obvious pathology [19].
- **Detrusor underactivity** during voiding is characterised by decreased detrusor voiding pressure leading to a reduced urine flow rate. Detrusor underactivity causes OAB syndrome which is characterised by voiding symptoms similar to those caused by BPO [20].

Figure 1 illustrates the potential causes of LUTS. In any man complaining of LUTS, it is common for more than one of these factors to be present.

**Figure 1: Causes of male LUTS**

- Acute retention of urine
- Chronic retention of urine
- Bladder outlet obstruction
- Benign prostatic obstruction
- Benign prostatic hyperplasia
- Detrusor overactivity
- Detrusor underactivity
- Nocturnal polyuria
- Underactive bladder/ Detrusor underactivity
- Chronic Pelvic Pain syndrome
- Neurogenic bladder dysfunction
- Urinary tract infection / Inflammation
- Bladder tumour
- Foreign body
- Distal ureteric stone
- Urethral stricture
4. DIAGNOSTIC EVALUATION

Tests are useful for diagnosis, monitoring, assessing the risk of disease progression, treatment planning, and the prediction of treatment outcomes. The clinical assessment of patients with LUTS has two main objectives:

- to identify the differential diagnoses, since the origin of male LUTS is multifactorial, the relevant EAU Guidelines on the management of applicable conditions should be followed;
- to define the clinical profile (including the risk of disease progression) of men with LUTS in order to provide appropriate care.

4.1 Medical history

The importance of assessing the patient's history is well recognised [21-23]. A medical history aims to identify the potential causes and relevant comorbidities, including medical and neurological diseases. In addition, current medication, lifestyle habits, emotional and psychological factors must be reviewed. The Panel recognises the need to discuss LUTS and the therapeutic pathway from the patient's perspective. This includes reassuring the patient that there is no definite link between LUTS and prostate cancer (PCa) [24, 25].

As part of the urological/surgical history, a self-completed validated symptom questionnaire (see section 4.2) should be obtained to objectify and quantify LUTS. Bladder diaries or frequency volume charts (FVC) are particularly beneficial when assessing patients with nocturia and/or storage symptoms (see section 4.3). Sexual function should also be assessed, preferably with validated symptom questionnaires such as the International Index of Erectile Function (IIEF) [26].

Summary of evidence LE

A medical history is an integral part of a patient's medical evaluation. 4

Recommendation Strength rating

Take a complete medical history from men with LUTS. Strong

4.2 Symptom score questionnaires

All published guidelines for male LUTS recommend using validated symptom score questionnaires [21, 23]. Several questionnaires have been developed which are sensitive to symptom changes and can be used to monitor treatment [27-33]. Symptom scores are helpful in quantifying LUTS and in identifying which type of symptoms are predominant; however, they are not disease-, gender-, or age-specific. A SR evaluating the diagnostic accuracy of individual symptoms and questionnaires, compared with urodynamic studies (the reference standard), for the diagnosis of BOO in males with LUTS found that individual symptoms and questionnaires for diagnosing BOO were not significantly associated with one another [34].

4.2.1 The International Prostate Symptom Score (IPSS)

The IPSS is an eight-item questionnaire, consisting of seven symptom questions and one QoL question [28]. The IPSS score is categorised as ‘asymptomatic’ (0 points), ‘mildly symptomatic’ (1-7 points), ‘moderately symptomatic’ (8-19 points), and ‘severely symptomatic’ (20-35 points). Limitations include lack of assessment of incontinence, post-micturition symptoms, and bother caused by each separate symptom.

4.2.2 The International Consultation on Incontinence Questionnaire (ICIQ-MLUTS)

The ICIQ-MLUTS was created from the International Continence Society (ICS) male questionnaire. It is a widely used and validated patient completed questionnaire including incontinence questions and bother for each symptom [29]. It contains thirteen items, with subscales for nocturia and OAB, and is available in seventeen languages.

4.2.3 Danish Prostate Symptom Score (DAN-PSS)

The DAN-PSS [32] is a symptom score used mainly in Denmark and Finland. The DAN-PSS also has questions on incontinence and measures the bother of each individual LUTS.

Summary of evidence LE

Symptom questionnaires are sensitive to symptom changes. 3

Symptom scores can quantify LUTS and identify which types of symptoms are predominant; however, they are not disease-, gender-, or age-specific. 3
### 4.3 Frequency volume charts and bladder diaries

The recording of volume and time of each void by the patient is referred to as a FVC. Inclusion of additional information such as fluid intake, use of pads, activities during recording, or which grades symptom severity and bladder sensation is termed a bladder diary [6]. Parameters that can be derived from the FVC and bladder diary include day-time and night-time voiding frequency, total voided volume, the fraction of urine production during the night (nocturnal polyuria index), and volume of individual voids.

The mean 24-hour urine production is subject to considerable variation. Likewise, circumstantial influence and intra-individual variation cause FVC parameters to fluctuate, though there is comparatively little data [35, 36]. The FVC/bladder diary is particularly relevant in nocturia, where it underpins the categorisation of underlying mechanism(s) [37-39]. The use of FVCs may cause a ‘bladder training effect’ and influence the frequency of nocturnal voids [40].

The duration of the FVC/bladder diary needs to be long enough to avoid sampling errors, but short enough to avoid non-compliance [41]. A SR of the available literature recommended FVCs should continue for three or more days [42]. The ICIQ-Bladder diary (ICIQ-BD) is the only diary that has undergone full validation [43].

#### Summary of evidence LE

| Frequency volume charts (FVC) and bladder diaries provide real-time documentation of urinary function and reduce recall bias. | 3 |
| Three- and seven-day FVCs provide reliable measurement of urinary symptoms in patients with LUTS. | 2b |

#### Recommendations Strength rating

- Use a validated symptom score questionnaire including bother and quality of life assessment during the assessment of male LUTS and for re-evaluation during and/or after treatment. **Strong**
- Tell the patient to complete a bladder diary for at least three days. **Strong**

### 4.4 Physical examination and digital-rectal examination

Physical examination particularly focusing on the suprapubic area, the external genitalia, the perineum, and lower limbs should be performed. Urethral discharge, meatal stenosis, phimosis, and penile cancer must be excluded.

#### 4.4.1 Digital-rectal examination and prostate size evaluation

Digital-rectal examination (DRE) is the simplest way to assess prostate volume, but the correlation to prostate volume is poor. Quality-control procedures for DRE have been described [44]. Transrectal ultrasound (TRUS) is more accurate in determining prostate volume than DRE. Underestimation of prostate volume by DRE increases with increasing TRUS volume, particularly where the volume is > 30 mL [45]. A model of visual aids has been developed to help urologists estimate prostate volume more accurately [46]. One study concluded that DRE was sufficient to discriminate between prostate volumes > or < 50 mL [47].

#### Summary of evidence LE

| Physical examination is an integral part of a patient's medical evaluation. | 4 |
| Digital-rectal examination can be used to assess prostate volume; however, the correlation to actual prostate volume is poor. | 3 |

#### Recommendation Strength rating

- Perform a physical examination including digital rectal examination in the assessment of male LUTS. **Strong**

### 4.5 Urinalysis

Urinalysis (dipstick or sediment) must be included in the primary evaluation of any patient presenting with LUTS to identify conditions, such as urinary tract infections (UTI), microhaematuria and diabetes mellitus. If abnormal findings are detected further tests are recommended according to other EAU Guidelines, e.g., Guidelines on urinary tract cancers and urological infections [48-51].

Urinalysis is recommended in most Guidelines in the primary management of patients with LUTS [52, 53]. There is limited evidence, but general expert consensus suggests that the benefits outweigh the costs.
The value of urinary dipstick/microscopy for diagnosing UTI in men with LUTS without acute frequency and dysuria has been questioned.

**Summary of evidence LE**

| Urinalysis (dipstick or sediment) may indicate a UTI, proteinuria, haematuria or glycosuria requiring further assessment. | 3 |
| The benefits of urinalysis outweigh the costs. | 4 |

**Recommendation**

| Use urinalysis (by dipstick or urinary sediment) in the assessment of male LUTS. | Strong |

### 4.6 Prostate-specific antigen

**Prostate-specific antigen and the prediction of prostatic volume**

Pooled analysis of placebo-controlled trials of men with LUTS and presumed BPO showed that prostate-specific antigen (PSA) has a good predictive value for assessing prostate volume, with areas under the curve (AUC) of 0.76-0.78 for various prostate volume thresholds (30 mL, 40 mL, and 50 mL). To achieve a specificity of 70%, whilst maintaining a sensitivity between 65-70%, approximate age-specific criteria for detecting men with prostate glands exceeding 40 mL are PSA > 1.6 ng/mL, > 2.0 ng/mL, and > 2.3 ng/mL, for men with BPH in their 50s, 60s, and 70s, respectively [56].

A strong association between PSA and prostate volume was found in a large community-based study in the Netherlands [57]. A PSA threshold value of 1.5 ng/mL could best predict a prostate volume of > 30 mL, with a positive predictive value (PPV) of 78%. The prediction of prostate volume can also be based on total and free PSA. Both PSA forms predict the TRUS prostate volume (± 20%) in > 90% of the cases [58, 59].

**Prostate-specific antigen and the probability of PCa**

The role of PSA in the diagnosis of PCa is presented by the EAU Guidelines on Prostate Cancer [60]. The potential benefits and harms of using serum PSA testing to diagnose PCa in men with LUTS should be discussed with the patient.

**Prostate-specific antigen and the prediction of BPO-related outcomes**

Serum PSA is a stronger predictor of prostate growth than prostate volume [61]. In addition, the PLESS study showed that PSA also predicted the changes in symptoms, QoL/bother, and maximum flow-rate (Qmax) [62]. In a longitudinal study of men managed conservatively, PSA was a highly significant predictor of clinical progression [63, 64]. In the placebo arms of large double-blind studies, baseline serum PSA predicted the risk of acute urinary retention (AUR) and BPO-related surgery [65, 66]. An equivalent link was also confirmed by the Olmsted County Study. The risk for treatment was higher in men with a baseline PSA of > 1.4 ng/mL [67]. Patients with BPO seem to have a higher PSA level and larger prostate volumes. The PPV of PSA for the detection of BPO was recently shown to be 68% [68]. Furthermore, in an epidemiological study, elevated free PSA levels could predict clinical BPH, independent of total PSA levels [69].

**Summary of evidence LE**

| Prostate-specific antigen (PSA) has a good predictive value for assessing prostate volume and is a strong predictor of prostate growth. | 1b |
| Baseline PSA can predict the risk of AUR and BPO-related surgery. | 1b |

**Recommendations**

| Measure prostate-specific antigen (PSA) if a diagnosis of prostate cancer will change management. | Strong |
| Measure PSA if it assists in the treatment and/or decision-making process. | Strong |

### 4.7 Renal function measurement

Renal function may be assessed by serum creatinine or estimated glomerular filtration rate (eGFR). Hydronephrosis, renal insufficiency or urinary retention are more prevalent in patients with signs or symptoms of BPO [70]. Even though BPO may be responsible for these complications, there is no conclusive evidence on the mechanism [71].

One study reported that 11% of men with LUTS had renal insufficiency [70]. Neither symptom score nor QoL was associated with the serum creatinine level. Diabetes mellitus or hypertension were the most likely causes of the elevated creatinine concentration. Comiter et al., [72] reported that non-neurogenic voiding
dysfunction is not a risk factor for elevated creatinine levels. Koch et al., [73] concluded that only those with an elevated creatinine level require investigational ultrasound (US) of the kidney.

In the Olmsted County Study community-dwelling men there was a cross-sectional association between signs and symptoms of BPO (though not prostate volume) and chronic kidney disease (CKD) [74]. In 2,741 consecutive patients who presented with LUTS, decreased Q\text{max}, a history of hypertension and/or diabetes were associated with CKD [75]. Another study demonstrated a correlation between Q\text{max} and eGFR in middle-aged men with moderate-to-severe LUTS [76]. Patients with renal insufficiency are at an increased risk of developing post-operative complications [77].

**Summary of evidence**

| LE | Decreased Q\text{max} and a history of hypertension and/or diabetes are associated with CKD in patients who present with LUTS. |
| LE | Patients with renal insufficiency are at an increased risk of developing post-operative complications. |

**Recommendation**

Assess renal function if renal impairment is suspected based on history and clinical examination, or in the presence of hydronephrosis, or when considering surgical treatment for male LUTS.

**Strength rating**

**3**

---

### 4.8 Post-void residual urine

Post-void residual (PVR) urine can be assessed by transabdominal US, bladder scan or catheterisation. Post-void residual is not necessarily associated with BOO, since high PVR volumes can be a consequence of obstruction and/or poor detrusor function/DU [78, 79]. Using a PVR threshold of 50 mL, the diagnostic accuracy of PVR measurement has a PPV of 63% and a negative predictive value (NPV) of 52% for the prediction of BOO [80]. A large PVR is not a contraindication to watchful waiting (WW) or medical therapy, although it may indicate a poor response to treatment and especially to WW. In both the MTOPS and ALTESS studies, a high baseline PVR was associated with an increased risk of symptom progression [65, 66].

Monitoring of changes in PVR over time may allow for identification of patients at risk of AUR [81]. This is of particular importance for the treatment of patients using antimuscarinic medication. In contrast, baseline PVR has little prognostic value for the risk of BPO-related invasive therapy in patients on α\text{1}-blockers or WW [82]. However, due to large test-retest variability and lack of outcome studies, no PVR threshold for treatment decision has yet been established; this is a research priority.

**Summary of evidence**

| LE | The diagnostic accuracy of PVR measurement, using a PVR threshold of 50 mL, has a PPV of 63% and a NPV of 52% for the prediction of BOO. |
| LE | Monitoring of changes in PVR over time may allow for identification of patients at risk of AUR. |

**Recommendation**

Measure post-void residual in the assessment of male LUTS.

**Strength rating**

**Weak**

---

### 4.9 Uroflowmetry

Urinary flow rate assessment is a widely used non-invasive urodynamic test. Key parameters are Q\text{max} and flow pattern. Uroflowmetry parameters should preferably be evaluated with voided volume > 150 mL. As Q\text{max} is prone to within-subject variation [83, 84], it is useful to repeat uroflowmetry measurements, especially if the voided volume is < 150 mL, or Q\text{max} or flow pattern is abnormal.

The diagnostic accuracy of uroflowmetry for detecting BOO varies considerably and is substantially influenced by threshold values. A threshold Q\text{max} of 10 mL/s has a specificity of 70%, a PPV of 70% and a sensitivity of 47% for BOO. The specificity using a threshold Q\text{max} of 15 mL/s was 38%, the PPV 67% and the sensitivity 82% [85]. If Q\text{max} is > 15 mL/s, physiological compensatory processes mean that BOO cannot be excluded. Low Q\text{max} can arise as a consequence of BOO [86], DU or an under-filled bladder [87]. Therefore, it is limited as a diagnostic test as it is unable to discriminate between the underlying mechanisms. Specificity can be improved by repeated flow rate testing. Uroflowmetry can be used for monitoring treatment outcomes [88] and correlating symptoms with objective findings.

**Summary of evidence**

| LE | The diagnostic accuracy of uroflowmetry for detecting BOO varies considerably and is substantially influenced by threshold values. Specificity can be improved by repeated flow rate testing. |

---
Recommendations Strength rating
Perform uroflowmetry in the initial assessment of male LUTS. Weak
Perform uroflowmetry prior to medical or invasive treatment. Strong

4.10 Imaging

4.10.1 Upper urinary tract
Men with LUTS are not at increased risk for upper tract malignancy or other abnormalities when compared to the overall population [73, 89-91]. Several arguments support the use of renal ultrasound (US) in preference to intravenous urography. Ultrasound allows for better characterisation of renal masses, the possibility of investigating the liver and retroperitoneum, and simultaneous evaluation of the bladder, PVR and prostate, together with a lower cost, no radiation dose and less side effects [89]. Ultrasound can be used for the evaluation of men with large PVR, haematuria, or a history of urolithiasis.

Summary of evidence LE
Men with LUTS are not at increased risk for upper tract malignancy or other abnormalities when compared to the overall population. 3
Ultrasound can be used for the evaluation of men with large PVR, haematuria, or a history of urolithiasis. 4

Recommendation Strength rating
Perform ultrasound of the upper urinary tract in men with LUTS. Weak

4.10.2 Prostate
Imaging of the prostate can be performed by transabdominal US, TRUS, computed tomography (CT), and magnetic resonance imaging (MRI). However, in daily practice, prostate imaging is performed by transabdominal (suprapubic) US or TRUS [89].

4.10.2.1 Prostate size and shape
Assessment of prostate size is important for the selection of interventional treatment, i.e., open prostatectomy (OP), enucleation techniques, transurethral resection, transurethral incision of the prostate (TUIP), or minimally invasive therapies. It is also important prior to treatment with 5α-reductase inhibitors (5-ARIs). Prostate volume predicts symptom progression and the risk of complications [91]. Transrectal US is superior to transabdominal volume measurement [92, 93]. The presence of a median lobe may guide treatment choice in patients scheduled for a minimally invasive approach since medial lobe presence can be a contraindication for some minimally invasive treatments (see section 5.3).

Summary of evidence LE
Assessment of prostate size by TRUS or transabdominal US is important for the selection of interventional treatment and prior to treatment with 5-ARIs. 3

Recommendations Strength rating
Perform imaging of the prostate when considering medical treatment for male LUTS, if it assists in the choice of the appropriate drug. Weak
Perform imaging of the prostate when considering surgical treatment. Strong

4.10.3 Voiding cysto-urethrogram
Voiding cysto-urethrogram (VCUG) is not recommended in the routine diagnostic work-up of men with LUTS, but it may be useful for the detection of vesico-ureteral reflux, bladder diverticula, or urethral pathologies. Retrograde urethrography may additionally be useful for the evaluation of suspected urethral strictures.

4.11 Urethrocystoscopy
Patients with a history of microscopic or gross haematuria, urethral stricture, or bladder cancer, who present with LUTS, should undergo urethrocystoscopy during diagnostic evaluation. The evaluation of a prostatic middle lobe with urethrocystoscopy should be performed when considering interventional treatments for which the presence of middle lobe is a contraindication.

A prospective study evaluated 122 patients with LUTS using uroflowmetry and urethrocystoscopy [94]. The pre-operative $Q_{\text{max}}$ was normal in 25% of 60 patients who had no bladder trabeculation, 21% of 73 patients with mild trabeculation and 12% of 40 patients with marked trabeculation on cystoscopy. All 21 patients who presented with diverticula had a reduced $Q_{\text{max}}$. 
Another study showed that there was no significant correlation between the degree of bladder trabeculation (graded from I to IV), and the pre-operative Q\textsubscript{max} value in 39 symptomatic men aged 53-83 years [95]. The largest study published on this issue examined the relation of urethrocystoscopic findings to urodynamic studies in 492 elderly men with LUTS [96]. The authors noted a correlation between cystoscopic appearance (grade of bladder trabeculation and urethral occlusion) and urodynamic indices, DO and low compliance. It should be noted, however, that BOO was present in 15% of patients with normal cystoscopic findings, while 8% of patients had no obstruction, even in the presence of severe trabeculation [96].

### Summary of evidence LE

| Patients with a history of microscopic or gross haematuria, urethral stricture, or bladder cancer, who present with LUTS, should undergo urethrocystoscopy during diagnostic evaluation. | 3 |
| None of the studies identified a strong association between the urethrocystoscopic and urodynamic findings. | 3 |

### Recommendation Strength rating

| Perform urethrocystoscopy in men with LUTS prior to minimally invasive/surgical therapies if the findings may change treatment. | Weak |

#### 4.12 Urodynamics

In male LUTS, the most widespread invasive urodynamic techniques employed are filling cystometry and pressure flow studies (PFS). The major goal of urodynamics (UDS) is to explore the functional mechanisms of LUTS, to identify risk factors for adverse outcomes and to provide information for shared decision-making. Most terms and conditions (e.g. DO, low compliance, BOO/BPO, DU) are defined by urodynamic investigation.

**4.12.1 Diagnosing bladder outlet obstruction**

Pressure flow studies are used to diagnose and define the severity of BOO, which is characterised by increased detrusor pressure and decreased urinary flow rate during voiding. Bladder outlet obstruction/BPO has to be differentiated from DU, which exhibits decreased detrusor pressure during voiding in combination with decreased urinary flow rate [6].

Urodynamic testing may also identify DO. Studies have described an association between BOO and DO [97, 98]. In men with LUTS attributed to BPO, DO was present in 61% and independently associated with BOO grade and ageing [97].

The prevalence of DU in men with LUTS is 11-40% [99, 100]. Detrusor contractility does not appear to decline in long-term BOO and surgical relief of BOO does not improve contractility [101, 102]. An RCT investigated whether urodynamics would reduce surgery without increasing urinary symptoms. The UPSTREAM study was a non-inferiority, RCT in men with bothersome LUTS, in whom surgery was an option, in 26 hospitals in England. From the 820 men, 153/408 (38%) were in the UDS arm and received surgery compared with 138/384 (36%) in the routine care (RC) arm. A total of 428 adverse events were recorded, with related events similar in both arms and eleven unrelated deaths. The UDS group was non-inferior to the RC group for IPSS, but UDS did not reduce surgical rates. The authors concluded that routine use of UDS in the evaluation of uncomplicated LUTS has a limited role and should be used selectively [103]. If urodynamic investigation is performed, a rigorous quality control is mandatory [104].

Due to the invasive nature of the test, a urodynamic investigation is generally only offered if conservative treatment has failed. The Guidelines Panel attempted to identify specific indications for PFS based on age, findings from other diagnostic tests and previous treatments. The Panel allocated a different degree of obligation for PFS in men > 80 years and men < 50 years, which reflects the lack of evidence. In addition, there was no consensus whether PFS should or may be performed when considering surgery in men with bothersome predominantly voiding LUTS and Q\textsubscript{max} > 10 mL/s, although the Panel recognised that with a Q\textsubscript{max} < 10 mL/s, BOO is likely and PFS is not necessarily needed.

Patients with neurological disease, including those with previous radical pelvic surgery, should be assessed according to the EAU Guidelines on Neuro-Urology [105].

**4.12.2 Videourodynamic**

Videourodynamics provides additional anatomical and functional information and may be recommended if the clinician considers this is needed to understand the pathophysiological mechanism of an individual patient’s LUTS.

### Summary of evidence LE

| Urodynamics is not a test for routine use prior to prostate surgery for all patients | 3 |

### 4.13 Non-invasive tests in diagnosing bladder outlet obstruction in men with LUTS

#### 4.13.1 Prostatic configuration/intravesical prostatic protrusion

Prostatic configuration can be evaluated with TRUS, using the concept of the presumed circle area ratio (PCAR) [108]. The PCAR evaluates how closely the transverse US image of the prostate approaches a circular shape. The ratio tends toward one as the prostate becomes more circular. The sensitivity of PCAR was 77% for diagnosing BPO when PCAR was > 0.8, with 75% specificity [108].

Ultrasound measurement of intravesical prostatic protrusion (IPP) assesses the distance between the tip of the prostate median lobe and bladder neck in the midsagittal plane, using a suprapubically positioned US scanner, with a bladder volume of 150-250 mL; grade I protrusion is 0-4.9 mm, grade II is 5-10 mm and grade III is > 10 mm.

Intravesical prostatic protrusion correlates well with BPO (presence and severity) on urodynamic testing, with a PPV of 94% and a NPV of 79% [107]. Intravesical prostatic protrusion may also correlate with prostate volume, DO, bladder compliance, detrusor pressure at maximum urinary flow, BOO index and PVR, and negatively correlates with $Q_{\text{max}}$ [108]. Furthermore, IPP also appears to successfully predict the outcome of a trial without catheter after AUR [109, 110]. However, no information with regards to intra- or inter-observer variability and learning curve is yet available. Therefore, whilst IPP may be a feasible option to infer BPO in men with LUTS, the role of IPP as a non-invasive alternative to PFS in the assessment of male LUTS remains under evaluation.

#### 4.13.2 Bladder/detrusor wall thickness and ultrasonic-estimated bladder weight

For bladder wall thickness (BWT) assessment, the distance between the mucosa and the adventitia is measured. For detrusor wall thickness (DWT) assessment, the only measurement needed is the detrusor sandwiched between the mucosa and adventitia [111].

A correlation between BWT and PFS parameters has been reported. A threshold value of 5 mm at the anterior bladder wall with a bladder filling of 150 mL was best at differentiating between patients with or without BOO [112]. Detrusor wall thickness at the anterior bladder wall with a bladder filling > 250 mL (threshold value for BOO > 2 mm) has a PPV of 94% and a specificity of 95%, achieving 89% agreement with PFS [73]. Threshold values of 2.0, 2.5, or 2.9 mm for DWT in patients with LUTS are able to identify 81%, 89%, and 100% of patients with BOO, respectively [113].

All studies found that BWT or DWT measurements have a higher diagnostic accuracy for detecting BOO than $Q_{\text{max}}$ or $Q_{\text{ave}}$ of free uroflowmetry, measurements of PVR, prostate volume, or symptom severity. One study could not demonstrate any difference in BWT between patients with normal UDS, BOO or DO. However, the study did not use a specific bladder filling volume for measuring BWT [114]. Disadvantages of the method include the lack of standardisation, and lack of evidence to indicate which measurement (BWT/DWT) is preferable [115]. Measurement of BWT/DWT is therefore not recommended for the diagnostic work-up of men with LUTS.

Ultrasound-estimated bladder weight (UEBW) may identify BOO with a diagnostic accuracy of 86% at a cut-off value of 35 g [116, 117]. Severe LUTS and a high UEBW (> 35 g) are risk factors for prostate/BPH surgery in men on $\alpha$-blockers [118].

#### 4.13.3 Non-invasive pressure-flow testing

The penile cuff method, in which flow is interrupted to estimate isovolumetric bladder pressure, shows promising data, with good test repeatability [119] and interobserver agreement [120]. A nomogram has also been derived [121] whilst a method in which flow is not interrupted is also under investigation [122].
The data generated with the external condom method [123] correlates with invasive PFS in a high proportion of patients [124]. Resistive index [125] and prostatic urethral angle [126] have also been proposed, but are still experimental.

4.13.4 **The diagnostic performance of non-invasive tests in diagnosing bladder outlet obstruction in men with LUTS compared with pressure-flow studies**

The diagnostic performance of non-invasive tests in diagnosing BOO in men with LUTS compared with PFS has been investigated in a SR [127]. A total of 42 studies were included in this review. The majority were prospective cohort studies, and the diagnostic accuracy of the following non-invasive tests were assessed: penile cuff test; uroflowmetry; DWT/BWT; bladder weight; external condom catheter method; IPP; Doppler US; prostate volume/height; and near-infrared spectroscopy. Overall, although the majority of studies have a low risk of bias, data regarding the diagnostic accuracy of these non-invasive tests is limited by the heterogeneity of the studies in terms of the threshold values used to define BOO, the different urodynamic definitions of BOO used across different studies and the small number of studies for each test. It was found that specificity, sensitivity, PPV and NPV of the non-invasive tests were highly variable. Therefore, even though several tests have shown promising results regarding non-invasive diagnosis of BOO, invasive urodynamics remains the modality of choice.

### Recommendation

**Do not offer non-invasive tests as an alternative to pressure-flow studies for diagnosing bladder outlet obstruction in men.**

**Strength rating**

**Strong**

4.14 **Novel assessment**

4.14.1 **Visual prostate symptom score**

A novel visual prostate symptom score (VPSS) has been prospectively tested vs. the IPSS and correlated positively with the IPSS score [128, 129]. This visual score can be used as an option in men with limited literacy.

4.14.2 **Micro-RNA**

The use of miR-221 has been shown to have the potential to be used as a biomarker and novel target in the early diagnosis and therapy of BPH [130].
Figure 2: Assessment algorithm of LUTS in men aged 40 years or older

Readers are strongly recommended to read the full text that highlights the current position of each test in detail.

**DRE** = digital-rectal examination; **FVC** = frequency volume chart; **LUTS** = lower urinary tract symptoms; **PCa** = prostate cancer; **PSA** = prostate specific antigen; **PVR** = post-void residual; **US** = ultrasound.
5. DISEASE MANAGEMENT

5.1 Conservative treatment

5.1.1 Watchful waiting

Many men with LUTS are not troubled enough by their symptoms to need drug treatment or surgical intervention. All men with LUTS should be formally assessed prior to any allocation of treatment in order to establish symptom severity and to differentiate between men with uncomplicated (the majority) and complicated LUTS. Watchful waiting is a viable option for many men with non-bothersome LUTS as few will progress to AUR and complications (e.g. renal insufficiency or stones) [131, 132], whilst others can remain stable for years [133]. In one study, approximately 85% of men with mild LUTS were stable on WW at one year [134].

A study comparing WW and transurethral resection of the prostate (TURP) in men with moderate LUTS showed the surgical group had improved bladder function (flow rates and PVR volumes), especially in those with high levels of bother; 36% of WW patients crossed over to surgery within five years, leaving 64% doing well in the WW group [135, 136]. Increasing symptom bother and PVR volumes are the strongest predictors of WW failure. Men with mild-to-moderate uncomplicated LUTS who are not too troubled by their symptoms are suitable for WW.

5.1.2 Behavioural and dietary modifications

It is customary for this type of management to include the following components:

- education (about the patient's condition);
- reassurance (that cancer is not a cause of the urinary symptoms);
- periodic monitoring;
- lifestyle advice [133, 134, 137, 138] such as:
  - reduction of fluid intake at specific times aimed at reducing urinary frequency when most inconvenient (e.g., at night or when going out in public);
  - avoidance/moderation of intake of caffeine or alcohol, which may have a diuretic and irritant effect, thereby increasing fluid output and enhancing frequency, urgency and nocturia;
  - use of relaxed and double-voiding techniques;
  - urethral milking to prevent post-micturition dribble;
  - distraction techniques such as penile squeeze, breathing exercises, perineal pressure, and mental tricks to take the mind off the bladder and toilet, to help control OAB symptoms;
  - bladder retraining that encourages men to hold on when they have urgency to increase their bladder capacity and the time between voids;
  - reviewing the medication and optimising the time of administration or substituting drugs for others that have fewer urinary effects (these recommendations apply especially to diuretics);
  - providing necessary assistance when there is impairment of dexterity, mobility, or mental state;
  - treatment of constipation.

Evidence exists that self-management as part of WW reduces both symptoms and progression [137, 138]. Men randomised to three self-care management sessions in addition to standard care had better symptom improvement and QoL than men treated with standard care only, for up to a year [137]. A SR and meta-analysis found reasonable certainty in estimates that self-management intervention significantly reduced symptom severity in terms of IPSS at six months compared with usual care [139]. The reduction in IPSS score with self-management was similar to that achieved with drug therapy at six to twelve weeks. Self-management had a smaller, additional benefit at six weeks when added to drug therapy [139].

5.1.3 Practical considerations

The components of self-care management have not been individually studied. The above components of lifestyle advice have been derived from formal consensus methodology [140]. Further research in this area is required.

<table>

### 5.2 Pharmacological treatment

#### 5.2.1 α1-Adrenoceptor antagonists (α1-blockers)

**Mechanism of action:** α1-blockers aim to inhibit the effect of endogenously released noradrenaline on smooth muscle cells in the prostate and thereby reduce prostate tone and BOO [141]. However, α1-blockers have little effect on urodynamically determined bladder outlet resistance [142], and treatment-associated improvement of LUTS correlates poorly with obstruction [143]. Thus, other mechanisms of action may also be relevant.

Alpha 1-adrenoceptors located outside the prostate (e.g. urinary bladder and/or spinal cord) and α1-adrenoceptor subtypes (α1B- or α1D-adrenoceptors) may play a role as mediators of effects. Alpha 1-adrenoceptors in blood vessels, other non-prostatic smooth muscle cells, and the central nervous system may mediate adverse events.

Currently available α1-blockers are: alfuzosin hydrochloride (alfuzosin); doxazosin mesylate (doxazosin); tamsulosin hydrochloride (tamsulosin); terazosin hydrochloride (terazosin); and naftopidil. Alpha 1-blockers exist in different formulations. Although different formulations result in different pharmacokinetic and tolerability profiles, the overall difference in clinical efficacy between the difference formulations seems negligible.

**Efficacy:** Indirect comparisons and limited direct comparisons between α1-blockers demonstrate that all α1-blockers have a similar efficacy in appropriate doses [144]. Clinical effects take a few weeks to develop fully, but significant efficacy over placebo can occur within hours to days [143].

Controlled studies show that α1-blockers typically reduce IPSS by approximately 30-40% and increase Qmax by approximately 20-25%. However, substantial improvements also occurred in the corresponding placebo arms [63, 145]. In open-label studies, an IPSS improvement of up to 50% and Qmax increase of up to 40% were documented [63, 145]. A recent SR and meta-analysis suggested that Qmax variation underestimates the real effect of α1-blockers on BPO, as small improvements in Qmax correspond to relevant improvements in BOO index in PFS [146].

Alpha 1-blockers can reduce both storage and voiding LUTS. Prostate size does not affect α1-blocker efficacy in studies with follow-up periods of less than one year, but α1-blockers do seem to be more efficacious in patients with smaller prostates (< 40 mL) in longer-term studies [65, 147-150]. The efficacy of α1-blockers is similar across age groups [145]. A pooled analysis of phase III and IV trials of silodosin 8 mg demonstrated that improvements in total, storage, voiding, and QoL IPSS scores were similar for the severe and not severe LUTS cohorts [151]. In addition, α1-blockers neither reduce prostate size nor prevent AUR in long-term studies [148-150]; however, recent evidence suggests that the use of α1-blockers (alfuzosin and tamsulosin) may improve resolution of AUR [152]. Nonetheless, IPSS reduction and Qmax improvement during α1-blocker treatment appears to be maintained over at least four years.

**Tolerability and safety:** Tissue distribution, subtype selectivity, and pharmacokinetic profiles of certain formulations seems negligible. The most frequent adverse events of α1-blockers are asthenia, dizziness and (orthostatic) hypotension. Vasodilating effects are most pronounced with doxazosin and terazosin and are less common with alfuzosin and tamsulosin [153]. Patients with cardiovascular comorbidity and/or vaso-active co-medication may be susceptible to α1-blocker-induced vasodilatation [154]. In contrast, the frequency of hypotension with the α1A-selective blocker silodosin is comparable with placebo [155]. In a large retrospective cohort analysis of men aged > 66 years treated with α1-blockers the risks of falling (odds ratio [OR] 1.14) and of sustaining a fracture (OR 1.16) was increased, most likely as a result of induced hypotension [156].

An adverse ocular event termed intra-operative floppy iris syndrome (IFIS) was reported in 2005, affecting cataract surgery [157]. A meta-analysis on IFIS after alfuzosin, doxazosin, tamsulosin or terazosin exposure showed an increased risk for all α1-blockers [158]. However, the OR for IFIS was much higher for
tamsulosin. It appears prudent not to initiate \(\alpha\)-blocker treatment prior to scheduled cataract surgery, and the ophthalmologist should be informed about \(\alpha\)-blocker use.

A SR concluded that \(\alpha\)-blockers do not adversely affect libido, have a small beneficial effect on erectile function, but can cause abnormal ejaculation [159]. Originally, abnormal ejaculation was thought to be retrograde, but more recent data demonstrate that it is due to a decrease or absence of seminal fluid during ejaculation, with young age being an apparent risk factor. In a recent meta-analysis ejaculatory dysfunction (EjD) was significantly more common with \(\alpha\)-1 blockers than with placebo (OR: 5.88). In particular, EjD was significantly more commonly related with tamsulosin or silodosin (OR: 8.57 and 32.5) than placebo, while both doxazosin and terazosin (OR: 0.80 and 1.78) were associated with a low risk of EjD [160]. In the meta-regression, the occurrence of EjD was independently associated with the improvement of urinary symptoms and flow rate, suggesting that the more effective the \(\alpha\)-1 blocker is the greater the incidence of EjD.

Practical considerations: \(\alpha\)-1 blockers are usually considered the first-line drug treatment for male LUTS because of their rapid onset of action, good efficacy, and low rate and severity of adverse events. However, \(\alpha\)-1 blockers do not prevent occurrence of urinary retention or need for surgery. Ophthalmologists should be informed about \(\alpha\)-1 blocker use prior to cataract surgery. Elderly patients treated with non-selective \(\alpha\)-1 blockers should be informed about the risk of orthostatic hypotension. Sexually active patients treated with selective \(\alpha\)-1 blockers should be counselled about the risk of EjD.

5.2.2 5\(\alpha\)-reductase inhibitors

Mechanism of action: Androgen effects on the prostate are mediated by dihydrotestosterone (DHT), which is converted from testosterone by the enzyme 5\(\alpha\)-reductase [161], which has two isoforms:
- 5\(\alpha\)-reductase type 1: predominant expression and activity in the skin and liver.
- 5\(\alpha\)-reductase type 2: predominant expression and activity in the prostate.

Two 5-ARIs are available for clinical use: dutasteride and finasteride. Finasteride inhibits only 5\(\alpha\)-reductase type 2, whereas dutasteride inhibits both 5\(\alpha\)-reductase types (dual 5-ARI). The 5-ARIs induce apoptosis of prostate epithelial cells [162] leading to prostate size reduction of about 18-28% and a decrease in circulating PSA levels of about 50% after six to twelve months of treatment [163]. Mean prostate volume and PSA reduction may be even more pronounced after long-term treatment. Continuous treatment reduces the serum DHT concentration by approximately 70% with finasteride and 95% with dutasteride. However, prostate DHT concentration is reduced to a similar level (85-90%) by both 5-ARIs.

Efficacy: Clinical effects relative to placebo are seen after treatment of at least six months. After two to four years of treatment 5-ARIs improve IPSS by approximately 15-30%, decrease prostate volume by 18-28%, and increase \(Q_{\text{max}}\) by 1.5-2.0 mL/s in patients with LUTS due to prostate enlargement [65, 149, 150, 164-170]. An indirect comparison and one direct comparative trial (twelve months duration) indicated that dutasteride and finasteride are equally effective in the treatment of LUTS [163, 171]. Symptom reduction depends on initial prostate size.

Finasteride may not be more efficacious than placebo in patients with prostates < 40 mL [172]. However, dutasteride seems to reduce IPSS, prostate volume, and the risk of AUR, and to increase \(Q_{\text{max}}\) even in patients with prostate volumes of between 30 and 40 mL [173, 174]. A long-term trial with dutasteride in symptomatic men with prostate volumes > 30 mL and increased risk for disease progression showed that dutasteride reduced LUTS at least as much as the \(\alpha\)-1 blocker tamsulosin [149, 170, 175]. The greater the baseline prostate volume (or serum PSA level), the faster and more pronounced the symptomatic benefit of dutasteride as compared to tamsulosin.
$5\alpha$-reductase inhibitors, but not $\alpha_1$-blockers, reduce the long-term (> 1 year) risk of AUR or need for surgery [65, 168, 176]. In the PLESS study, finasteride reduced the relative risk of AUR by 57% and need for surgery by 55% (absolute risk reduction 4% and 7%, respectively) at four years, compared with placebo [168]. In the MTOPS study, finasteride reduced the relative risk of AUR by 68% and need for surgery by 64% (absolute risk reduction 2% and 3%, respectively), also at four years [65]. A pooled analysis of three RCTs with two-year follow-up data, reported that treatment with finasteride decreased the relative risk of AUR by 57%, and surgical intervention by 34% (absolute risk reduction 2% for both) in patients with moderately symptomatic LUTS [177]. Dutasteride has also demonstrated efficacy in reducing the risks for AUR and BPO-related surgery. Open-label trials have demonstrated relevant changes in urodynamic parameters [178, 179]. Furthermore, finasteride might reduce blood loss during transurethral prostate surgery, probably due to its effects on prostatic vascularisation [180, 181].

**Tolerability and safety:** The most common adverse events are reduced libido, erectile dysfunction (ED) and less frequently, ejaculation disorders such as retrograde ejaculation, ejaculation failure, or decreased semen volume [65, 150, 163, 182]. Gynaecomastia (with breast or nipple tenderness) develops in 1-2% of patients. Two studies have suggested that treatment with 5-ARIs is associated with a higher incidence of high-grade cancers although no causal relationship has been proven [183, 184]. There is a long-standing debate regarding potential cardiovascular side effects of 5-ARIs, in particular dutasteride [185]. Population-based studies in Taiwan and Ontario did not find an association between the use of 5-ARIs and increased cardiovascular side effects [185, 186]. In a British-Taiwanese population-based cohort study, the risk of type II diabetes was higher in men with 5-ARIs than in men receiving tamsulosin but did not differ between dutasteride and finasteride [187].

**Practical considerations:** Treatment with 5-ARIs should be considered in men with moderate-to-severe LUTS and an enlarged prostate (> 40 mL) and/or elevated PSA concentration (> 1.4-1.6 ng/mL). They can prevent the risk of AUR and need for surgery. Due to the slow onset of action, they are not suitable for short-term use. Their effect on PSA needs to be considered in relation to PCa screening.

### 5.2.3 Muscarinic receptor antagonists

**Mechanism of action:** The detrusor is innervated by parasympathetic nerves whose main neurotransmitter is acetylcholine, which stimulates muscarinic receptors (M-cholinoreceptors) on the smooth muscle cells. Muscarinic receptors are also present on other cell types, such as bladder urothelial cells and epithelial cells of the salivary glands. Five muscarinic receptor subtypes (M1-M5) have been described, of which M2 and M3 are predominant in the detrusor. The M2 subtype is more numerous, but the M3 subtype is functionally more important in bladder contractions [188, 189]. Antimuscarinic effects might also be induced or modulated through other cell types, such as the bladder urothelium or by the central nervous system [190, 191].

The following muscarinic receptor antagonists are licensed for treating OAB/storage symptoms: darifenacin hydrobromide (darifenacin); fesoterodine fumarate (fesoterodine); oxybutynin hydrochloride (oxybutynin); propiverine hydrochloride (propiverine); solifenacin succinate (solifenacin); tolterodine tartrate (tolterodine); and trospium chloride. Transdermal preparations of oxybutynin have been formulated and evaluated in clinical trials [192, 193].

**Efficacy:** Antimuscarinics were mainly tested in females in the past, as it was believed that LUTS in men were caused by the prostate, so should be treated with prostate-specific drugs. However, there is no scientific data for this assumption [194]. A sub-analysis of an open-label trial of OAB patients showed that age, but
not gender had an impact on urgency, frequency, or urgency incontinence [195]. In a pooled analysis, which included a sub-analysis of male patients, fesoterodine 8 mg was superior to tolterodine extended release (ER) 4 mg for the improvement of severe urgency episodes/24 hours and the OAB-q Symptom Bother score at week twelve, the urinary retention rate was around 2% [196].

The efficacy of antimuscarinics as single agents in men with OAB in the absence of BOO have been tested [197-202]. Most trials lasted only twelve weeks. Four post hoc analyses of large RCTs on the treatment of OAB in women and men without presumed BOO were performed focusing only on the men [194, 198, 203]. Tolterodine can significantly reduce urgency incontinence, daytime or 24-hour frequency and urgency-related voiding whilst improving patient perception of treatment benefit [204]. Solifenacin significantly improved mean patient perception of bladder condition scores, mean OAB questionnaire scores, and overall perception of bladder problems. Fesoterodine improved micturition frequency, urgency episodes, and UUI episodes. In open-label trials with tolterodine, daytime frequency, nocturia, UUI, and IPSS were significantly reduced compared with baseline values after twelve to 25 weeks [199, 202]. The TIMES RCT reported that tolterodine ER monotherapy significantly improved UUI episodes per 24 hours compared to placebo, at week twelve. Tolterodine ER did not significantly improve urgency, IPSS total or QoL score compared with placebo [201].

A further analysis showed that men with PSA levels of < 1.3 ng/mL (smaller prostates) might benefit more from antimuscarinics [205]. Two other studies found a positive effect of antimuscarinics in patients with OAB and concomitant BPO [202, 206]. In a small RCT propiverine improved frequency and urgency episodes [206].

**Tolerability and safety:** Antimuscarinic drug trials generally show approximately 3-10% withdrawals, which is similar to placebo. Drug-related adverse events include dry mouth (up to 16%), constipation (up to 4%), micturition difficulties (up to 2%), nasopharyngitis (up to 3%), and dizziness (up to 5%).

Increased PVR in men without BOO is minimal and similar to placebo. Nevertheless, fesoterodine 8 mg showed higher PVRs (+20.2 mL) than placebo (-0.6 mL) or fesoterodine 4 mg (+9.6 mL) [199]. Incidence of urinary retention in men without BOO was similar to placebo for tolterodine (0-1.3% vs. 0-1.4%). With fesoterodine 8 mg, 5.3% had symptoms, which was higher than placebo or fesoterodine 4 mg (both 0.8%). These symptoms appeared during the first two weeks of treatment and mainly affected men aged 66 years or older.

Theoretically antimuscarinics might decrease bladder strength, and hence might be associated with PVR or urinary retention. A twelve week safety study on men with mild-to-moderate BOO showed that tolterodine increased the PVR (49 mL vs. 16 mL) but not AUR (3% in both arms) [207]. The urodynamic effects included larger bladder volumes at first detrusor contraction, higher maximum cystometric capacity, and decreased bladder contractility index, Q\text{max} was unchanged. This trial indicated that short-term treatment with antimuscarinics in men with BOO is safe [194].

**Practical considerations:** Not all antimuscarinics have been tested in elderly men, and long-term studies on the efficacy of muscarinic receptor antagonists in men of any age with LUTS are not yet available. In addition, only patients with low PVR volumes at baseline were included in the studies. These drugs should therefore be prescribed with caution, and regular re-evaluation of IPSS and PVR is advised. Men should be advised to discontinue medication if worsening voiding LUTS or urinary stream is noted after initiation of therapy.

5.2.4 **Beta-3 agonist**

**Mechanism of action:** Beta-3 adrenoceptors are the predominant beta receptors expressed in the smooth muscle cells of the detrusor and their stimulation is thought to induce detrusor relaxation. The mode of action of beta-3 agonists is not fully elucidated [208].
Efficacy: Mirabegron 50 mg is the first clinically available beta-3 agonist with approval for use in adults with OAB. Mirabegron has undergone extensive evaluation in RCTs conducted in Europe, Australia, North America and Japan [209-213]. Mirabegron demonstrated significant efficacy in treating the symptoms of OAB, including micturition frequency, urgency and UUI and also patient perception of treatment benefit. These studies had a predominantly female study population. A meta-analysis of eight RCTs including 10,248 patients (27% male) found that mirabegron treatment resulted in reduced frequency, urgency and UUI rates, as well as an improved voided volume with a statistically significant improvement of nocturia compared with both placebo and tolterodine [214].

Mirabegron has been evaluated in male patients with OAB in the context of LUTS either associated or not associated with BPO confirmed by urodynamics [215]. Mirabegron 25 mg daily led to increased satisfaction and improved QoL, but symptoms assessed by validated questionnaires (IPSS and OAB-SS), only improved in non-obstructed patients. Mirabegron as an add-on therapy has been studied in OAB patients with incontinence despite antimuscarinic therapy [216], again in a predominantly female study population. An Asian study with a higher proportion of male subjects (approximately one third) reported superiority over placebo in reducing frequency of micturition, but did not report the results separately for the genders [217].

In a study of more than 1,000 patients of whom approximately 30% were male, combination therapy of mirabegron 25/50 mg and solifenacin 5/10 mg was associated with statistically significant improvements in patient outcomes and health related QoL vs. solifenacin 5 mg and placebo; however, they did not separate out the effects in men and women [218]. In another study, in which 28% patients were male, mirabegron significantly improved patient reported perception of their condition and QoL whether or not patients were incontinent [219]. A phase IV study, with a small proportion of male subjects, reported addition of mirabegron in people with persisting urgency despite solifenacin in a Japanese population [220].

Tolerability and safety: The most common treatment-related adverse events in the mirabegron groups were hypertension, UTI, headache and nasopharyngitis [209-212]. Mirabegron is contraindicated in patients with severe uncontrolled hypertension (systolic blood pressure ≥ 180 mmHg or diastolic blood pressure ≥ 110 mmHg, or both). Blood pressure should be measured before starting treatment and monitored regularly during treatment. A combination of thirteen clinical studies including 13,396 patients, 25% of whom were male, showed that OAB treatments (anticholinergics or mirabegron) were not associated with an increased risk of hypertension or cardiovascular events compared to placebo [221]. The proportion of patients with dry mouth and constipation in the mirabegron groups was notably lower than reported in RCTs of other OAB agents or of the active control tolterodine [209]. Evaluation of urodynamic parameters in men with combined BOO and OAB concluded that mirabegron did not adversely affect voiding urodynamic parameters compared to placebo in terms of Q\text{max}, detrusor pressure at maximum flow and bladder contractility index [222]. The overall change in PVR with mirabegron is small [222].

A small prospective study (mainly focused on males) has shown that mirabegron 25 mg is safe in patients aged 80 years or more with multiple comorbidities [223]. A pooled analysis of three trials, each of twelve weeks and a one-year trial showed, in patients aged > 65 years, a more favourable tolerability profile for mirabegron than antimuscarinics [224]. The PILLAR phase IV study also showed that in a large population of 888 patients ≥ 65 years (approx. 30% of males), mirabegron 50 mg was safe and effective [225]. In an eighteen-week study of 3,527 patients (23% male), mirabegron 50 mg was safe and effective [225]. The incidence of adverse events was higher in the combined group compared with solifenacin 5 mg and mirabegron 25 mg group (40%) than the mirabegron 25 mg alone group (32%). Events recorded as urinary retention were low (< 1%) but were reported more frequently in the combined group when compared with the monotherapy and placebo groups. The PVR volume was slightly increased in the combined group compared with solifenacin 5 mg, and the mirabegron monotherapy and placebo groups. Combined therapy with solifenacin 5 mg plus mirabegron 25 mg and solifenacin 5 mg plus mirabegron 50 mg provided improvements in efficacy generally consistent with an additive effect [226].

In a retrospective analysis of persistence and adherence in 21,996 patients, of whom 30% were male, the median time to discontinuation was significantly longer for mirabegron (169 days) compared to tolterodine (56 days) and other antimuscarinics (30-78 days). There was no statistical difference between men and women [227].

The phase III EMPOWUR trial comparing vibegron to placebo and tolterodine showed once daily 75 mg vibegron provided statistically significant reductions in micturitions, urgency episodes and UUI [228]. Treatment was well tolerated with a favourable safety profile. However, the majority of the study population (85%) were female and vibegron is not yet licenced in Europe.

Practical considerations: Long-term studies on the efficacy and safety of mirabegron in men of any age with LUTS are not yet available. Available studies on mirabegron in combination with antimuscarinics in OAB patients had a predominantly female study population, while further trials are still pending.
5.2.5 Phosphodiesterase 5 inhibitors

**Mechanism of action:** Phosphodiesterase 5 inhibitors (PDE5Is) increase intracellular cyclic guanosine monophosphate, thus reducing smooth muscle tone of the detrusor, prostate and urethra. Nitric oxide and PDE5Is might also alter reflex pathways in the spinal cord and neurotransmission in the urethra, prostate, or bladder [229]. Moreover, chronic treatment with PDE5Is seems to increase blood perfusion and oxygenation in the LUT [230]. Phosphodiesterase 5 inhibitors could also reduce chronic inflammation in the prostate and bladder [231]. The exact mechanism of PDE5Is on LUTS remains unclear.

Although clinical trials of several selective oral PDE5Is have been conducted in men with LUTS, only tadalafil 5 mg once daily has been licensed for the treatment of male LUTS.

**Efficacy:** Randomised controlled trials have demonstrated that PDE5Is reduce IPSS, storage and voiding LUTS, and improve QoL. However, $Q_{\text{max}}$ did not significantly differ from placebo in most trials [232]. A Cochrane review included a total of sixteen RCTs that examined the effects of PDE5Is compared to placebo and other standard of care drugs ($\alpha$-blockers and 5-ARIs) in men with LUTS [233]. In the updated meta-analysis, PDE5Is led to a small reduction (mean difference (MD) 1.89 lower; 95% CI: 2.27 lower to 1.50 lower; n = 4293) in IPSS compared to placebo [233]. There was no difference between PDE5Is and $\alpha$-blockers in IPSS [234]. Most evidence was limited to short-term treatment up to twelve weeks. In other meta-analyses, PDE5Is were also found to improve IPSS and IIEF score, but not $Q_{\text{max}}$ [235, 236]. A meta-regression suggested that younger men with low body mass index and more severe LUTS benefit the most from treatment with PDE5Is [235].

In a post hoc analysis of data pooled from four blinded trials of tadalafil 5 mg vs. placebo once daily, a minimum improvement of 25% in IPSS score was found in 60% in the tadalafil group vs. 44% in the placebo group [237]. The maximum trial duration was 52 weeks [238]. A subgroup analysis of pooled data from four RCTs demonstrated a significant reduction in LUTS, regardless of baseline severity, age, previous use of $\alpha$-blockers or PDE5Is, total testosterone level or predicted prostate volume [239]. In a post hoc analysis of pooled data from four RCTs, tadalafil was shown to also be effective in men with cardiovascular risk factors/comorbidities, except for patients receiving more than one antihypertensive medication. Among sexually active men > 45 years, tadalafil improved both LUTS/BPH and ED [239].

An integrated data analyses from four placebo controlled clinical studies showed that total IPSS improvement was largely attributed to direct (92.5%) vs. indirect (7.5%) treatment effects via IIEF-EF improvement [240]. Another analysis showed a small but significant increase in $Q_{\text{max}}$ without any effect on PVR [241]. An integrated analysis of RCTs showed that tadalafil was not superior to placebo for IPSS improvement at twelve weeks in men $\geq$ 75 years (with varied effect size between studies), but was for men < 75 years [242]. An open label urodynamic study of 71 patients showed significant improvements in both voiding and storage symptoms, confirmed by improvements in BOO index (61.3 to 47.1), and resolution of DO in fifteen (38%) of 38 patients. Significant flow rate improved from 7.1 to 9.1 mL/s and mean IPSS from 18.2 to 13.4 [249].

A multicenter, double blind, placebo controlled RCT compared once daily tadalafil 20 mg vs. placebo during twelve weeks in men with LUTS with or without BOO. Urodynamic measures including detrusor pressure at maximum urinary flow rate, $Q_{\text{max}}$, maximum detrusor pressure, BOO or bladder capacity remained largely unchanged during the study with no statistically significant or clinically adverse event differences between tadalafil and placebo [243].

A combination of PDE5Is and $\alpha$-blockers has also been evaluated. A meta-analysis of five RCTs (two studies with tadalafil 20 mg, two with udenafil 25 mg, and one with vardenafil 20 mg), showed that combination therapy significantly improved IPSS score (-1.8), IIEF score (+3.6) and $Q_{\text{max}}$ (+1.5 mL/s) compared with $\alpha$-blockers alone [235]. Both a SR and Cochrane review found similar findings [233, 244]. The effects of tadalafil 5 mg combined with finasteride 5 mg were assessed in a 26-week placebo-controlled RCT. The combination of tadalafil and finasteride provided a significant early improvement in urinary symptoms at four, twelve and 26 weeks as well as a significant improvement of storage and voiding symptoms and QoL. Combination therapy was well tolerated and improved erectile function [245]. However, only tadalafil 5 mg has been licensed in the context of LUTS management while data on combinations of PDE5Is and other LUTS medications is emerging.
Tolerability and safety: Reported adverse effects in RCTs comparing the effect of all PDE5Is vs. placebo in men with LUTS include flushing, gastroesophageal reflux, headache, dyspepsia, back pain and nasal congestion [235].

Tadalafil is contraindicated in patients using nitrates or guanylate cyclase stimulators, such as riociguat, and in men with cardiac disease for whom sexual activity is inadvisable [246]. Tadalafil is also contraindicated in patients with myocardial infarction within the last 90 days, - patients with unstable angina or angina occurring during sexual intercourse, - patients with New York Heart Association Class 2 or greater heart failure in the last six months, - patients with uncontrolled arrhythmias, hypotension (< 90/50 mm Hg), or uncontrolled hypertension, - patients with a stroke within the last six months or if anterior ischaemic optic neuropathy with sudden loss of vision is known or was reported after previous use of PDE5Is [246]. Detailed information regarding tolerability/safety of all available PDE5Is for the treatment of ED in men treated with α-blockers for LUTS are provided by the EAU Guidelines on Sexual and Reproductive Health [247].

Practical considerations: To date, only tadalafil 5 mg once daily has been officially licensed for the treatment of male LUTS with or without ED. Long-term experience with tadalafil in men with LUTS is limited to one trial with a one-year follow-up [238]; limiting conclusions about efficacy or tolerability greater than one year. There is limited information on reduction of prostate size and no data on disease progression.

#### Plant extracts - phytotherapy

**Potential mechanism of action:** Herbal drug preparations are made of roots, seeds, pollen, bark, or fruits. There are single plant preparations (mono-preparations) and preparations combining two or more plants in one pill (combination preparations) [248].

Possible relevant compounds include phytosterols, 8-sitosterol, fatty acids, and lectins [248]. *In vitro*, plant extracts can have anti-inflammatory, anti-androgenic and oestrogenic effects; decrease sexual hormone binding globulin; inhibit aromatase, lipooxygenase, growth factor-stimulated proliferation of prostatic cells, α-adrenoceptors, 5 α-reductase, muscarinic cholinoceptors, dihydroxypiridine receptors and vanilloid receptors; and neutralise free radicals [248-250]. The *in vivo* effects of these compounds are uncertain, and the precise mechanisms of plant extracts remain unclear.

**Efficacy:** The extracts of the same plant produced by different companies do not necessarily have the same biological or clinical effects; therefore, the effects of one brand cannot be extrapolated to others [251]. In addition, batches from the same producer may contain different concentrations of active ingredients [252]. A review of recent extraction techniques and their impact on the composition/biological activity of available *Serenoa repens* based products showed that results from different clinical trials must be compared strictly according to the same validated extraction technique and/or content of active compounds [253], as the pharmacokinetic properties of the different preparations can vary significantly.

Heterogeneity and a limited regulatory framework characterise the current status of phytotherapeutic agents. The European Medicines Agency (EMA) has developed the Committee on Herbal Medicinal Products (HMPC). European Union (EU) herbal monographs contain the HMPC’s scientific opinion on safety and efficacy data about herbal substances and their preparations intended for medicinal use. The HMPC evaluates all available information, including non-clinical and clinical data, whilst also documenting long-standing use and experience in the EU. European Union monographs are divided into two sections: a) Well established use (marketing authorisation): when an active ingredient of a medicine has been used for more than ten years and its efficacy and safety have been well established (including a review of the relevant literature); and b) Traditional use (simplified registration): for herbal medicinal products which do not fulfil the requirements for a marketing authorisation, but there is sufficient safety data and plausible efficacy on the basis of long-standing use and experience.

The HPMC periodically invites all interested parties to submit any scientific data that the Committee should consider during their periodic review of the monographs. Table 1 lists the available EU monographs for herbal medicinal products and the current calls for update.

Panel interpretation: Only hexane extracted *Serenoa repens* (HESr) has been recommended for well-established use by the HMPC. Based on this a detailed scoping search covering the timeframe between the search cut-off date of the EU monograph and May 2021 was conducted for HESr.

A large meta-analysis of 30 RCTs with 5,222 men and follow-up ranging from four to 60 weeks, demonstrated no benefit of treatment with *S. repens* in comparison to placebo for the relief of LUTS [260]. It was concluded that *S. repens* was not superior to placebo, finasteride, or tamsulosin with regard to IPSS improvement, $Q_{\text{max}}$, or prostate size reduction; however, the similar improvement in IPSS or $Q_{\text{max}}$ compared with finasteride or tamsulosin could be interpreted as treatment equivalence. Importantly, in the meta-analysis all different brands of *S. repens* were included regardless or not of the presence of HESr as the main ingredient in the extract.

Another SR focused on data from twelve RCTs on the efficacy and safety of HESr [261]. It was concluded that HESr was superior to placebo in terms of improvement of nocturia and $Q_{\text{max}}$ in patients with enlarged prostates. Improvement in LUTS was similar to tamsulosin and short-term use of finasteride. An updated SR analysed fifteen RCTs and also included twelve observational studies. It confirmed the results of the previous SR on the efficacy of HESr [262]. Compared with placebo, HESr was associated with 0.64 (95% CI: 0.57 - 0.71) fewer voids/night and an additional mean increase in $Q_{\text{max}}$ of 2.75 mL/s (95% CI: 0.71 - 4.75), both were significant. When compared with α-blockers, HESr showed similar improvements in IPSS (WMD 0.57, 95% CI: 0.27 - 1.42) and a comparable increase in $Q_{\text{max}}$ when compared to tamsulosin (WMD 0.02; 95% CI: 0.71 - 0.66). Efficacy assessed using IPSS was similar after six months of treatment between HESr and 5-ARIs. Analysis of all available published data for HESr showed a mean significant improvement in IPSS from baseline of 5.73 points (95% CI: 6.91 - 4.54) [262].

A network meta-analysis tried to compare the clinical efficacy of *S. repens* (HESr and non-HESr) against placebo and α1-blockers in men with LUTS. Interestingly, only two RCTs on HESr were included in the analysis. It was found that *S. repens* achieved no clinically meaningful improvement against placebo or α1-blockers in short-term follow-up. However, *S. repens* showed a clinical benefit after a prolonged period of treatment, and HESr demonstrated a greater improvement than non-HESr in terms of IPSS [263].

With respect to safety and tolerability data from the SRs showed that HESr had a favourable safety profile with gastrointestinal disorders being the most frequent adverse effects (mean incidence 3.8%) while HESr had very limited impact on sexual function.
A cross-sectional study compared the combination of HESr with silodosin to silodosin monotherapy in patients treated for at least twelve months (mean duration 13.5 months) [264]. It was reported that 69.9% of the combination therapy patients achieved the predefined clinically meaningful improvement (improvement more than three points in baseline IPSS) compared to 30.1% of patients treated only with silodosin. In addition, a greater than 25% improvement in IPSS was found in 68.8% and 31.2% of the patients in the combination and the monotherapy groups, respectively. These data suggest that combination of an α1-blocker with HESr may result in greater clinically meaningful improvements in LUTS compared to an α1-blocker monotherapy [264].

Practical considerations: Available RCTs do not use the same endpoints (e.g. IPSS). More studies on the use of HESr in combination with other pharmacotherapeutic agents for male LUTS are pending. There is a need to define the subpopulation of patients who will benefit most from therapy with HESr.

### 5.2.7 Combination therapies

#### 5.2.7.1 α1-blockers + 5α-reductase inhibitors

**Mechanism of action:** Combination therapy consists of an α1-blocker (Section 5.2.1) together with a 5-ARI (Section 5.2.2). The α1-blocker exhibits clinical effects within hours or days, whereas the 5-ARI needs several months to develop full clinical efficacy. Finasteride has been tested in clinical trials with alfuzosin, terazosin, doxazosin or terazosin, and dutasteride with tamsulosin.

**Efficacy:** Several studies have investigated the efficacy of combination therapy against an α1-blocker, 5-ARI or placebo alone. Initial studies with follow-up periods of six to twelve months demonstrated that the α1-blocker was superior to finasteride in symptom reduction, whereas combination therapy of both agents was not superior to an α1-blocker monotherapy [165, 166, 265]. In studies with a placebo arm, the α1-blocker was consistently more effective than placebo, but finasteride was not. Data at one year in the MTOPS study showed similar results [65].

Long-term data (four years) from the MTOPS and CombAT studies showed that combination treatment is superior to monotherapy for symptoms and $Q_{\text{max}}$ and superior to an α1-blocker alone in reducing the risk of AUR or need for surgery [65, 149, 150].

The CombAT study demonstrated that combination treatment is superior to either monotherapy regarding symptoms and flow rate starting from month nine, and superior to an α1-blocker for AUR and the need for surgery after eight months [150]. Thus, the differences in MTOPS may reflect different inclusion and exclusion criteria and baseline patient characteristics.

Discontinuation of the α1-blocker after six to nine months of combination therapy was investigated in an RCT and an open-label multicentre trial [266, 267]. The first trial evaluated the combination of tamsulosin with dutasteride and the impact of tamsulosin discontinuation after six months [266], with almost three quarters of patients reporting no worsening of symptoms. However, patients with severe symptoms (IPSS > 20) at baseline may benefit from longer combination therapy.

A more recent trial evaluated the symptomatic outcome of finasteride monotherapy at three and nine months after discontinuation of nine-month combination therapy [267]. Lower urinary tract symptom improvement after combination therapy was sustained at three months (IPSS difference 1.24) and nine months (IPSS difference 0.4). The limitations of the studies include the short duration of the studies and the short follow-up period after discontinuation.

In both the MTOPS and CombAT studies, combination therapy was superior to monotherapy in preventing clinical progression as defined by an IPSS increase of at least four points, AUR, UTI, incontinence, or an increase in creatinine > 50%. The MTOPS study found that the risk of long-term clinical progression (primarily due to increasing IPSS) was reduced by 66% with combined therapy vs. placebo and to a greater extent than with either finasteride or doxazosin monotherapy (34% and 39%, respectively) [65]. In addition, finasteride (alone or in combination), but not doxazosin alone, significantly reduced both the risks of AUR and the need
for BPO-related surgery over the four-year study. In the CombAT study, combination therapy reduced the relative risks of AUR by 68%, BPO-related surgery by 71%, and symptom deterioration by 41% compared with tamsulosin, after four years [268]. To prevent one case of urinary retention and/or surgical treatment thirteen patients need to be treated for four years with dutasteride and tamsulosin combination therapy compared to tamsulosin monotherapy while the absolute risk reduction (risk difference) was 7.7%.

The CONDUCT study compared efficacy and safety of a fixed-dose combination of dutasteride and tamsulosin to a WW approach with the potential initiation of tamsulosin (step-up approach) in a two-year RCT with a total of 742 patients. In both arms detailed lifestyle advice was given. This fixed-dose combination resulted in a rapid and sustained improvement in men with moderate LUTS at risk of disease progression, the difference in IPSS at 24 months was 5.4 in the active arm and 3.6 in the placebo arm [269]. Furthermore, tamsulosin plus dutasteride significantly reduced the relative risk of clinical progression (mainly characterised as a worsening in symptoms) by 43.1% when compared with WW, with an absolute risk reduction of 11.3% (number needed to treat [NNT] = 9).

The influence of baseline variables on changes in IPSS after combination therapy with dutasteride plus tamsulosin or either monotherapy was tested based on the four-year results of the CombAT study. Combination therapy provided consistent improvement of LUTS over tamsulosin across all analysed baseline variables at 48 months [270].

A combination of the 5-ARI finasteride and tadalafil 5 mg was tested in a large scale RCT against finasteride monotherapy. This study supports the concept of this novel combination therapy and is described in more detail in section 5.2.5 [245].

Tolerability and safety: Adverse events for both drug classes have been reported with combination treatment [65, 149, 150]. The adverse events observed during combination treatment were typical of α1-blockers and 5-ARIs. The frequency of adverse events was significantly higher for combination therapy. The MTOPS study demonstrated that the incidence of treatment related adverse events is higher during the first year of combined treatment between doxazosin and finasteride [271]. A meta-analysis measuring the impact of medical treatments for LUTS/BPH on ejaculatory function, reported that combination therapy with α1-blockers and 5-ARIs resulted in a three-fold increased risk of EjD compared with each monotherapy [160].

Practical considerations: Compared with α1-blockers or 5-ARI monotherapy, combination therapy results in a greater improvement in LUTS and increase in Qmax and is superior in prevention of disease progression. However, combination therapy is also associated with a higher rate of adverse events. Combination therapy should therefore be prescribed primarily in men who have moderate-to-severe LUTS who are at risk of disease progression (higher prostate volume, higher PSA concentration, advanced age, higher PVR, lower Qmax, etc.). Combination therapy should only be used when long-term treatment (more than twelve months) is intended, and patients should be informed of this. Discontinuation of the α1-blocker after six months might be considered in men with moderate LUTS.

### Summary of evidence

| LE |
|---|---|
| **Long-term data (four years) from the MTOPS and CombAT studies showed that combination treatment is superior to monotherapy for symptoms and Qmax and superior to α1-blocker alone in reducing the risk of AUR or need for surgery.** | 1b |
| The MTOPS study found that the risk of long-term clinical progression (primarily due to increasing IPSS) was reduced by 66% with combined therapy vs. placebo and to a greater extent than with either finasteride or doxazosin monotherapy. | 1b |
| The CombAT study found that combination therapy reduced the relative risks of AUR by 68%, BPH-related surgery by 71%, and symptom deterioration by 41% compared with tamsulosin, after four years. | 1b |
| Adverse events of both drug classes are seen with combined treatment using α1-blockers and 5-ARIs. | 1b |

### Recommendation

| Strength rating |
|---|---|
| Offer combination treatment with an α1-blocker and a 5α-reductase inhibitor to men with moderate-to-severe LUTS and an increased risk of disease progression (e.g. prostate volume > 40 mL). | Strong |

5.2.7.2  α1-blockers + muscarinic receptor antagonists

**Mechanism of action:** Combination treatment consists of an α1-blocker together with an antimuscarinic aiming to antagonise both α1-adrenoceptors and muscarinic receptors. The possible combinations have not all been tested in clinical trials to date.
Efficacy: Several RCTs and prospective studies investigated combination therapy, lasting four to twelve weeks, either as an initial treatment in men with OAB and presumed BPO or as a sequential treatment for storage symptoms persisting while on an α1-blocker [193, 204, 268, 272-279]. Combination treatment is more efficacious in reducing urgency, UUI, voiding frequency, nocturia, or IPSS compared with α1-blockers or placebo alone, and improves QoL [204, 279]. A SR showed that combination therapy of tolterodine and an α1-blocker was significantly more efficacious than either monotherapy for 24-hours and night voiding frequency, and 24-hours urgency episodes [204].

One trial used the α1-blocker naftopidil (not registered in most European countries) with and without antimuscarinics [280]. A high proportion of men with voiding and storage LUTS need to add anticholinergics after α1-blocker monotherapy, particularly those with longer duration of symptoms at presentation, and men with storage symptoms and a small prostate volume [281].

Symptom improvement is higher regardless of PSA concentration with combination therapy, whereas tolterodine alone improved symptoms mainly in men with a serum PSA of < 1.3 ng/mL [205].

Persistent LUTS during α1-blocker treatment can be reduced by the additional use of an antimuscarinic, [268, 272, 278, 282, 283]. Two SRs of the efficacy and safety of antimuscarinics in men suggested that combination treatment provides significant benefit [284, 285]. In a meta-analysis of sixteen studies with 3,548 patients with BPH/OAB, initial combination treatment of an α1-blocker with anticholinergic medication improvement storage symptoms and QoL compared to α1-blocker monotherapy without causing significant deterioration of voiding function [286]. There was no difference in total IPSS and Qmax between the two groups.

Effectiveness of therapy is evident primarily in those men with moderate-to-severe storage LUTS [287]. Long term use of combination therapy has been reported in patients receiving treatment for up to one year, showing symptomatic response is maintained, with a low incidence of AUR [288]. In men with moderate-to-severe storage symptoms, voiding symptoms and PVR < 150 mL, the reduction in symptoms using combination therapy is associated with patient-relevant improvements in health related QoL compared with placebo and α1-blocker monotherapy [289].

The intake of fixed-dose combination tablet containing solifenacin 6 mg and tamsulosin 0.4 mg improved OAB-q symptom bother in > 80% of LUTS/BPH patients not adequately responding to monotherapy, with a high treatment persistence (77% at weeks 40 to 52), and a low risk of AUR [290]. Combined behavioural and drug therapy yielded greater improvements in OAB symptoms than drug therapy alone, but not behavioural therapy alone, in a RCT evaluating the effectiveness of combined behavioural strategies and drug therapy for OAB symptoms in men [291].

Tolerability and safety: Adverse events of both drug classes are seen with combined treatment using α1-blockers and antimuscarinics. The most common side-effect is dry mouth. Some side-effects (e.g. dry mouth or ejaculation failure) may show increased incidence which cannot simply be explained by summing the incidence with the drugs used separately. Increased PVR may be seen, but is usually not clinically significant, and risk of AUR is low up to one year of treatment [201, 284, 292]. Antimuscarinics do not cause evident deterioration in Qmax used in conjunction with an α1-blocker in men with OAB symptoms [279, 293].

A recent RCT investigated safety in terms of maximum detrusor pressure and Qmax for solifenacin (6 mg or 9 mg) with tamsulosin in men with LUTS and BOO compared with placebo [294]. The combination therapy was non-inferior to placebo for the primary urodynamic variables; Qmax was increased vs. placebo [294].

Practical considerations: Class effects are likely to underlie efficacy and QoL using an α1-blocker and antimuscarinic. Trials used mainly storage symptom endpoints, were of short duration, and included only men with low PVR volumes at baseline. Therefore, measuring PVR is recommended during combination treatment.

5.2.7.3 $\alpha_1$-blockers + Beta-3 agonist

Mechanism of action: Combination therapy consists of an $\alpha_1$-blocker (Section 5.2.1) together with a beta-3 agonist (Section 5.2.4) as an add-on therapy in males receiving $\alpha_1$-blockers with persisting OAB symptoms.

Efficacy: The MATCH study explored the effect of the addition of mirabegron 50 mg to tamsulosin 0.2 mg compared to tamsulosin plus placebo in 544 patients [295]. A statistically significant difference of 0.52 voids per day was seen in favour of mirabegron. Total IPSS score also improved, but was not significant between the groups. Another RCT evaluated add-on therapy with mirabegron for OAB symptoms persisting after treatment with tamsulosin 0.2 mg daily in men with BPO [296]. Combination therapy was associated with greater improvements in OAB symptom score, in urinary urgency and daytime frequency as well as the storage sub-score of IPSS and QoL index compared to monotherapy with tamsulosin [297].

The PLUS phase IV trial [296] compared mirabegron and placebo in a population of males treated with a standard dose of tamsulosin 0.4 mg. After a four-week run-in period of treatment with tamsulosin 0.4 mg alone, 715 patients were randomised between placebo and mirabegron 25 mg, upgraded to 50 mg after one month. While mean number of micturition’s were significantly reduced in the experimental arm, the effect size was deemed as low (mean adjusted difference of 0.39 voids per day). Similar results were seen for mean voided volume and urgency episodes, but total IPSS, IPSS sub-scores and OAB-q symptom score were not significantly different between the groups.

A RCT comparing the efficacy of mirabegron 50 mg or fesoterodine 4 mg add-on therapy to silodosin in LUTS patients with persisting OAB symptoms reported that at three months, fesoterodine add-on therapy showed a significantly greater improvement than mirabegron add-on therapy in OAB symptom score and urgency score and IPSS-QoL score [218]. Fesoterodine was also superior in alleviating DO.

Tolerability and safety: In the MATCH study main adverse events were in line with previous trials, and cardiovascular events were uncommon in the studied populations [295]. The PLUS phase IV trial also reported adverse events similar to those seen in previous trials (hypertension, headache and nasopharyngitis being the most frequent) [296]. There were six episodes of retention recorded (1.7%) and overall, no clinically significant specific change was seen in Q$_{\text{max}}$ and PVR. An open-label, randomised, 2-arm, 2-sequence study reported that the addition of mirabegron or tamsulosin to patients under tamsulosin or mirabegron monotherapy did not cause clinically relevant changes in cardiovascular safety or safety profiles [298].

Solifenacin and mirabegron were also compared in another RCT that has shown comparable efficacy but a better safety profile for mirabegron [299].

Practical considerations: Add-on therapy with mirabegron in patients with remaining symptoms under $\alpha_1$-blocker therapy has been evaluated only in short-term clinical trials. The short-term benefit remains uncertain with a low effect size in urinary frequency compared to placebo, and more studies with longer follow-up are required.

5.3 Surgical treatment

Surgical treatment is one of the cornerstones of LUTS/BPO management. Based on its ubiquitous availability, as well as its efficacy, M-TURP has long been considered as the reference technique for the surgical management of LUTS/BPO. However, in recent years various techniques have been developed with the aim of providing a safe and effective alternative to M-TURP. Previously, the surgical section of the Guidelines was based on technology rather than surgical approach. As the clinical reality is primarily reflected by surgical approach and not necessarily by a specific technology, the chapter on surgical management has been restructured. It is now divided into the following five sections:

1. Resection;
2. Enucleation;
3. Vaporisation;
4. Alternative ablative techniques; and
5. Non-ablative techniques.

In addition, most of the studies are restricted by prostate size, which is also reflected in the present Guidelines. Notably, only a small fraction of RCTs are performed in patients with a prostate > 80 mL; therefore, high-level evidence for larger prostates are limited.

Based on Panel consensus, timeframes defining short-, mid- and long-term follow-up of patients submitted to surgical treatments are twelve, 36, and over 36 months, respectively. The durability of a technique is reflected by the re-operation rate during follow-up, the failure to wean patients off medication as well as the initiation of novel LUTS medication after surgery. However, for the majority of techniques only the re-operation rate is reported, and clinicians should inform patients that long-term surgical RCTs are often lacking. Some patients value sexual function and perceived higher safety over maximum efficacy and it is not therefore surprising that some patients consciously choose an alternative ablative or non-ablative technique despite the knowledge that it might not be their definitive treatment. In contrast, many urologists are critical about these procedures due to their inferior relief of BOO.

Recommendations on new devices or interventions will only be included in the Guidelines once supported by a minimum level of evidence. To clarify this the Panel have published their position on certainty of evidence (CoE) [300]. In summary, a device or technology is only included once supported by RCTs looking at both efficacy and safety, with adequate follow-up, and secondary studies to confirm the reproducibility and generalisability of the first pivotal studies [300]. Otherwise, there is a danger that a single pivotal study can be overexploited by device manufacturers. Studies that are needed include proof of concept, RCTs on efficacy and safety, as well as cohort studies with a broad range of inclusion and exclusion criteria to confirm both reproducibility and generalisability of the benefits and harms [300]. The panel assesses the quality of all RCTs and if they do not meet the standard required the intervention will continue to have no recommendation i.e., a RCT does not guarantee inclusion in the Guidelines.

In addition, the Guidelines continues to include techniques under investigation. These are devices or technologies that have shown promising results in initial studies; however, they do not meet the aforementioned criteria yet to provide a CoE which allows the Panel to regard these devices or technologies as recommended alternatives. To account for evolving evidence, recommendations for some techniques under investigation have been made; however, these techniques remain under investigation until further studies provide the recommended CoE.

5.3.1 Resection of the prostate

5.3.1.1 Monopolar and bipolar transurethral resection of the prostate

Mechanism of action: Transurethral resection of the prostate (TURP) is performed using two techniques: monopolar TURP (M-TURP) and bipolar TURP (B-TURP). Monopolar transurethral resection of the prostate removes tissue from the transition zone of the gland. Bipolar TURP addresses a major limitation of M-TURP by allowing performance in normal saline. Prostatic tissue removal is identical to M-TURP. Contrary to M-TURP, in B-TURP systems, the energy does not travel through the body to reach a skin pad. Bipolar circuitry is completed locally; energy is confined between an active (resection loop) and a passive pole situated on the resectoscope tip (“true” bipolar systems) or the sheath (“quasi” bipolar systems). The various bipolar devices available differ in the way in which current flow is delivered [301, 302].

Efficacy: In a meta-analysis of twenty RCTs with a maximum follow-up of five years, M-TURP resulted in a substantial mean $Q_{\text{max}}$ improvement (+162%), a significant reduction in IPSS (-70%), QoL score (-69%), and PVR (-77%) [303]. Monopolar-TURP delivers durable outcomes as shown by studies with a follow-up of 8-22 years. There are no similar data on durability for any other surgical treatment for BPO [304]. One study with a mean follow-up of thirteen years reported a significant and sustained decrease in most symptoms and improvement in urodynamic parameters. Failures were associated with DUA rather than re-development of
Bipolar TURP is the most widely investigated alternative to M-TURP. Pooled results from 59 RCTs have been reported to date [308]. Early pooled results as well as at twelve months, concluded that no clinically relevant differences exist in short-term efficacy (IPSS, QoL score and Qmax) [308, 309]. Subsequent meta-analyses supported these conclusions though trial quality was generally poor [303, 310-313]. The largest meta-analysis published to date, confirmed that B-TURP compared to M-TURP results in little to no difference in urological symptoms and bother (IPSS and QoL score) at twelve months [308]. Data from RCTs with mid- to long-term follow-up (up to 60 months) showed no differences in efficacy parameters [314-322]. A meta-analysis of RCTs comparing B-TURP vs. M-TURP, reported similar efficacy at 36 months in terms of IPSS, and Qmax [323].

A meta-analysis was conducted to evaluate the quasi-bipolar transurethral resection in saline (TURis, Olympus Medical) system vs. M-TURP. Ten unique RCTs (1,870 patients) were included, and it was concluded that TURis was of equivalent efficacy to M-TURP [324].

Tolerability and safety: Peri-operative mortality and morbidity of M-TURP have decreased over time, but morbidity remains considerable (0.1% and 11.1%, respectively) [325]. Data from an Austrian nationwide study of two cohorts totalling 41,059 men submitted to M-TURP showed a 20% reduction in mortality rate over time, to 0.1% at 30 days and 0.5% at 90 days [306, 307].

The risk of TUR-syndrome decreased to < 1.1% [305, 326]. Data from 10,654 M-TURPs reported bleeding requiring transfusion in 2.9% [325]. Short- to mid-term complications reported in an analysis of RCTs using M-TURP as a comparator were: bleeding requiring transfusion 2% (0-9%), TUR-syndrome 0.8% (0-5%), AUR 4.5% (0-13.3%), clot retention 4.9% (0-39%), and UTI 4.1% (0-22%) [303]. Long-term complications of M-TURP comprise urinary incontinence (UI), urinary retention and UTIs, bladder neck contracture (BNC), urethral stricture, retrograde ejaculation and ED [305].

Early pooled results concluded that no differences exist in short-term urethral stricture/BNC rates, but B-TURP is preferable to M-TURP due to a more favourable peri-operative safety profile (elimination of TUR-syndrome; lower clot retention/blood transfusion rates; shorter irrigation, catheterisation, and possibly hospitalisation times) [309]. Subsequent meta-analyses supported these conclusions [303, 310-313, 323]; however, trial quality was relatively poor and limited follow-up might cause under-reporting of late complications, such as urethral stricture/BNC [309]. The largest meta-analysis published to date, concluded that B-TURP compared to M-TURP reduced TUR syndrome and blood transfusion events by twenty and 28 fewer events per 1000 participants, respectively [308]. The study also concluded that B-TURP may carry a similar risk of UI and may result in similar rates of re-TURP in the short-term (four fewer events and one more re-TURP per 1000 participants, respectively) compared to M-TURP [308]. An RCT based meta-analysis has shown that TURis reduces the risk of TUR-syndrome and the need for blood transfusion compared to M-TURP [313]. It was concluded that TURis is associated with improved peri-operative safety, eliminating the risk of TUR syndrome, reducing the risk of blood transfusion/clot retention and hospital stay. No significant difference was detected in urethral stricture rates.

Data from the vast majority of individual RCTs with mid- to long-term follow-up (up to 60 months), showed no differences between M-TURP and B-TURP in urethral stricture/BNC rates [314-322], in accordance with all published meta-analyses. However, two individual RCTs have shown opposing results [321, 327]. A significantly higher stricture (urethral stricture + BNC) rate was detected in the B-TURP arm performed with a “quasi” bipolar system (TURis, Olympus Medical) in patients with a prostate volume > 70 mL at 36 months follow-up [321]. In addition, a significantly higher BNC, but not urethral stricture, rate was detected in the B-TURP arm performed with a “true” bipolar system (Gyrus PK SuperPulse, Olympus Medical) in 137 patients at twelve months follow-up [327].

Randomised controlled trials using the erectile function domain of the IIEF (IIEF-ED) and the ejaculatory domain of the male sexual-health questionnaire (Ej-MSHQ) showed that M-TURP and B-TURP have a similar effect on erectile and ejaculatory function [328, 329]. Comparative evaluations of the effects on overall sexual function, quantified with IIEF-15, showed no differences between B-TURP and M-TURP at twelve months follow-up (erection, orgasmic function, sexual desire, intercourse satisfaction, overall satisfaction) [329, 330]. Furthermore, the largest meta-analysis published to date, showed that erectile function measured by IIEF-5 appears to be similar at twelve months follow-up after B-TURP and M-TURP [308].
A comparative study [331] evaluated the safety of B-TURP in patients taking therapeutic oral anticoagulation (phenprocoumon) or anti-platelet drug therapy (acetylsalicylic acid or clopidogrel), without stopping or bridging the medication. Outcomes under acetylsalicylic acid were comparable to the unmedicated control group. Under oral anticoagulation therapy catheterisation (median 41-hours vs. 24-hours) and hospitalisation time was longer (median four days vs. three days), AUR rate was higher (18% vs. 6%), but blood transfusion rates did not differ to the control group. Under anti-platelet therapy blood transfusion (19% vs. 1%) and re-hospitalisation rates (19% vs. 3%) were higher.

**Practical considerations:** Monopolar-TURP is an effective treatment for moderate-to-severe LUTS secondary to BPO. The choice should be based primarily on prostate volume (30-80 mL suitable for M-TURP). No studies on the optimal cut-off value exist, but the complication rates increase with prostate size [325]. The upper limit for M-TURP is suggested as 80 mL (based on Panel consensus, under the assumption that this limit depends on the surgeon’s experience, choice of resectoscope size and resection speed), as surgical duration increases, there is a significant increase in the rate of complications and the procedure is safest when performed in under 90 minutes [332].

Bipolar TURP in patients with moderate-to-severe LUTS secondary to BPO, has similar efficacy with M-TURP, but lower peri-operative morbidity. The duration of improvements with B-TURP were documented in a number of RCTs with mid-term follow-up. Long-term results (up to five years) for B-TURP showed that safety and efficacy are comparable to M-TURP [314-322]. The choice of B-TURP should be based on equipment availability, surgeon's experience, and patient’s preference.

### Summary of evidence

| Bipolar- or monopolar-TURP is the current standard surgical procedure for men with prostate sizes of 30-80 mL and bothersome moderate-to-severe LUTS secondary to BPO. | LE 1a |
| Bipolar-TURP achieves short-, mid- and long-term results comparable with M-TURP, but B-TURP has a more favourable peri-operative safety profile. | LE 1a |

### Recommendation

**Offer bipolar- or monopolar-transurethral resection of the prostate to surgically treat moderate-to-severe LUTS in men with prostate size of 30-80 mL.**  
**Strength rating:** Strong

---

#### Holmium laser resection of the prostate

With the advent of holmium laser enucleation of the prostate (section 5.3.2.3) and the fact that no relevant publications on holmium laser resection of the prostate (HoLRP) have been published since 2004, HoLRP of the prostate does not play a role in contemporary treatment algorithms.

#### Thulium:yttrium-aluminium-garnet laser (Tm:YAG) vapouresection of the prostate

**Mechanism of action:** In the Tm:YAG laser, a wavelength between 1,940 and 2,013 nm is emitted in continuous wave mode. The laser is primarily used in front-fire applications [333]. Different applications such as vapouresection (ThuVARP) have been published [334].

**Efficacy:** Several meta-analyses with pooled data from both RCTs and non-RCTs have evaluated ThuVARP vs. M-TURP [335-337], and B-TURP [338-340]. The largest meta-analyses included nine RCTs and seven non-RCTs and reported no clinically relevant differences in efficacy (IPSS, QoL score and Qmax) between ThuVARP and M-TURP or B-TURP at twelve months [339]. A multicentre, RCT with 410 men reported that ThuVARP and TURP are equivalent in terms of IPSS but not Qmax, with TURP deemed superior at twelve months follow-up [341]. The beneficial effect of TURP in terms of Qmax was strengthened in men aged < 70 years and in those diagnosed with LUTS rather than urinary retention. No differences in individual patient-reported urinary symptoms were seen between arms, with the exception of some evidence to indicate potential reduction in nocturia in the TURP arm. Data from one RCT with long-term follow-up showed no difference in efficacy and re-operation rates between ThuVARP and M-TURP (2.1% vs. 4.1%, respectively) [342]. A prospective multicentre study on ThuVARP, including 2,216 patients, showed durable post-operative improvement in IPSS, QoL, Qmax, and PVR for the entire eight years of follow-up [343].

**Tolerability and safety:** In a number of meta-analyses longer operation times, shorter catheterisation/hospitalisation times and less blood loss without significant differences in transfusion rates or in any other short-term complication rates have been reported for ThuVARP compared to TURP [335-340]. A significantly higher transfusion rate was reported after M-TURP in two meta-analyses [337, 339]. However, overall RCT quality was relatively low with limited follow-up potentially accounting for under-reporting of late complications,
such as urethral stricture/BNC [339]. A multicentre RCT with 410 men, followed up for twelve months reported that ThuVARP and TURP show similar operation, catheterisation, and hospitalisation times between arms with no difference in the frequency or severity of surgical complications or in blood transusions rate or haemoglobin change [341, 344]. Patients with urinary retention had similarly positive outcomes to those with LUTS [341, 344]. Data from three RCTs with mid- to long-term follow-up (18 to 48 months) showed no differences in late complication rates between ThuVARP and TURP (BNC: 0.0%-2.1% vs. 0.0%-4.1%; stricture: 0.0%-2.2% vs. 0.0%-2.2%, respectively) [342, 345, 346].

Haemoglobin drop was significantly higher in the bridging group in a retrospectively analysed case series of 103 patients who underwent ThuVARP and received either low molecular weight heparin bridging or continued antiplatelet/anticoagulant therapy [347].

Practical considerations: As a limited number of RCTs with mid- to long-term follow-up support the efficacy of ThuVARP, there is a need for ongoing investigation of the technique.

5.3.1.4 Transurethral incision of the prostate

Mechanism of action: Transurethral incision of the prostate (TUIP) involves incising the bladder outlet without tissue removal. Transurethral incision of the prostate is conventionally performed with Collins knife using monopolar electrocautery; however, alternative energy sources such as holmium laser may be used [348]. This technique may replace M-TURP in selected cases, especially in prostate sizes < 30 mL without a middle lobe.

Efficacy: An RCT comparing conventional TUIP vs. TUIP using holmium laser in prostates ≤ 30 mL with a follow-up of twelve months, found both procedures to be equally effective in relieving BOO with similarly low re-operation rates [348]. A meta-analysis of ten RCTs found similar LUTS improvements and lower but significant improvements in Qmax for TUIP [349]. In this meta-analysis, an upper limit of prostate size was reported as an entry criterion for eight studies with five ≤ 30 mL and three < 60 mL. A meta-analysis of six trials showed that re-operation was more common after TUIP (18.4%) than after M-TURP (7.2%) [349].

Tolerability and safety: An RCT comparing conventional TUIP vs. TUIP using holmium laser reported both procedures to be safe with low complication rates; however, the operation time and retrograde ejaculation rate was significantly lower in the conventional TUIP arm [348]. No cases of TUR-syndrome have been recorded after TUIP. The risk of bleeding after TUIP is small [349].

Practical considerations: Transurethral incision of the prostate is an effective treatment for moderate-to-severe LUTS secondary to BPO. The choice between M-TURP and TUIP should be based primarily on prostate volume (< 30 mL TUIP) [349].

5.3.2 Enucleation of the prostate

5.3.2.1 Open prostatectomy

**Mechanism of action:** Open prostatectomy is the oldest surgical treatment for moderate-to-severe LUTS secondary to BPO. Obstructive adenomas are enucleated using the index finger, approaching from within the bladder (Freyer procedure) or through the anterior prostatic capsule (Millin procedure). It is used for substantially enlarged glands (> 80-100 mL).

**Efficacy:** Open prostatectomy reduces LUTS by 63-86% (12.5-23.3 IPSS points), improves QoL score by 60-87%, increases mean Q\textsubscript{max} by 375% (+16.5-20.2 mL/s), and reduces PVR by 86-98%. Efficacy is maintained for up to six years [350-355]. Data from an Austrian nationwide study of 1,286 men submitted to OP showed that the endourological re-intervention rates after primary OP were 0.9%, 3.0%, 6.0%, and 8.8%, at three months, one year, five years, and eight years, respectively. The respective incidence of re-TURP was 0.5%, 1.8%, 3.7% and 4.3%, respectively [9].

Two meta-analyses [356, 357] evaluated the overall efficacy of OP performed via a transvesical approach vs. two transurethral enucleation techniques for treating patients with large glands, namely bipolar transurethral enucleation of the prostate (B-TUEP) and holmium laser enucleation of the prostate (HoLEP). The larger study included nine RCTs involving 758 patients [357]. Five RCTs compared OP with B-TUEP [355, 358-361] and four RCTs compared OP with HoLEP [350, 351, 362, 363]. At three, six, twelve and 24-months follow-up there were no significant differences in Q\textsubscript{max} [357]. Post-void residual, PSA, IPSS and QoL score showed no significant differences at one-, three-, six- and twelve-months follow-up [357]. Randomised controlled trials indicate that OP is as effective as HoLEP for improving micturition in large prostates [350, 351], with similar improvement regarding Q\textsubscript{max}, IPSS score and re-operation rates after five years [350].

**Tolerability and safety:** Open prostatectomy mortality has decreased significantly during the past two decades (< 0.25%) [354]. Data from an Austrian nationwide study of 1,286 men submitted to OP showed mortality rates of 0.2% at 30 days and 0.4% at 90 days [307]. The estimated transfusion rate is about 7-14% [350, 353, 354, 356]. Long-term complications include transient UI (up to 10%), BNC and urethral stricture (about 6%) [350-352, 356, 364].

Two meta-analyses evaluated the overall safety of OP performed via a transvesical approach vs. B-TUEP and HoLEP [356, 357]. Operation time did not differ significantly between OP and B-TUEP but was significantly shorter for OP compared to HoLEP. Catheterisation and hospitalisation time were significantly longer for OP, which was also associated with more blood transfusions. There were no significant differences regarding other complications. There was no significant difference in IIEF-5 at three, six, twelve and 24-months follow-up.

**Practical considerations:** Open prostatectomy is the most invasive surgical method, but it is an effective and durable procedure for the treatment of LUTS/BPO. In the absence of an endourological armamentarium including a holmium laser or a bipolar system and with appropriate patient consent, OP is a reasonable surgical treatment of choice for men with prostates > 80 mL.

5.3.2.2 Bipolar transurethral enucleation of the prostate

**Mechanism of action:** Following the principles of bipolar technology (section 5.3.1.1), the obstructive adenoma is enucleated endoscopically by the transurethral approach. Bipolar-transurethral enucleation of the prostate (B-TUEP) evolved from plasmakinetic (PK) B-TURP and was introduced by Gyrus ACMI. The technique, also referred to as PK enucleation of the prostate (PKEP), utilises a bipolar high-frequency generator and
a variety of detaching instruments, for this true bipolar system, including a point source in the form of a axipolar cystoscope electrode suitable for enucleation [365] or a resectoscope tip/resection loop [366, 367]. More recently, a novel form of B-TUEP has been described, bipolar plasma enucleation of the prostate (BPEP), stemming from B-TURP (TURis, Olympus Medical), that utilises a bipolar high frequency generator and a variety of detaching instruments including a mushroom- or button-like vapo-electrode [361, 368] and a Plasmasect enucleation electrode [369] for this quasi-bipolar system. Bipolar transurethral enucleation of the prostate is followed by either morcellation [361, 365] or resection [366-368, 370-372] of the enucleated adenoma.

**Efficacy:** One RCT evaluating PKEP vs. M-TURP in 204 patients with mean prostate volume < 80 mL reported a significant improvement in IPSS, QoL score, and Q\textsubscript{max} with urodynamically proven de-obstruction favouring PKEP at 36 months follow-up [367]. The RCT concluded that the mid-term clinical efficacy of PKEP was comparable to M-TURP [367]. One RCT evaluating PKEP vs. B-TURP in patients with prostate volume > 80 mL reported no clinically relevant differences in IPSS, QoL score, and Q\textsubscript{max} at six months follow up [373]. Another RCT evaluating BPEP vs. B-TURP in patients with prostate volume > 80 mL reported not clinically relevant differences in IPSS, QoL score, Q\textsubscript{max} and PVR at 24 months follow-up [374]. Two meta-analyses, reported similar efficacy at twelve months in terms of IPSS, QoL score and Q\textsubscript{max} for B-TUEP (PKEP or BPEP) vs. B-TURP [375, 376]. Another meta-analysis evaluating B-TUEP vs. B-TURP, reported similar efficacy at 36 months in terms of IPSS, and Q\textsubscript{max} [323]. Two RCTs evaluated the mid-term efficacy of PKEP vs. B-TURP at 36 months [366, 371] and one RCT evaluated long-term efficacy at 60 months [372]. Efficacy was significantly better for PKEP in patients with large prostates at 36, 48 and 60 months [366, 372]. Comparative data on efficacy for B-TUEP vs. OP and the various forms of laser enucleation are presented in section 5.3.2.1 – 5.3.2.5, respectively.

**Tolerability and safety:** An RCT evaluating PKEP vs. M-TURP in patients with prostate volume < 80 mL and 36-month follow-up reported that PKEP is superior to M-TURP in terms of haemoglobin drop, irrigation, catheterisation, and hospitalisation time [367]. No significant differences between the arms were reported in operation time, blood transfusion rates, sexual function, or any other reported complications (TUR-syndrome, clot retention, incontinence, retrograde ejaculation, urethral structures/BNC) [367]. One RCT evaluating PKEP vs. B-TURP in patients’ prostate volume > 80 mL and six months follow-up reported that PKEP is superior to B-TURP in terms of operation, irrigation, catheterisation, hospitalisation time and haemoglobin drop [373]. Significant differences were reported in blood transfusion, BNC and retrograde ejaculation rates favouring PKEP, but no differences in urethral stricture and ED rates were reported [373]. Another RCT evaluating BPEP vs. B-TURP in patients with prostate volume > 80 mL reported that BPEP had longer operative time but shorter irrigation, catheterisation, hospitalisation time and lower haemoglobin drop with no differences in blood transfusion, urethral stricture and UI rates at 24 months follow-up [374]. A meta-analysis evaluating PKEP vs. TUR reported that mid-term IIEF-5 scores were comparable [377]. Another meta-analysis reported less bleeding with B-TUEP compared to M-TURP but similar UI rates and AUR after catheter removal [323]. Two meta-analyses evaluating B-TUEP vs. B-TURP reported similar operation, catheterisation and hospitalisation times; lower acute urine retention rates; significantly reduced haemoglobin drop and blood transfusion rates; no difference in erectile function; and no difference in all other reported complication rates including urethral stricture/BNC rates for B-TUEP at 24 months follow-up [375, 376]. No difference in urethral stricture/BNC rates was reported at 60 months follow-up [372]. Comparative data on efficacy for B-TUEP vs. OP and the various forms of laser enucleation are presented in section 5.3.2.1 – 5.3.2.5, respectively.

**5.3.2.3 Holmium laser enucleation of the prostate**

**Mechanism of action:** The holmium:yttrium-aluminium garnet (Ho:YAG) laser (wavelength 2,140 nm) is a pulsed solid-state laser that is absorbed by water and water-containing tissues. Tissue coagulation and necrosis are limited to 3-4 mm, which is enough to obtain adequate haemostasis [378].
Efficacy: An initial meta-analysis reported no significant differences in short-term efficacy ($Q_{max}$) and re-intervention rates (4.3% vs. 8.5%) between HoLEP and M-TURP [379]; however, subsequent meta-analyses reported favourable short-term efficacy ($Q_{max}$ and IPSS) for HoLEP [303, 336, 375, 380]. Another meta-analysis reported similar efficacy at 24 months in terms of IPSS, and $Q_{max}$ [323]. Three meta-analyses evaluating HoLEP vs. B-TURP showed no significant differences in short-term efficacy (IPSS, QoL score and $Q_{max}$) [323, 375, 381]. One RCT comparing HoLEP with M-TURP in a small number of patients with mean prostate volume < 80 mL reported no significant difference in IPSS, QoL score and $Q_{max}$ at 24 months [383]. Long-term (72 months) improvement in IPSS and $Q_{max}$ was better for HoLEP, but there were no clinically relevant differences between the arms [384]. Another RCT comparing HoLEP with B-TURP in patients with prostate volume > 80 mL reported no significant difference in IPSS, QoL score and $Q_{max}$ at 36 months, however, the overall re-treatment rate was significantly lower following HoLEP with less patients restarting α-blockers and less re-operations [385]. Comparative efficacy data for HoLEP vs. OP is presented in section 5.3.2.1. One small RCT evaluating HoLEP vs. PKEP in patients with mean prostate volume < 80 mL reported similar improvements in IPSS and $Q_{max}$ as well as similar re-operation rates at twelve months follow-up [365]. An RCT comparing HoLEP vs. bipolar EEP reported no significant difference in IPSS, QoL score, PVR, and $Q_{max}$ at one, three-, and twelve-months follow-up [386].

Tolerability and safety: Data from a large national database on peri-operative outcomes of 2,869 laser enucleation of the prostate and 37,577 TURP procedures supports that laser enucleation of the prostate is associated with longer operation times, shorter hospitalisation times, similar complication rates (including transfusions, and re-operations), but lower rates of infectious complications [387]. Several meta-analyses found that HoLEP has longer operation times, shorter catheterisation and hospitalisation times, reduced blood loss, fewer blood transfusions but no significant differences in urethral strictures (2.6% vs. 4.4%) and stress urinary incontinence (SUI) (1.5% vs. 1.5%) rates compared to M-TURP [336, 375, 379, 380, 388]. Another meta-analysis reported that HoLEP has shorter catheterisation times, lower haemoglobin drops, fewer blood transfusions, urethral strictures and UTIs but no significant differences in clot retention rates and AUR after catheter removal compared to M-TURP [323]. Three meta-analyses evaluated HoLEP vs. B-TURP [375, 381, 389]. One, reported longer operation times for HoLEP but no significant differences in hospitalisation time or complication rates [375] whilst another reported no significant differences in operation and catheterisation times or short-term complication rates [381]. A SR reported that HoLEP has lower AUR rates after catheter removal but similar haemoglobin drop, UTI, urethral stricture, and UI rates [323]. A RCT comparing HoLEP with B-TURP in patients with prostate volume < 80 mL reported longer operation time, shorter catheterisation and hospitalisation times and a lower risk for haemorrhage for HoLEP with no significant differences in blood transfusion rates or other complication rates at 24 months [383]. Another RCT comparing HoLEP with B-TURP in patients with prostate volume > 80 mL reported shorter operation, catheterisation and hospitalisation times and lower blood transfusion rates for HoLEP but no differences in complication rates including UI and IIEF-5 score at 36 months [385]. Comparative data on safety of HoLEP vs. OP are presented in section 5.3.2.1. One small RCT evaluating HoLEP vs. PKEP in patients with mean prostate volume < 80 mL reported significantly shorter operation times for HoLEP, but similar catheterisation and hospitalisation times and complication rates at twelve months follow-up [365]. An RCT comparing HoLEP vs. bipolar B-TUEP demonstrated shorter operation and hospitalisation times and earlier catheter removal for HoLEP [386].

An RCT of pulse modulation in HoLEP (Virtual basket) demonstrated significantly less haemoglobin drop and reduced operation times when compared to conventional HoLEP [390].

Holmium laser enucleation of the prostate has been safely performed in patients using anti-coagulant and/or antiplatelet medications [391, 392]. However, current limitations include: a lack of RCTs; limited data on short- and mid-term complications and bridging therapy; data presentation does not allow for separate interpretation of either antiplatelet and anti-coagulant therapy.

The impact on erectile function and retrograde ejaculation is comparable between HoLEP and TURP [393, 394]. Erectile function did not decrease from baseline in either group; three quarters of sexually active patients had retrograde ejaculation after HoLEP. Data have shown that ejaculation and orgasm perception are the two most impacted domains after HoLEP [395]. Attempts to maintain ejaculatory function with HoLEP have been reported to be successful in up to 46.2% of patients [396].

A meta-analysis of seven RCTs evaluating HoLEP vs. TURP reported that short- and mid-term IIEF-5 scores were comparable, whilst long-term scores were significantly better for HoLEP [397]. Two other meta-analyses detected no difference in mid-term retrograde ejaculation rates [398].

An RCT comparing HoLEP vs B-TUER reported shorter operation and hospitalisation times and earlier catheter removal for HoLEP [386].
Practical considerations: Holmium laser enucleation of the prostate requires experience and relevant endoscopic skills. The experience of the surgeon is the most important factor affecting the overall occurrence of complications [399, 400]. Mentorship programmes are advised to improve surgical performance from both an institutional and personal learning curve perspective [401-403].

5.3.2.4 Thulium:yttrium-aluminium-garnet laser (Tm:YAG) enucleation of the prostate

Mechanism of action: The Tm:YAG laser has been described in section 5.3.1.3. Enucleation using the Tm:YAG laser includes ThuVEP (vapoenucleation i.e. excising technique) and ThuLEP (blunt enucleation).

Efficacy: Two meta-analyses evaluating ThuLEP vs. M-TURP and B-TURP reported no clinically relevant differences in short-term efficacy (QoL, IPSS and QoL score) [323, 375]. An RCT with five years follow-up comparing ThuLEP with B-TURP found no difference between the two procedures for QoL, IPSS, PVR, and QoL [404]. A meta-analysis [405] evaluating ThuLEP vs. HoLEP showed no clinically relevant differences in QoL, QoL score and Qmax at twelve months in accordance with one RCT showing similar results at eighteen months [406]. Furthermore, ThuLEP and PKEP were compared in one RCT with twelve months follow-up the outcome of which showed no difference with regard to efficacy [407]. There are mainly prospective case studies on ThuVEP showing a significant improvement in IPSS, Qmax and PVR after treatment [408-411]. A cohort study with median follow-up of 36.5 months reported improved Qmax (19.1 vs. 7.75 mL/s), PVR (31.9 vs. 150 mL), IPSS (4.5 vs. 24), and QoL scores (1 vs. 5), with a PSA reduction of 86.5% [412].

Tolerability and safety: Two meta-analyses evaluating ThuLEP vs. M-TURP and B-TURP reported a longer operation time and shorter catheterisation time for ThuLEP compared to M-TURP and a shorter hospitalisation time for ThuLEP compared to B-TURP [323, 375]. Lower blood transfusion rates compared to M-TURP, lower clot retention rates compared to B-TURP, and no difference in the other complication rates were also reported for ThuLEP [323, 375]. An RCT comparing ThuLEP with B-TURP reported a significant difference in IIEF-5 score favouring ThuLEP at twelve months [413]. A meta-analysis evaluating ThuLEP vs. HoLEP showed significantly lower haemoglobin drop for ThuLEP [405]. Transient UI was more common for HoLEP. Intraoperatively ThuLEP showed shorter operation times when compared to HoLEP [375] and a multicenter RCT demonstrated lower haemoglobin loss for ThuLEP compared to HoLEP [390].

Another meta-analysis [414] evaluating ThuLEP vs. HoLEP showed a significant difference is enucleation time favouring ThuLEP, but no significant differences in operation, catheterisation and hospitalisation times and short-term complication rates. These results were in accordance with one RCT showing similar results, including no urethral and bladder neck strictures, at eighteen months [406]. ThuLEP and PKEP were compared in one RCT with twelve months follow-up [407]. No significant difference in complication rates was detected, but haemoglobin level decrease and catheterisation time was significantly lower for ThuLEP.

In comparative studies ThuVEP shows high intra-operative safety [415], also in case series of patients with large prostates [406] and anticoagulation or bleeding disorders [409, 410]. In a cohort study on ThuVEP, UTIs occurred in two patients, urethral stricture and BNC developed in one patient each, respectively and one patient was treated for recurrent adenoma of the prostate [412]. A study focusing on post-operative complications after ThuLEP reported adverse events in 31% of cases, with 6.6% complications greater than Clavien grade 2 [416]. One case control study on ThuVEP with 48-month follow-up reported long-term durability of voiding improvements and overall re-operation rates of 2.4% [410]. Two studies addressed the impact of ThuVEP on sexual function, demonstrating no effect on erectile function with increased prevalence of retrograde ejaculation post-operatively [417, 418].
Practical considerations: ThuLEP seems to offer similar efficacy and safety when compared to TURP, bipolar enucleation and HoLEP; whereas, ThuVEP is not supported by RCTs. Based on the limited number of RCTs there is a need for ongoing investigation of these techniques.

### Summary of evidence

| Enucleation of the prostate using the Tm:YAG laser demonstrates similar efficacy when compared to M-TURP/bipolar transurethral (plasmakinetic) enucleation, HoLEP and B-TURP in the short-, mid-, and long-term, respectively. | 1b |
| Enucleation of the prostate using the Tm:YAG laser (ThuLEP) demonstrates similar safety compared to TURP/bipolar transurethral (plasmakinetic) enucleation, and HoLEP in the short- and mid-term, respectively. | 1b |
| Vapoenucleation of the prostate using a Tm:YAG laser (ThuVEP) seems to be safe in patients with large prostates and those receiving anticoagulant or antiplatelet therapy. | 2b |

### Recommendations

- Offer enucleation of the prostate using the Tm:YAG laser (ThuLEP, ThuVEP) to men with moderate-to-severe LUTS as an alternative to transurethral resection of the prostate, holmium laser enucleation or bipolar transurethral (plasmakinetic) enucleation.  
  **Strength rating:** Weak
- Offer Tm:YAG laser enucleation of the prostate to patients receiving anticoagulant or antiplatelet therapy.  
  **Strength rating:** Weak

#### 5.3.2.5 Diode laser enucleation of the prostate (DiLEP)

**Mechanism of action:** For prostate surgery, diode lasers with a wavelength of 940, 980, 1,318, and 1,470 nm (depending on the semiconductor used) are marketed for vaporisation and enucleation. Only a few have been evaluated in clinical trials [385].

**Efficacy:** One small RCT comparing 1,318 nm DiLEP with B-TURP in patients with mean prostate volume < 80 mL reported no significant differences in IPSS, QoL score, Q\text{max} and PVR at six months follow-up [419]. Another RCT comparing 1,470 nm DiLEP with B-TURP in 157 patients with mean prostate volume < 80 mL also reported no significant differences in IPSS, QoL score, Q\text{max} and PVR at twelve months follow-up [420]. In addition, three RCTs comparing 980 nm DiLEP with PKEP in patients with mean prostate volume < 80 mL [421, 422] and > 80 mL [423] reported no significant differences in IPSS, QoL score, Q\text{max} and PVR at twelve months follow-up. An RCT of DiLEP (980 nm) vs. HoLEP detected no significant difference in Q\text{max}, PVR, IPSS, and QoL at three, six and twelve months follow-up [424].

**Tolerability and safety:** One small RCT comparing 1,318 nm DiLEP with B-TURP in patients with mean prostate volume < 80 mL and six months follow-up reported a significantly longer operation time for DiLEP, but shorter catheterisation and hospitalisation times, as well as less blood loss (without differences in blood transfusion rates) [419]. Another RCT comparing 1,470 nm DiLEP with B-TURP in 157 patients with prostate volume < 80 mL and twelve months follow-up reported significantly shorter operation, catheterisation, and hospitalisation times with less blood loss (without differences in blood transfusion rates) for DiLEP, with no differences in complication rates between the two arms [420]. Three RCTs comparing 980 nm DiLEP with PKEP in patients with prostate volume < 80 mL [421, 422] and > 80 mL [423] and twelve months follow-up reported conflicting per-operative outcomes: operation time (no difference between arms [421], significantly shorter for DiLEP [422] or significantly longer for DiLEP [423]); catheterisation time (no difference between the two arms [421], significantly shorter for DiLEP [422, 423]); hospitalisation time (no difference between arms [421, 422], significantly shorter for DiLEP [423]); blood loss (no difference in haemoglobin drop between arms [421], significantly lower haemoglobin drop for DiLEP [422, 423]). All trials reported no differences in blood transfusion rates and complication rates [421-423]. An RCT of DiLEP (980 nm) vs. HoLEP with twelve months follow-up demonstrated no significant difference in peri-operative outcomes including operation and hospitalisation times, resected tissue weight and catheter duration with the DiLEP group also showing lower haemoglobin drop [424].

**Practical considerations:** Diode laser enucleation seems to offer similar efficacy and safety when compared to either B-TURP or bipolar transurethral (plasmakinetic) enucleation. Based on the limited number of mainly low-quality RCTs, and controversial data on the retreatment rate, results for DiLEP should be evaluated in further higher quality RCTs.
Laser enucleation of the prostate using the 1,318 nm or 1,470 laser showed comparable short-term efficacy and safety to B-TURP. Peri-operative parameters like blood loss, catheterisation time and hospital stay are in favour of diode enucleation.

Laser enucleation of the prostate using the 980 nm laser showed comparable short-term efficacy and safety to bipolar transurethral (plasmakinetic) enucleation.

Recommendation

Offer 120-W 980 nm, 1,318 nm or 1,470 nm diode laser enucleation of the prostate to men with moderate-to-severe LUTS as a comparable alternative to bipolar transurethral (plasmakinetic) enucleation or bipolar transurethral resection of the prostate.

Weak

5.3.2.6 Enucleation techniques under investigation

5.3.2.6.1 Minimal invasive simple prostatectomy

Mechanism of action: The term minimal invasive simple prostatectomy (MISP) includes laparoscopic simple prostatectomy (LSP) and robot-assisted simple prostatectomy (RASP). The technique for LSP was first described in 2002 [425], while the first RASP was reported in 2008 [426]. Both LSP and RASP are performed using different personalised techniques, based on the transcapsular (Millin) or transvesical (Freyer) techniques of OP.

Efficacy: A SR and meta-analysis showed that in 27 observational studies including 764 patients, the mean increase in Q\text{max} was 14.3 mL/s, and the mean improvement in IPSS was 17.2 [427]. There were no differences in improvements in Q\text{max} and IPSS [427]. A meta-analysis comparing MISP vs. OP reported no significant differences with regard to functional and symptom parameters between the two techniques [428]. A multicentre RCT with median follow-up of 26 months did not demonstrate any significantly different functional or peri-operative results between LSP, RASP and HoLEP [429].

Two recent retrospective series on RASP were not included in the meta-analysis which confirm these findings [430, 431]. The largest retrospective series reports 1,330 consecutive cases including 487 RASP (36.6%) and 843 LSP (63.4%) cases. The authors confirm that both techniques can be safely and effectively done in selected centres [430].

Tolerability and safety: In the largest series, the post-operative complication rate was 10.6% (7.1% for LSP and 16.6% for RASP), most of the complications being of low grade. The most common complications in the RASP series were haematuria requiring irrigation, UTI and AUR; in the LSP series, the most common complications were UTI, ileus and AUR. In the most recent, largest comparative analysis of robotic vs. OP for large-volume prostates, a propensity score-matched analysis was performed with five covariates. Robotic compared with OP demonstrated a significant shorter average length of hospital stay, but longer mean operative time. The robotic approach was also associated with a lower estimated blood loss. Improvements in maximal flow rate, IPSS, QoL, PVR and post-operative PSA levels were similar before and after surgery for both groups. There was no difference in complications between the groups [432]. In a multicentre RCT comparing LSP, RASP and HoLEP LSP demonstrated significantly longer catheterisation times than RASP and HoLEP, whilst RASP and LSP showed longer hospitalisation times and lower rates of de novo bladder storage symptoms [429]. A meta-analysis comparing MISP vs. OP demonstrated shorter hospital stay, irrigation time, as well as blood loss and transfusion rates for MISP [428]. A SR and meta-analysis reported the mean duration of operation was 141 minutes and the mean intra-operative blood loss was 284 mL. One hundred and four patients (13.6%) developed a surgical complication. In comparative studies to OP, length of hospital stay, length of catheter use, and estimated blood loss were significantly lower in the MISP group, while the duration of operation was longer. There were no differences in peri-operative complications between both procedures [427].

Practical considerations: Minimal invasive simple prostatectomy seems comparable to OP in terms of efficacy and safety, providing similar improvements in Q\text{max} and IPSS [427]. However, most studies are of a retrospective nature. High-quality studies are needed to compare the efficacy, safety, and hospitalisation times of MISP and both OP and endoscopic methods. Long-term outcomes, learning curve and cost of MISP should also be evaluated.

Summary of evidence

Minimal invasive simple prostatectomy is feasible in men with prostate sizes > 80 mL needing surgical treatment; however, RCTs are needed.
Mechanism of action: The Potassium-Titanyl-Phosphate (KTP) and the lithium triborate (LBO) lasers work at a wavelength of 532 nm. Laser energy is absorbed by haemoglobin, but not by water. Vaporisation leads to immediate removal of prostatic tissue. Three “Greenlight” lasers exist, which differ not only in maximum power output, but more significantly in fibre design and the associated energy tissue interaction of each. The standard Greenlight device today is the 180-W XPS laser, but the majority of evidence is published with the former 80-W KTP or 120-W HPS (LBO) laser systems.

Two approaches for KTP/LBO laser-based enucleation technique exist [433]. GreenLEP is an anatomical enucleation technique following the principle of blunt dissection of the adenoma with the sheath and laser energy for incision as described for ThuLEP [434]. En bloc GreenLEP preparation has been popularised with the same approach. A variation of the most commonly applied GreenLEP technique, with tissue morcellation, is the in-situ vapourisation of apically enucleated tissue, also referred to as anatomic vapourisation-incision technique [434, 435]. To date, no RCTs evaluating enucleation using the KTP/LBO laser have been carried out [436].

Vaporisation of the prostate

5.3.3.1 Bipolar transurethral vapourisation of the prostate

Mechanism of action: Bipolar transurethral vapourisation of the prostate (B-TUVP) was introduced in the late 1980s (“PK” B-TUVP). The technique was derived from PK B-TURP and utilised a bipolar electrode and a high-frequency generator to create a plasma effect able to vapourise prostatic tissue [437]. With minimal direct tissue contact (near-contact; hovering technique) and heat production the bipolar electrode produces a constant plasma field (thin layer of highly ionized particles; plasma corona), allowing it to glide over the tissue and vapourise a limited layer of prostate cells without affecting the underlying tissue whilst achieving haemostasis, leaving behind a TURP-like cavity [438]. A distinct difference between B-TUVP and its ancestor (monopolar TURP), is that B-TUVP displays thinner (< 2 mm) coagulation zones [439], compared to the disproportionate extent of those created by the former (up to 10 mm) [440], potentially resulting in mostly irritative side-effects and SUI [439, 441, 442].

Efficacy: Bipolar-TUVP has been evaluated as a TURP alternative for treating moderate-to-severe LUTS in thirteen RCTs, including a total of 1,244 men with a prostate size of < 80 mL [317, 443-454]. Early RCTs evaluated the PK B-TUVP system [443-447]; however, during the last decade, only the “plasma” B-TUVP system with the “mushroom- or button-like” electrode (Olympus, Medical) has been evaluated [317, 448-454]. Results have been pooled in three meta-analyses [303, 455, 456], and a narrative synthesis has been produced in two SRs [303, 457]. The follow-up in most RCTs is twelve months [443-446, 448-450, 452, 454]. The longest follow-up is 36 months in a small RCT (n = 40) and eighteen months in a subsequent RCT (n = 340); evaluating PK [447] and plasma B-TUVP [317], respectively.

Early pooled results concluded that no significant differences exist in short-term efficacy (IPSS, QoL score, Q\textsubscript{max} and PVR) between PK B-TUVP and TURP [303]. However, the promising initial efficacy profile of the former may be compromised by inferior clinical outcomes (IPSS and Q\textsubscript{max}) at mid-term. Larger RCTs with longer follow-up are necessary to draw definite conclusions [303, 447]. A SR of seven RCTs comparing PK and plasma B-TUVP with TURP concluded that functional outcomes of B-TUVP and TURP do not differ [457]. The poor quality of the included RCTs and the fact that most data was derived from a single institution was highlighted [457]. A similar SR of eight RCTs comparing both B-TUVP techniques with TURP concluded that: not enough consistent data suitable for a meta-analysis exists; that the main functional results are contradictory; and that heterogeneity of RCTs, non-standardised techniques and methodological limitations do not permit firm conclusions [303]. A meta-analysis comparing B-TUVP with TURP reported similar efficacy at twelve-month follow-up in terms of IPSS, and Q\textsubscript{max} [323]. A meta-analysis of six RCTs specifically evaluating plasma B-TUVP vs. TURP, concluded that both techniques result in a similar improvement of LUTS [456].

Tolerability and safety: Early pooled results concluded that no statistically significant differences exist for intra-operative and short-term complications between PK B-TUVP and TURP, but peri-operative complications are significantly fewer after B-TUVP [303]. However, the results of a statistical analysis comparing pooled specific complication rates were not directly reported in this meta-analysis [303]. Mid-term safety results (urethral stricture, ED, and retrograde ejaculation) have also been reported to be similar [447], but larger RCTs with longer follow-up are necessary to draw definite conclusions [303, 447]. A SR of seven RCTs comparing PK and plasma B-TUVP with TURP concluded that most RCTs suggest a better haemostatic efficiency for B-TUVP, resulting in shorter catheterisation (42.5 vs. 77.5 hours) and hospitalisation times (3.1 vs. 4.4 days) [457]. A similar SR of eight RCTs comparing both B-TUVP techniques with TURP concluded that not enough consistent data suitable for a meta-analysis exists and that heterogeneity of RCTs, non-standardised techniques and methodological limitations do not permit firm conclusions [303]. A meta-analysis reported that B-TUVP has
shorter and similar catheterisation time compared to M-TURP and B-TURP, respectively; lower haemoglobin drop compared to either TURP technique; significantly fewer clot retentions/blood transfusions compared to M-TURP but not B-TURP; and no difference in other complication rates compared to either TURP technique [323]. A meta-analysis of six RCTs specifically evaluating plasma B-TUVP vs. TURP, concluded that no significant differences exist between the techniques in overall complication and transfusion rates [456]. However, a statistically significant difference was detected in major complication rates (Clavien 3, 4); including urethral stricture, severe bleeding necessitating re-operation and UI) and in the duration of catheterisation favouring plasma B-TUVP.

Practical considerations: Bipolar-TUVP and TURP have similar short-term efficacy. Plasmakinetic B-TUVP has a favourable peri-operative profile, similar mid-term safety, but inferior mid-term efficacy compared to TURP. Plasma B-TUVP has lower short-term major morbidity compared to TURP. Randomised controlled trials of higher quality, multicentre RCTs, and longer follow-up periods are needed to evaluate B-TUVP in comparison to TURP.

### Recommendation

Offer bipolar transurethral vaporisation of the prostate as an alternative to transurethral resection of the prostate to surgically treat moderate-to-severe LUTS in men with a prostate volume of 30-80 mL.  

**Strength rating**: Weak

#### 532 nm (‘Greenlight’) laser vaporisation of the prostate

**Mechanism of action**: The Potassium-Titanyl-Phosphate (KTP) and the lithium triborate (LBO) lasers have been described in section 5.3.2.6.2.

**Efficacy**: A meta-analysis of the nine available RCTs comparing photoselective vaporisation of the prostate (PVP) using the 80-W and 120-W lasers with TURP was performed in 2012 [458]. No differences were found in $Q_{\text{max}}$ and IPSS between 80-W PVP and TURP, but only three RCTs provided sufficient twelve-month data to be included in the meta-analysis [459-461]. Another meta-analysis from 2016 of four RCTs including 559 patients, on the 120-W laser, demonstrated no significant difference in functional and symptomatic parameters at six-, twelve-, and 24-month follow-up when compared to TURP [462]. A meta-analysis of two RCTs reported similar efficacy of 120-W PVP, compared to M-TURP at 36-months follow-up [323].

The only available RCT for the 180-W laser reported non-inferiority to TURP in terms of IPSS, $Q_{\text{max}}$, PVR volume, prostate volume reduction, PSA decrease and QoL questionnaires. Efficacy outcomes were similar to TURP with stable results at 24 months follow-up [463].

The longest RCT comparing the 120-W HPS laser with TURP had a follow-up of 36 months and showed a comparable improvement in IPSS, $Q_{\text{max}}$, and PVR [464]. Comparable improvements in IPSS, QoL, $Q_{\text{max}}$, or urodynamic parameters were reported from two RCTs with a maximum follow-up of 24 months [460, 465]. A SR and meta-analysis of eleven RCTs comparing M-TURP with the 80-W KTP or 120-W HPS system found no significant difference with respect to IPSS and $Q_{\text{max}}$ improvement [466].

One RCT comparing HoLEP to PVP, in patients with prostates > 60 mL, showed comparable symptom improvement, but significantly higher flow rates and lower PVR volume after HoLEP at short-term follow-up; in addition, PVP showed a 22% conversion rate to TURP [467].

One RCT compared B-TUVP with PVP with the 180-W XPS Laser. Comparable improvement in IPSS and $Q_{\text{max}}$ were reported at 24 months follow-up [468].

**Tolerability and safety**: A meta-analysis of RCTs comparing the 80-W and 120-W lasers with TURP showed a significantly longer operating time, but shorter catheterisation time and length of hospital stay after PVP [303]. Blood transfusions and clot retention were less with PVP. No difference was noted in post-operative urinary retention, UTI, meatal stenosis, urethral stricture, or bladder neck stenosis [303]. In a meta-analysis including trials with the 120-W laser, patients in the PVP group demonstrated significantly lower transfusion rates, shorter catheterisation time and shorter duration of hospital stay compared to TURP. Re-operation rates and operation time were in favour of TURP. No significant differences were demonstrated for treatment for urethral stricture, BNC, incidence of incontinence and UTI [462]. A SR and meta-analysis of eleven RCTs comparing M-TURP with the 80-W KTP or 120-W HPS system found that PVP was superior to M-TURP with regard to transfusion
rate, clot retention, catheterisation and hospitalisation time. A meta-analysis confirmed that PVP was superior to both M-TURP/B-TURP with regard to catheterisation and to M-TURP but not to B-TURP with regard to transfusion rate and clot retention [323].

180-W Greenlight laser prostatectomy is non-inferior to TURP in terms of peri-operative complications. Re-operation free survival during a 24 month follow-up was comparable between the TURP-arm and the 180-W XPS laser-arm [463]. In an RCT comparing the 120-W HPS laser with TURP, with a follow-up of 36 months, the re-operation rate was significantly higher after PVP (11% vs. 1.8%; p = 0.04) [464].

Based mostly on case series, the 80-,120- and 180-W Greenlight laser appears to be safe in high-risk patients undergoing anticoagulation treatment [469-472]; however, patients under anticoagulation therapy were either excluded from or represented a very small sample in currently available RCTs. In one study, anticoagulant patients had significantly higher rates of bladder irrigation (17.2%) compared with those not taking anticoagulants (5.4%) [472]. In contrast, another retrospective study focusing on the 180-W LBO laser did not find any significant differences between patients receiving or not receiving anticoagulants [473]. A retrospective study of a mixed cohort of patients, treated with 80-W KTP PVP and 120-W LBO HPS, revealed that delayed gross haematuria was common in patients (33.8%) during an average follow-up of 33 months [474]. A retrospective review of a database of patients undergoing 180-W PVP, without interruption of anticoagulation therapy, had a 30.5% rate of peri-operative adverse events with a significant occurrence of high grade Clavien Dindo events [475].

Safety in patients with urinary retention, impaired detrusor contractility, elderly patients or prostates > 80 mL was shown in various prospective short-term non-randomised trials. No RCT including prostates > 100 mL has been reported; therefore, comparison of retreatment rates between prostate volumes of different sizes is not possible [476-478].

A meta-analysis of five RCTs comparing collectively all three “Greenlight” lasers with TURP detected no difference in retrograde ejaculation rates [398]. An RCT with twelve months follow-up reported a retrograde ejaculation rate of 49.9% following PVP with an 80-W laser vs. 56.7% for TURP; there was no impact on erectile function in either arm of the trial [479]. Additional studies have also reported no difference between OP/TURP and Greenlight PVP for erectile function [480, 481]. However, IIEF-5 scores were significantly decreased at six-, twelve-, and 24- months in patients with pre-operative IIEF-5 greater than nineteen [482].

No significant difference with respect to peri- and post-operative complications was reported in an RCT comparing B-TUVP and PVP with the 180-W XPS Laser. Redo TURP for recurrent adenoma was required in 9.8% (B-TUVP) and 1.7% (PVP) of the patients during 24-months follow-up, respectively [468].

Practical considerations: The 180-W XPS represents the current standard of generators for PVP; however, the number and quality of supporting publications are low, especially for large glands (> 100 mL), with no long-term follow-up.

### Summary of evidence

| Laser vaporisation of the prostate using the 80-W KTP and the 120-W LBO laser (PVP) demonstrated higher intra-operative safety with regard to haemostatic properties when compared to TURP. Peri-operative parameters such as catheterisation time and hospital stay are in favour of PVP, whereas operation time and risk of re-operation are in favour of TURP. Short-term results for the 80-W KTP laser and mid-term results for the 120-W LBO laser were comparable to TURP. | 1a |
| Laser vaporisation of the prostate using the 180-W LBO laser (PVP) demonstrated higher intra-operative safety with regard to haemostatic properties when compared to TURP. Peri-operative parameters such as catheterisation time and hospital stay are in favour of PVP, whereas operation time was in favour of TURP. Short- to mid-term results are comparable to TURP. | 1b |
| Laser vaporisation of the prostate using the 80-W KTP and 120-W LBO lasers seems to be safe for the treatment of patients receiving antiplatelet or anticoagulant therapy. | 2 |
| Laser vaporisation of the prostate using the 180-W LBO laser seems to be safe for the treatment of patients receiving antiplatelet or anticoagulant therapy; however, the level of evidence available is low. | 3 |

Offer laser vaporisation of the prostate using 80-W KTP, 120- or 180-W LBO lasers for the treatment of patients receiving antiplatelet or anticoagulant therapy with a prostate volume < 80 mL. Weak

5.3.3.3 Vaporisation techniques under investigation
5.3.3.3.1 Diode laser vaporisation of the prostate

**Mechanism of action:** For prostate surgery, diode lasers with a wavelength of 980 nm are marketed for vaporisation; however, only a few have been evaluated in clinical trials [333].

**Efficacy:** Two RCTs for 120-W 980 nm diode laser vaporisation vs. M-TURP are available [483, 484]. The first RCT with 24-month follow-up reported equal symptomatic and clinical parameters at one and six months. However, at twelve- and 24-months the results were significantly in favour of TURP, repeat TURP was more frequent in the diode laser group [483]. The second RCT reported equivocal results for both interventions at three-month follow-up [484].

**Tolerability and safety:** Published studies on 980 nm diode laser vaporisation indicate high haemostatic potential, although anticoagulants or platelet aggregation inhibitors were taken in 24% and 52% of patients, respectively [485, 486]. In a number of studies, a high rate of post-operative dysuria was reported [483, 485-487]. A meta-analysis comparing diode laser vaporisation vs. M-TURP reported shorter catheterisation time and lower transfusion rates for diode laser vaporisation [323]. In an RCT reflecting on peri-operative and post-operative complications no significant differences were demonstrated for clot retention, AUR after catheter removal, UUI and UTI [483]. Moreover, for late complications no significant differences could be demonstrated for re-operation rate, urethral stricture, bladder neck sclerosis, de novo sexual dysfunction and mean time of dysuria [483].

Fibre modifications can potentially reduce surgical time [488]. Early publications on diode vaporisation reported high re-operation rates (8-33%) and persisting SUI (9.1%) [483, 485-487].

**Practical considerations:** Diode laser vaporisation leads to similar improvements in clinical and symptomatic parameters during short-term follow-up and provides good haemostatic properties. Based on the limited number of mainly low quality RCTs, and controversial data on the retreatment rate, results for diode laser vaporisation should be evaluated in further higher quality RCTs.

5.3.4 Alternative ablative techniques
5.3.4.1 Aquablation – image guided robotic waterjet ablation: AquaBeam

**Mechanism of action:** AquaBeam uses the principle of hydro-dissection to ablate prostatic parenchyma while sparing collagenous structures like blood vessels and the surgical capsule. A targeted high velocity saline stream ablates prostatic tissue without the generation of thermal energy under real-time transrectal ultrasound guidance; therefore, it is truly a robotic operation. After completion of ablation haemostasis is performed with a Foley balloon catheter on light traction or diathermy or low-powered laser if necessary [489].

**Efficacy:** In a double-blind, multicentre, prospective RCT 181 patients were randomised to TURP or Aquablation [490, 491]. Mean total operative time was similar for Aquablation and TURP (33 vs. 36 minutes), but resection time was significantly lower for Aquablation (4 vs. 27 minutes). At six months patients treated with Aquablation and TURP experienced large IPSS improvements (-16.9 and -15.1, respectively). The study non-inferiority hypothesis was satisfied. Larger prostates (50-80 mL) demonstrated a more pronounced benefit. At one year follow-up, mean IPSS reduction was 15.1 with a mean percent reduction in IPSS score of 67% for both groups. Ninety three percent and 86.7% of patients had improvements of at least five points from baseline, respectively. No significant difference in improvement of IPSS, QoL, Qmax and reduction of PVR was
reported between the groups. One TURP subject (1.5%) and three Aquablation subjects (2.6%) underwent re-TURP within one year of the study procedure [492].

At two years, improvements in IPSS and flow rate were maintained in both groups [493]. Surgical retreatment rates after twelve months for Aquablation were 1.7% and 0% for TURP. Over three years, mean IPSS improvements were 14.4 and 13.9 points in the Aquablation and TURP groups, respectively. Similarly, three-year improvements in $Q_{max}$ were 11.6 and 8.2 cc/sec. There were no surgical retreatments for BPH beyond twenty months, for either Aquablation or TURP [494]. Over three years, surgical retreatments were 4.3% and 1.5% respectively. A limitation of RCTs is whether they are generalisable; however, a cohort study reported similar results in their first 118 consecutive patients [495].

A subgroup analysis of the WATER study [490] reported that in men with larger more complex prostates, Aquablation was associated with both superior symptom improvement and a better safety profile with less post-operative anejaculation [496].

In a cohort study of 101 men (WATER II) with a prostate volume between 80-150 mL, mean IPSS improved from 23.2 at baseline to 5.9 at six months. Improvement in IPSS, QoL, $Q_{max}$ and reduction of PVR were also significant at six months [497]. At twelve months, significant improvements were seen in $Q_{max}$ (increase of 12.5 cc/sec) and PVR (drop of 171 cc) in those with PVR > 100 at baseline. No patient underwent a repeat procedure for BPH symptoms [498]. In a comparison of the WATER (RCT: prostates 30-80 cc) and WATER II (cohort study; > 80 cc) at two years, the improvements were maintained in both IPSS and flow rates. At two years, the surgical retreatment rate was 4% in WATER and 2% in WATER II [499].

Another RCT comparing Aquablation with TURP performed urodynamic studies on 66 patients at six months follow-up and reported significant changes in pdet$Q_{max}$ (reductions of 35 and 34 cm H$_2$O, respectively) and large improvements in BOO index in both groups [500].

Tolerability and safety: An RCT has shown that fewer men in the Aquablation group had a persistent Clavien-Dindo grade 1 or 2 or higher adverse event compared to TURP (26% vs. 42%) at three months following treatment. Among sexually active men the rate of anejaculation was lower in those treated with Aquablation compared to TURP (10% vs. 36%, respectively). There were no procedure-related adverse events after six months [492]. Maintenance of antegrade ejaculation was slightly lower in WATER II 81% compared to 90% in the smaller prostates of WATER I [501].

In patients with a prostate volume between 80-150 mL, bleeding related events were observed in fourteen patients (13.9%) of which eight (7.9%) occurred prior to discharge and six (5.9%) occurred within one month of discharge. Blood transfusions were required in eight (7.9%) patients, return to the theatre for fulguration in three (3.0%) patients, and both transfusion and fulguration in two patients (2.0%) [497]. In WATER II there was a 2% incontinence rate at twelve months, and ten patients did require a transfusion post-operatively while five required take-back fulgurations [498].

In a SR of seven patient groups involving 446 patients treated by aquablation, although there was a significant haemoglobin drop (2.06 g/dL), it did not translate into increased transfusion rates. Aquablation achieves overall lower rates of adverse events. In the first three months of the WATER RCT Clavien Dindo 2-5 events occurred in 19% for aquablation and 29% for TURP (NS). Between three and twelve months they occurred in 5.3% and 10.7% respectively and there was no statistically significant difference again between the one- and two-year follow-up [502].

Practical considerations: During mid-term follow-up, aquablation provides non-inferior functional outcomes compared to TURP in patients with LUTS and a prostate volume between 30-80 mL. Longer term follow-up is necessary to assess the clinical value of aquablation.

* Aquablation remains under investigation
5.3.4.2 Prostatic artery embolisation

**Mechanism of action:** Prostatic artery embolisation (PAE) can be performed as a day procedure under local anaesthesia with access through the femoral or radial arteries. Digital subtraction angiography displays arterial anatomy, and the appropriate prostatic arterial supply is selectively embolised to effect stasis in treated prostatic vessels. Different techniques have been used for PAE. Atherosclerosis, excessive tortuosity of the arterial supply and the presence of adverse collaterals are anatomical obstacles for the technical approach. Cone beam computed tomography and contrast enhanced MR angiography can help identify prostatic arteries and prevent off-target embolisation particularly in patients with challenging anatomical configurations [503, 504].

**Efficacy:** Superior efficacy of PAE compared with a sham procedure was found in a six-month randomised, single-blind, sham-controlled trial in 80 patients with severe LUTS, refractory to medical treatment. The decrease in IPSS was significant at six months, 5.03 +/- 8.13 in the sham group and 17.1 +/- 7.25 in the PAE group [505].

In two earlier RCTs conducted for direct comparison of PAE with TURP [506, 507], both studies observed significant treatment outcomes for both procedures as compared to baseline values, but TURP was superior when considering urodynamic parameters such as \( Q_{\text{max}} \) and PVR. Improvement of LUTS as determined by IPSS and QoL was slightly more pronounced after TURP, and reduction of prostate volume was significantly more efficient after TURP than PAE.

An RCT comparing PAE with TURP in 99 patients showed a mean reduction in IPSS from baseline to twelve weeks of ~9.23 points after PAE and ~10.77 points after TURP. At twelve weeks, PAE was less effective than TURP regarding improvements in \( Q_{\text{max}} \) (5.19 mL/s vs. 15.34 mL/s), PVR (~86.36 mL vs. ~199.98 mL), prostate volume (~12.17 mL vs. ~30.27 mL), and significant de-obstructive effectiveness according to pressure flow studies (56% vs. 93% shift towards less obstructive category) [503]. An RCT of 60 patients randomised into three equal arms of M-TURP, B-TURP, and PAE followed up at six months concluded that improvement in IPSS score, and \( Q_{\text{max}} \), but not in PVR were statistically significantly better for M-TURP and B-TURP vs. PAE [508]. A two-year follow up of this RCT showed no significant difference in IPSS improvement (9.21 points for PAE and 12.09 points for TURP) but TURP was superior for flow rate, prostate volume and PVR improvement. Twenty one percent of patients who initially had PAE underwent TURP within two years. There were less complications for PAE [509].

A SR and meta-analysis including the three above mentioned RCTs and two non-RCTs comparative studies (n = 708 patients), showed that TURP achieved a significantly higher mean post-operative difference for IPSS and IPSS-QoL, 3.80 and 0.73 points, respectively compared to PAE [510]. All of the functional outcomes assessed were superior after TURP: 3.62 mL/s for \( Q_{\text{max}} \) 11.51 mL for prostate volume, 11.86 mL for PVR, and 1.02 ng/mL for PSA [510]. A meta-analysis of four RCTs concluded that TURP is associated with significantly higher improvements in \( Q_{\text{max}} \) [511]. The mean differences in IPSS, QoL score and PVR were not significantly different between TURP and PAE [511].

A recent SR and Meta-analysis including six studies with 598 patients showed that TURP resulted in significantly greater improvement in \( Q_{\text{max}} \), prostate volume, and PSA compared to PAE [511]. However, there was no significant difference between PAE and TURP in IPSS improvement, IPSS QoL, IIEF and PVR. PAE was associated with significantly fewer adverse events (39.0% vs. 77.7%) and shorter hospitalisation times (mean difference = -1.94 days), but longer procedural times (mean difference = 51.43 min) [511].

Another SR and meta-analysis of ten RCTs (one vs. sham, five vs. TURP and four exploring variations in PAE technique) confirmed that PAE is non-inferior to TURP in improving patient reported outcome measures (PROMs), though TURP is superior to PAE for most objective outcomes [512].

In a single centre retrospective analysis of 75 PAE patients over a three-year period, PAE was shown to be a safe, effective, and durable treatment option for non-index patients with urinary retention (87% catheter free) or gross haematuria (resolved 87.5%) [513].

**Tolerability and safety:** In a SR of comparative studies PAE resulted in significantly more adverse events than TURP/OP (41.6% vs. 30.4%). The frequency of AUR after the procedures was significantly higher in the PAE group (9.4% vs. 2.0%) [514].

Another RCT however, reported significantly fewer adverse events occurred after PAE than after TURP (36 vs. 70 events). For secondary outcomes, PAE showed favourable results in terms of blood loss [503]. A RCT of 60 patients randomised into three equal arms of M-TURP, B-TURP, and PAE followed up at six months concluded that operative time was significantly longer for PAE (89 min for PAE vs. 59 min and 68 min for M-TURP and B-TURP) [508]. Catheter was removed on the third and fifth day in the TURP and PAE arms, respectively. No significant haemoglobin drop was detected (no need for blood transfusions) among arms. One patient developed TUR syndrome in the M-TURP arm; two patients from the PAE group developed AUR after catheter removal and four patients from the PAE group developed postembolisation syndrome [508].
A subsequent SR and meta-analysis of four studies (506 patients) comparing PAE and TURP found no significant difference in the post-operative complication rate between TURP and PAE [515]. A SR of 708 patients reported fewer side effects than established surgical procedures [510]. A meta-analysis of four RCTs concluded that PAE was associated with significantly shorter hospitalisation time, longer procedural time, fewer total side effects but similar rates of severe side effects [511]. The mean differences in IIEF-5 score were not significantly different between TURP and PAE [511]. Another meta-analysis of two RCTs detected no difference in retrograde ejaculation rates [398]. Post-operative erectile function measured by IIEF-5 was in favour of PAE with mean difference in change of 2.56 points. In another updated meta-analysis PAE was associated with lower sexual dysfunction than TURP (OR 0.24) [516].

Concerns still exist about non-target embolisation, reported in earlier studies [517]; however, more recent studies report less incidents [510, 518].

A SR of 22 studies reporting radiation exposure during PAE, with a twenty-fold range of exposures, estimated that the median risk for a 66-year-old patient of a cancer related death was 0.117%, equivalent to a reduced life expectancy of 5.4 days. Radiation exposure therefore should be part of the counselling for patients considered for PAE. These data suggest there is potential for significant radiation reduction in some centres using appropriate protocols [519].

For secondary outcomes, procedural time was shorter for TURP, but in PAE patients, bladder catheter indwelling time, and duration of hospital stay were significantly shorter [462].

Practical considerations: A multidisciplinary team approach of urologists and radiologists is mandatory and patient selection should be done by urologists and interventional radiologists. The investigation of patients with LUTS to indicate suitability for invasive techniques should be performed by urologists only. This technically demanding procedure should only be done by an interventional radiologist with specific mentored training and expertise in PAE [520]. There are data suggesting that larger prostates have a higher chance of a superior outcome with PAE in post hoc analysis of RCTs, but larger trials are required to clarify the most suitable patients for PAE [497, 521].

Further data with medium- and long-term follow-up are still required and comparison with other minimally invasive techniques would be valuable. However, current evidence of safety and efficacy of PAE appears adequate to support the use of this procedure for men with moderate-to-severe LUTS provided proper arrangements for consent and audit are in place; therefore, a recommendation has been given, but PAE remains under investigation.

5.3.4.3 Alternative ablative techniques under investigation

5.3.4.3.1 Convective water vapour energy (WAVE) ablation: The Rezum system

**Mechanism of action:** The Rezum system uses radiofrequency power to create thermal energy in the form of water vapour, which in turn deposits the stored thermal energy when the steam phase shifts to the liquid phase upon cell contact. The steam disperses through the tissue interstices and releases stored thermal energy onto prostatic tissue effecting cell necrosis. The procedure can be performed in an office-based setting. Usually, one to three injections are needed for each lateral lobe and one to two injections may be delivered into the median lobe.

**Efficacy:** In a multicentre RCT, 197 men were enrolled and randomised in a 2:1 ratio to treatment with water vapour energy ablation or sham treatment [522]. At three months relief of symptoms, measured by a change in
IPSS and $Q_{\text{max}}$ were significantly improved and maintained compared to the sham arm, although only the active treatment arm was followed up to twelve months. No relevant impact was observed on PVR. Quality of life outcome was significantly improved with a meaningful treatment response of 52% at twelve months. Further validated objective outcome measures such as BPH impact index (BPHII), Overactive Bladder Questionnaire Short Form for OAB bother, and impact on QoL and ICS Male Item Short Form Survey for male incontinence demonstrated improvement of symptoms at three months follow-up with sustained efficacy throughout the study period of twelve months. The reported two-year results in the Rezum cohort arm of the same study and the recently reported four-year results confirmed durability of the positive clinical outcome after convective water vapour energy ablation [523, 524]. Surgical retreatment rate was 4.4% over four years [524]. A Cochrane review found no studies comparing convective radiofrequency water vapour thermal therapy to any other active treatment form, such as TURP [525].

**Tolerability and safety:** Safety profile was favorable with adverse events documented to be mild-to-moderate and resolving rapidly. Preservation of erectile and ejaculatory function after convective water vapour thermal therapy was demonstrated utilizing validated outcome instruments such as IIEF and Male Sexual Health Questionnaire-Ejaculation Disorder Questionnaire [522].

**Practical considerations:** There are two SRs of the Rezum cohort studies. One concludes that Rezum provides improvement in BPH symptoms that exceeds established minimally clinically important difference thresholds, preserves sexual function, and is associated with low surgical retreatment rates over four years. Therefore, suggesting that it may be a valuable addition to the urological armamentarium to treat LUTS in men with BPH [526]. The other, a Cochrane review reported that the certainty of evidence ranged from moderate to very low, with study limitations and imprecision being the most common reasons for down-grading of the evidence [525]. Randomised controlled trials against a reference technique are needed to confirm the first promising clinical results and to evaluate mid- and long-term efficacy and safety of water vapour energy treatment.

### 5.3.5 Non-ablative techniques

#### 5.3.5.1 Prostatic urethral lift

**Mechanism of action:** The prostatic urethral lift (PUL) represents a novel minimally invasive approach under local or general anaesthesia. Encroaching lateral lobes are compressed by small permanent suture-based implants delivered under cystoscopic guidance (Urolift®) resulting in an opening of the prostatic urethra leaving a continuous anterior channel through the prostatic fossa extending from the bladder neck to the verumontanum.

**Efficacy:** In general, PUL achieves a significant improvement in IPSS (-39% to -52%), $Q_{\text{max}}$ (+32% to +59%) and QoL (-48% to -53%) [527-532]. Prostatic urethral lift was initially evaluated vs. sham in a multicentre study with one [529] three [533] and five [534] years follow-up of the treated cohort. The primary endpoint was met at three months with a 50% reduction in IPSS. In addition, $Q_{\text{max}}$ increased significantly from 8.1 to 12.4 mL/s compared to baseline at three months and this result was confirmed at twelve months. The difference in clinical response for $Q_{\text{max}}$ between both groups was of statistical significance. A relevant benefit with regard to PVR was not demonstrated compared to baseline or sham. At three years, average improvements from baseline were significant for total IPSS, QoL, $Q_{\text{max}}$ and individual IPSS symptoms. There was no, de novo, sustained ejaculatory or erectile dysfunction events and all sexual function assessments showed average stability or improvement after PUL. Improvements in IPSS, QoL, BPHII, and $Q_{\text{max}}$ were durable throughout the five years with improvement rates of 36%, 50%, 52%, and 44%, respectively. The re-treatment rate was 13.6% over five years. Adverse events were mild to moderate and transient. Sexual function was stable over five years with no, de novo, sustained erectile or ejaculatory dysfunction.

Another RCT of 80 patients was conducted in three European countries, comparing PUL to TURP. At twelve months, IPSS improvement was -11.4 for PUL and -15.4 for TURP. There was no retrograde ejaculation among PUL patients with 40% in the TURP patients. Surgical recovery was measured using a validated instrument and confirmed that recovery from PUL is more rapid and more extensive in the first three to six months [535]. However, TURP resulted in much greater improvements in $Q_{\text{max}}$ after twelve months compared to PUL. At 24 months, significant improvements in IPSS, IPSS QoL, BPHII, and $Q_{\text{max}}$ were observed in both arms. Change in IPSS and $Q_{\text{max}}$ in the TURP arm were superior to the PUL arm [536]. Improvements in QoL and BPHII score were not statistically different between the study arms. Prostatic urethral lift resulted in superior quality of recovery and ejaculatory function preservation. Ejaculatory function and bother scores did not change significantly in either treatment arm.

In a meta-analysis of retrospective and prospective trials, pooled estimates showed an overall improvement following PUL, including IPSS, $Q_{\text{max}}$, and QoL [532]. Sexual function was preserved with a small improvement estimated at twelve months.
A retrospective observational study of 1,413 consecutive patients from North America and Australia split patients into those still voiding (Group A) and those in retention (Group B). The results from Group A were comparable to the results from the clinical trials and of the 165 patients in Group B, 69% were catheter free after five days, 83% after one month and 89% by study end [537].

A Cochrane review of the sham RCT and the RCT against TURP concluded that PUL appears less effective than TURP in improving urological symptoms in both the short- and long term, while QoL outcomes may be similar. The effect on erectile function appears similar but ejaculatory function may be better with PUL [538].

A SR of surgical re-interventions of eleven studies (2,016 patients), among which TURP/laser (51.0%), repeat PUL (32.7%) and device explant (19.6%) were most common, revealed an annual rate of surgical re-intervention of 6.0% per year (95% CI: 3.0-8.9) [539].

**Tolerability and safety:** The most common complications reported post-operatively included haematuria (16-63%), dysuria (25-58%), pelvic pain (5-17.9%), urgency (7.1-10%), transient incontinence (3.6-16%), and UTI (2.9-11%) [529, 532-534]. Most symptoms were mild-to-moderate in severity and resolved within two to four weeks after the procedure.

Prostatic urethral lift seems to have no significant impact on sexual function. Evaluation of sexual function as measured by IIEF-5, Male Sexual Health Questionnaire-Ejaculatory Dysfunction, and Male Sexual Health Questionnaire-Bother in patients undergoing PUL showed that erectile and ejaculatory function were preserved [527-531]. A SR and meta-analysis found that sexual function remained stable or improved slightly during the 24-month follow-up period [512].

**Practical considerations:** There are only limited data on treating patients with an obstructed/protruding middle lobe [540]. It appears that they can be effectively treated with a variation in the standard technique, but further data are needed [540]. The effectiveness in large prostate glands has not been shown yet. Long-term studies are needed to evaluate the duration of the effect in comparison to other techniques.

**Recommendation**

Offer Prostatic urethral lift (Urolift®) to men with LUTS interested in preserving ejaculatory function, with prostates < 70 mL and no middle lobe. **Strong**

5.3.5.2 Intra-prostatic injections

**Mechanism of action:** Various substances have been injected directly into the prostate in order to improve LUTS, these include Botulinum toxin-A (BoNT-A), fexapotide triflutate (NX-1207) and PRX302. The primary mechanism of action of BoNT-A is through the inhibition of neurotransmitter release from cholinergic neurons [541]. The detailed mechanisms of action for the injectables NX-1207 and PRX302 are not completely understood, but experimental data suggests apoptosis-induced atrophy of the prostate with both drugs [541].

**Efficacy:** Results from clinical trials have shown only modest clinical benefits, that do not seem to be superior to placebo, for BoNT-A [542, 543]. A SR and meta-analysis showed no differences in efficacy compared with placebo and concluded that there is no evidence of clinical benefit in medical practice [544]. The positive results from Phase II-studies have not been confirmed in Phase III-trials for PRX302 [545, 546]. NX-1207 was evaluated in two multicentre placebo controlled double-blind randomised parallel group trials including a total of 995 patients with a mean follow-up of 3.6 years, IPSS change from baseline was significantly higher and AUR rate was significantly reduced in the treatment arm. The authors concluded that NX-1207 is an effective transrectal injectable for long-term treatment for LUTS and that treated patients have reduced need for further intervention [547].

**Safety:** Studies including safety assessments have reported only a few mild and self-limiting adverse events for all injectable drugs [541]. A SR and meta-analysis showed low incident rates of procedure-related adverse
events [544]. Two multicentre placebo controlled double-blind randomised parallel group trials with long-term follow-up evaluating NX-1207 detected no significant safety differences between the study arms [547].

**Practical considerations:** Although experimental evidence for compounds such as PRX302 were promising for their transition to clinical use positive results from Phase II-studies have not been confirmed in Phase III-trials. Nevertheless, an RCT evaluating transperineal intraprostatic BoNT-A injection vs. TURP concluded that IPSS significantly decreased in all patients, with a non-significant difference between the arms and that the BoNT-A injection significantly maintained erectile function compared to TURP at twelve months [548]. More high-quality evidence against reference techniques is needed.

### 5.3.5.3 Non-ablative techniques under investigation

#### (i) iTIND

**Mechanism of action:** The iTIND is a device designed to remodel the bladder neck and the prostatic urethra and is composed of three elongated struts and an anchoring leaflet, all made of nitinol. Under direct visualisation the iTIND is deployed inside the prostate in expanded configuration. The intended mode of action is to compress obstructive tissue by the expanded device, thereby exerting radial force leading to ischaemic necrosis in defined areas of interest. The iTIND is left in position for five days. The resulting incisions may be similar to a Turner Warwick incision. In an outpatient setting the device is removed by standard urethroscopy.

**Efficacy:** A single-arm, prospective study of 32 patients with a follow-up of three years was conducted to evaluate feasibility and safety of the procedure [549]. The change from baseline in IPSS, QoL score and Q\text{max} was significant at every follow-up time point [550].

In a prospective multicentre study, 81 patients were enrolled and treated with a second generation iTIND device. Mean Q\text{max} at one month increased from 7.3 to 11.2 (5.7) ml/s and was 14.7 ml/s at twelve months. The IPSS decreased from 22.5 to 11.7 after one month and to 8.8 at twelve months. In parallel, the mean IPSS QoL score drop reached 1.6 by the end of the study. During the twelve-month period, two patients required medical therapy, two patients required TURP, and ten patients were lost to follow-up [551].

In a multicenter RCT, 175 men were randomised 2:1 between iTIND and sham procedures. Patients were assessed at baseline, 45 days, three, and twelve months postoperatively. Unblinding occurred at three months. A total of 78.6% of patients in the iTIND arm showed a reduction of ≥ 3 points in IPSS, vs. 60% of patients in the control arm at three months. At twelve months, compared to baseline, the iTIND group reported a mean 9.25 decrease in IPSS, a 3.52mL/s increase in peak urinary flow rate and a 1.9-point reduction in QoL. There was a comparable loss of follow-up from baseline groups to three months of 29% of patients in the iTIND arm, and 30% of patients in the sham arm [552].

**Tolerability and safety:** The device have been reported as well tolerated by all patients. Four early complications (12.5%) were recorded, including one case of urinary retention (3.1%), one case of transient incontinence due to device displacement (3.1%), and two cases of infection (6.2%). No further complications were recorded during the 36-month follow-up period.

Using the second-generation device none of the 61 sexually active patients who completed the twelve-month follow-up period reported sexual or ejaculatory dysfunction compared to baseline[551].

In the RCT against sham study adverse events were typically mild and transient, most were Clavien-Dindo grade 1 or 2 with 38.1% in the iTIND arm and 17.5% in the control arm. No new ejaculatory or erectile dysfunction occurred [552].

**Practical considerations:** Randomised controlled trials comparing iTIND to a reference technique are ongoing.
5.4 Patient selection

The choice of treatment depends on the assessed findings of patient evaluation, ability of the treatment to change the findings, treatment preferences of the individual patient, and the expectations to be met in terms of speed of onset, efficacy, side effects, QoL, and disease progression.

Behavioural modifications, with or without medical treatments, are usually the first choice of therapy. Figure 3 provides a flow chart illustrating treatment choice according to evidence-based medicine and patient profiles. Surgical treatment is usually required when patients have experienced recurrent or refractory urinary retention, overflow incontinence, recurrent UTIs, bladder stones or diverticula, treatment-resistant macroscopic haematuria due to BPH/BPE, or dilatation of the upper urinary tract due to BPO, with or without renal insufficiency (absolute operation indications, need for surgery).

Additionally, surgery is usually needed when patients have not obtained adequate relief from LUTS or PVR using conservative or medical treatments (relative operation indications). The choice of surgical technique depends on prostate size, comorbidities of the patient, ability to have anaesthesia, patients’ preferences, willingness to accept surgery-associated specific side-effects, availability of the surgical armamentarium, and experience of the surgeon with these surgical techniques. An algorithm for surgical approaches according to evidence-based medicine and the patient’s profile is provided in Figure 4.
Figure 3: Treatment algorithm of male LUTS using medical and/or conservative treatment options. Treatment decisions depend on results assessed during initial evaluation. Note that patients’ preferences may result in different treatment decisions.

HoLEP = holmium laser enucleation; PU = prostatic urethral; TUIP = transurethral incision of the prostate; TURP = transurethral resection of the prostate.

5.5 Management of Nocturia in men with lower urinary tract symptoms

The following section reports a SR of therapy for the management of nocturia in men with LUTS. It also emphasises the need to consider the wide range of possible causes of nocturia [553].

Nocturia has been defined as the complaint of waking at night to void [6]. The ICS Standardisation Steering Committee has introduced the concept of main sleep period, defined as “the period from the time of
falling asleep to the time of intending to rise for the next “day” [554].

Nocturia reflects the relationship between the amount of urine produced while asleep, and the ability of the bladder to store the urine received. Nocturia can occur as part of lower urinary tract dysfunction (LUTD), such as OAB and chronic pelvic pain syndrome. Nocturia can also occur in association with other forms of LUTD, such as BOO, but here it is debated whether the link is one of causation or simply the co-existence of two common conditions. Crucially, nocturia may have behavioural, sleep disturbance (primary or secondary) or systemic causes unrelated to LUTD (Table 2). Differing causes often co-exist and each has to be considered in all cases. Only where LUTD is contributory should nocturia be termed a LUTS.

### Table 2: Categories of nocturia

<table>
<thead>
<tr>

<td>“Bladder awareness” due to primary sleep disturbance</td>
</tr>
<tr>
<td><strong>LUTD</strong></td>
<td></td>
<td>Impaired storage function and increased filling sensation</td>
</tr>
</tbody>
</table>

5.5.1 **Diagnostic assessment**

Evaluation is outlined in Figure 5:

1. Evaluate for LUTD according to the relevant guidelines. The severity and bother of individual LUTS should be identified with a symptom score, supplemented by directed questioning if needed. A validated bladder diary is mandatory.
2. Review whether behavioural factors affecting fluid balance and sleep are contributing.
3. Review of medical history and medications, including directed evaluation for key conditions, such as renal failure, diabetes mellitus, cardiac failure, and obstructive sleep apnoea. If systemic factors or sleep disorders are potentially important, consider involving appropriate medical expertise (see Figure 6). This is appropriate where a known condition is sub optimally managed, or symptoms and signs suggest an undiagnosed condition.

5.5.2 **Medical conditions and sleep disorders Shared Care Pathway**

Causative categories for nocturia comprise [555]:

1. bladder storage problems;
2. 24-hour polyuria (> 40 mL/kg urine output over a 24-hour period);
3. nocturnal polyuria (NP; defined as excessive production of urine during the individual’s main sleep period, i.e. nocturnal output exceeding 20% of 24-hour urine output in the young, or 33% of urine output in people > 65 [6]);
4. sleep disorders;
5. mixed aetiology.

Potentially relevant systemic conditions are those which impair physiological fluid balance, including influences on the levels of free water, salt, other solutes, and plasma oncotic pressure; endocrine regulation e.g., by antidiuretic hormone; natriuretic peptides; cardiovascular and autonomic control; renal function; neurological regulation, e.g., circadian regulation of the pineal gland, and renal innervation. As nocturia is commonly referred to the specialty without full insight into cause, the urologist must review the likely mechanisms underlying a presentation with nocturia and instigate review by relevant specialties accordingly. Thus, the managing urologist needs to evaluate nocturia patients in a context where additional medical expertise is available (Table 3). They should not proceed along any LUTD management pathway unless a causative link with LUTD is justifiably suspected, and systemic or sleep abnormalities have been considered.

In patients with non-bothersome nocturia, the medical evaluation (history and physical examination) should consider the possibility of early stages of systemic disease, and whether there is possibility of earlier diagnosis or therapy adjustment.

Some important potentially treatable non-urological causes of nocturia include obstructive sleep apnoea, congestive cardiac failure, poorly controlled diabetes mellitus and medications (e.g., diuretics, or lithium).
Figure 5. Evaluation of Nocturia in non-neurogenic Male LUTS.

Assessment must establish whether the patient has polyuria, LUTS, a sleep disorder or a combination. Therapy may be driven by the bother it causes, but non-bothersome nocturia may warrant assessment with a frequency volume chart (indicated by the dotted line) depending on history and clinical examination since potential presence of a serious underlying medical condition must be considered.

FVC = frequency volume chart; DRE = digital rectal examination; NP = nocturnal polyuria; MoA = mechanism of action; PVR = post-void residual; PSA = prostate-specific antigen; US = ultrasound.
Table 3: Shared care pathway for nocturia, highlighting the need to manage potentially complex patients using relevant expertise for the causative factors.

5.5.3 Treatment for Nocturia
5.5.3.1 Antidiuretic therapy

The antidiuretic hormone arginine vasopressin (AVP) plays a key role in body water homeostasis and control of urine production by binding to V2 receptors in the renal collecting ducts. Arginine vasopressin increases water re-absorption and urinary osmolality, so decreasing water excretion and total urine volume. Arginine vasopressin also has V1 receptor mediated vasoconstrictive/hypertensive effects and a very short serum half-life, which makes the hormone unsuitable for treating nocturia/nocturnal polyuria.

Desmopressin is a synthetic analogue of AVP with high V2 receptor affinity and no relevant V1 receptor affinity. It has been investigated for treating nocturia [556], with specific doses, titrated dosing, differing formulations, and options for route of administration. Most studies have short follow-up. Global interpretation of existing studies is difficult due to the limitations, imprecision, heterogeneity and inconsistencies of the studies.

A SR of randomised or quasi-randomised trials in men with nocturia found that desmopressin may decrease the number of nocturnal voids by -0.46 compared to placebo over short-term follow-up (up to three months); over intermediate-term follow-up (three to twelve months) there was a change of -0.85 in nocturnal voids in a substantial number of participants without increase in major adverse events [557].

Another SR of comparative trials of men with nocturia as the primary presentation and LUTS including nocturia or nocturnal polyuria found that antidiuretic therapy using dose titration was more effective than placebo in relation to nocturnal voiding frequency and duration of undisturbed sleep [553]. Adverse events include headache, hyponatremia, insomnia, dry mouth, hypertension, abdominal pain, peripheral edema, and nausea. Three studies evaluating titrated-dose desmopressin in which men were included, reported seven serious adverse events in 530 patients (1.3%), with one death. There were seventeen cases of hyponatraemia (3.2%) and seven of hypertension (1.3%). Headache was reported in 53 (10%) and nausea in fifteen (2.8%) [553]. Hyponatremia is the most important concern, especially in patients > 65 years of age, with potential life-threatening consequences. Baseline values of sodium over 130 mmol/L have been used as inclusion criteria in some research protocols. Assessment of sodium levels must be undertaken at baseline, after initiation of treatment or dose titration and during treatment. Desmopressin is not recommended in high-risk groups [553].
Desmopressin oral disintegrating tablets (ODT) have been studied separately in the sex-specific pivotal trials CS41 and CS40 in patients with nocturia [558, 559]. Almost 87% of included patients had nocturnal polyuria and approximately 48% of the patients were > 65 years. The co-primary endpoints in both trials were change in number of nocturia episodes per night from baseline and at least a 33% decrease in the mean number of nocturnal voids from baseline during three months of treatment. The mean change in nocturia episodes from baseline was greater with desmopressin ODT compared to placebo (difference: women = -0.3 [95% CI: -0.5 to -0.1]; men = -0.4 [95% CI: -0.6 to -0.2]). The 33% responder rate was also greater with desmopressin ODT compared to placebo (women: 78% vs. 62%; men: 67% vs. 50%).

Analysis of three published placebo-controlled trials of desmopressin ODT for nocturia showed that clinically significant hyponatraemia was more frequent in patients aged ≥ 65 years than in those aged < 65 years in all dosage groups, including those receiving the minimum effective dose for desmopressin (11% of men aged ≥ 65 years vs. 0% of men aged < 65 years receiving 50 mcg; 4% of women ≥ 65 aged years vs. 2% of women aged < 65 years receiving 25 mcg). Severe hyponatraemia, defined as ≤ 125 mmol/L serum sodium, was rare, affecting 22/1,431 (2%) patients overall [560].

Low dose desmopressin ODT has been approved in Europe, Canada and Australia for the treatment of nocturia with ≥ 2 episodes in gender-specific low doses 50 mcg for men and 25 mcg for women; however, it initially failed to receive FDA approval, with the FDA citing uncertain benefit relative to risks as the reason. Following resubmission to the FDA in June 2018 desmopressin acetate sublingual tablet, 50 mcg for men and 25 mcg for women, was approved for the treatment of nocturia due to nocturnal polyuria in adults who awaken at least two times per night to void with a boxed warning for hyponatremia.

Desmopressin acetate nasal spray is a new low-dose formulation of desmopressin and differs from other types of desmopressin formulation due to its bioavailability and route of administration. Desmopressin acetate nasal spray has been investigated in two RCTs including men and women with nocturia (over two episodes per night) and a mean age of 66 years. The average benefit of treatment relative to placebo was statistically significant but low, -0.3 and -0.2 for the 1.5 mcg and 0.75 mcg doses of desmopressin acetate, respectively. The number of patients with a reduction of more than 50% of nocturia episodes was 48.5% and 37.9%, respectively compared with 30% in the placebo group [561]. The reported adverse event rate of the studies was rather low, and the risk of hyponatraemia was 1.2% and 0.9% for desmopressin acetate 1.5 mcg and 0.75 mcg, respectively. Desmopressin acetate nasal spray was approved by the FDA in 2017 for the treatment of nocturia due to nocturnal polyuria, but it is not available in Europe.

**Practical considerations:** A complete medical assessment should be made, to exclude potentially non-urological underlying causes, e.g., sleep apnoea, before prescribing desmopressin in men with nocturia due to nocturnal polyuria. The optimal dose differs between patients, in men < 65 years desmopressin treatment should be initiated at a low dose (0.1 mg/day) and may be gradually increased up to a dosage of 0.4 mg/day every week until maximum efficacy is reached. Desmopressin is taken once daily before sleeping. Patients should avoid drinking fluids at least one hour before and for eight hours after dosing. Low dose desmopressin may be prescribed in patients > 65 years. In men ≥ 65 years or older, low dose desmopressin should not be used if the serum sodium concentration is below normal: all patients should be monitored for hyponatremia. Urologists should be cautious when prescribing low-dose desmopressin in patients under-represented in trials (e.g., patients > 75 years) who may have an increased risk of hyponatremia.

5.5.3.2 **Medications to treat LUTD**

Where LUTD is diagnosed and considered causative of nocturia, relevant medications for storage (and voiding) LUTS may be considered. Applicable medications include: selective α1-adrenergic antagonists [562], antimuscarinics [563-565], 5-ARIs [566] and PDE5Is [567]. However, effect size of these medications is generally small, or not significantly different from placebo when used to treat nocturia [553]. Data on OAB medications (antimuscarinics, beta-3 agonist) generally had a female-predominant population. No studies specifically addressing the impact of OAB medications on nocturia in men were identified [553]. Benefits with combination therapies were not consistently observed.

5.5.3.3 **Other medications**

Agents to promote sleep [568], diuretics [569], non-steroidal anti-inflammatory agents (NSAIDs) [570] and phytotherapy [571] were reported as being associated with response or QoL improvement [553]. Effect size of these medications in nocturia is generally small, or not significantly different from placebo. Larger responses have been reported for some medications, but larger scale confirmatory RCTs are lacking. Agents to promote sleep do not appear to reduce nocturnal voiding frequency but may help patients return to sleep.

5.6 Management of male urinary incontinence

The aim of the following section is to provide evidence-based recommendations for the management of male urinary incontinence.

5.6.1 Epidemiology and Pathophysiology

Urinary incontinence is defined as an unintentional loss of urine and is reported to have a prevalence of 11% in men aged 60 to 64 years old to 31% in men ≥ 85 years and to affect up to 32% of men with LUTS [572-574]. Urinary incontinence can be further classified into three types: stress urinary incontinence (SUI); urgency urinary incontinence (UUI); and mixed urinary incontinence (MUI). Overflow urinary incontinence, post-micturition dribble, nocturnal enuresis, and total incontinence are specific forms of UI that are outside the current scope of this guideline. An overview of the epidemiology and pathophysiology of male UI is given in Table 4.
Table 4: Epidemiology and pathophysiology overview of male UI [574-578].

</table>
| Stress UI:            | Urine loss during movement or efforts or in general during increased abdominal pressure. | • Benign Prostatic Obstruction surgery  
• Neurogenic condition  
• Pelvic surgery  
• Radical prostatectomy  
• Urethral surgery | Sphincter deficiency | Symptoms: UI during physical activity, exercises, e.g. during coughing, sneezing, no leakage during sleep, no nocturnal enuresis  
Voiding diary/Pad test: with activity  
Cough stress test: leakage can coincide with coughing |
| Stress UI: prevalence < 10% |                                                                            |                                                                                                 |                          |                                                                                        |
| Urgency UI:           | Urine loss concomitant or immediately following an urgency episode.         | • Ageing process  
• Anorectal dysfunction/GI disorders  
• Behavioural factors (fluid intake and caffeine consumption)  
• Chronic BPO  
• Idiopathic  
• Intrinsic bladder diseases (cystitis, fibrosis, interstitial cystitis)  
• Metabolic syndrome  
• Neurogenic conditions  
• UTIs | Detrusor overactivity (neurogenic or not)  
• Urothelial stimulation  
• Increased afferent signalling  
• Others (pelvic organ cross talk, bladder wall ischemia etc.) | Symptoms: urgency, usually associated with, increased frequency and nocturia  
Voiding diary: urgency, frequency and nocturia |
| Urgency UI: prevalence 40-80% |                                                                            |                                                                                                 |                          |                                                                                        |
| Mixed UI:             | Any combination of SUI and UUI.                                            | Causes of both SUI and UUI                                                                      | Combination of SUI and UUI | Symptoms: UI equally as often with physical activity as with a sense of urgency  
Voiding diary: varies  
Cough stress test: may show leakage with coughing |
| Mixed UI: prevalence 10-30% |                                                                            |                                                                                                 |                          |                                                                                        |

BPO = benign prostatic obstruction; GI = gastrointestinal; SUI = stress urinary incontinence; UI = urinary incontinence; UTI = urinary tract infection; UUI = urgency urinary incontinence

5.6.2 Diagnostic Evaluation

Medical history and physical examination of males with UI is the same as for male LUTS and should allow UI to be categorised into SUI, UUI or MUI and to identify other types of UI (overflow UI, nocturnal enuresis), or those who need rapid referral to an appropriate specialist (e.g., pelvic diseases, neurological conditions).

Specific validated questionnaires can help to quantify UI severity; however, a detailed description of the different urinary symptoms questionnaires and PROMs is beyond the scope of this guideline. For more information on available questionnaires see the 6th ICI review on patient reported outcomes assessment [579].
Voiding diaries are a standardised method of measuring symptom severity, including frequency and extent of UI episodes, voided volume and 24-hour or nocturnal total urine volume [43].

Pad tests can be used to quantify severity of UI and to monitor patient’s response to treatment although the usefulness of these tests in predicting outcome of treatment is uncertain. Despite this, early post-operative testing with pad tests may predict future continence in men after prostatectomy [580, 581].

Urodynamic testing (multichannel cystometry, video-urodynamics) and specific tests of urethral function (urethral pressure profilometry, Valsalva leak point pressure, retrograde urethral resistance) should be considered on an individual basis, such as in cases when invasive treatment is considered. A Cochrane review showed that use of urodynamic tests increased the likelihood of prescribing drugs or avoiding surgery, while there is limited evidence that it should be used for the assessment of post prostatectomy UI [579].

Post-void residual volume measurement can be applied with caution to men with non-neurogenic UI, as the prevalence, severity, and clinical application of PVR in men with UI is uncertain.

Imaging (US, MRI, CT scan) can improve the understanding of the anatomical and functional abnormalities that may cause UI and thus help its management [582].

Urinalysis: Reagent strip (‘dipstick’) urinalysis may indicate UTI, proteinuria, haematuria, or glycosuria, requiring further tests as recommended according to other EAU Guidelines, e.g., Guidelines on urinary tract cancers and urological infections [48-51].

**5.6.3 Conservative treatment**

**5.6.3.1 Simple clinical interventions**

**5.6.3.1.1 Lifestyle interventions**

Examples of lifestyle factors that may be associated with UI include obesity, smoking, level of physical activity and diet. Modification of these factors may improve UI, but most of the evidence for these interventions come from studies with predominately female study populations. However, as many of these interventions are now generalised public health measures their recommendation is in line with general medical practice [583-585].

Modification of fluid intake, particularly restriction, is a strategy commonly used by people with UI to relieve symptoms. Advice on fluid intake given by healthcare professionals should be based on 24-hour fluid intake and urine output measurements. From a general health point of view, it should be advised that fluid intake should be sufficient to avoid thirst and that low or high 24-hour urine output should be investigated [583, 586]. A cross-sectional population survey found no statistical association between caffeine intake and UI [587]. Conversely, an RCT showed that reduction of caffeine intake, associated with behavioural therapy, resulted in reduced urgency but not UI compared to behavioural therapy alone [588].

**5.6.3.1.2 Treatment of comorbidities**

Urinary incontinence, especially in the elderly, has been associated with multiple comorbid conditions [589]. It is possible that improvement of associated disease may reduce the severity of urinary symptoms. However, this is often difficult to assess as patients frequently suffer from more than one condition. Interventions may be combined and individualised, making it impossible to decide which alteration in an underlying disease has affected a patient’s UI.
In patients with existing UI, particularly the elderly, it may be difficult or impossible to distinguish between the effects of medication, comorbidities or ageing on UI. Although changing drug regimens for underlying diseases may be considered as a possible early intervention, there is limited evidence of benefit [590]. There is also a risk that stopping or altering medication may result in greater harm than benefit.

5.6.3.1.3 Constipation

One RCT, with a majority female population, found that a multimodal intervention in elderly patients, involving assisted toileting, fluid intake, etc., reduced the occurrence of UI and constipation, while behavioural therapy appeared to improve both [591]. However, there is no evidence to show whether treating constipation improves UI, although both constipation and UI appear to be improved by certain behavioural interventions.

5.6.3.1.4 Containment

Containment includes the use of absorbent pads, urinary catheters, external collection devices and penile clamps. A SR of six RCTs comparing different types of pads found that pads filled with super absorbent material were better than standard pads [592]. For men with light UI, a randomised crossover trial found that a leaf-shaped type of pad was preferred to rectangular pads [593].

A Cochrane review compared different types of long-term indwelling catheters and found no evidence that one catheter material or type of catheter was superior to another [594]. A SR of non-randomised studies found no differences in UTI outcome or Upper Urinary Tract (UUT) changes between use of suprapubic or urethral catheter drainage; however, patients with suprapubic catheters were less likely to have urethral complications [595]. For people using intermittent catheterisation, a Cochrane review found no evidence that one type of catheter or regimen of catheterisation was better than another [596].

An RCT in 56 men with post-prostatectomy incontinence (PPI) compared sheath drainage system, body-worn urinal, penile clamp, and absorbent pads. It was found that the three devices and absorbent pads have different strengths and limitations that make them more (or less) suitable for particular activities. Most men prefer to use a combination of devices and pads to meet their lifestyle needs. Hinge-type penile clamp was good for short vigorous activities as it was the most secure, least likely to leak and most discreet, although almost all men described it as uncomfortable or painful [597].

5.6.3.2 Behavioural and Physical therapies

Behavioural and physical therapies encompass all treatments which require a form of self-motivated personal retraining by the patient and include techniques which are used to augment this effect. Usually in clinical practice, these will be introduced as part of a package of care including lifestyle changes, patient education, and possibly cognitive therapy. Further details for behavioural treatments are outlined in section 5.1.2 of these guidelines.

5.6.3.2.1 Prompted or timed voiding

With prompted voiding, carers rather than the patient, initiate the decision to void. Two SRs confirmed a positive effect on continence outcomes for prompted voiding in comparison to standard care [598, 599]. Timed voiding is defined as fixed, pre-determined, time intervals between toileting, applicable for those with or without cognitive impairment. A Cochrane review of timed voiding, including two RCTs, found inconsistent improvement in continence compared with standard care in cognitively impaired adults [600].

5.6.3.2.2 Bladder training

Bladder training goals are to correct faulty habit patterns of frequent urination, improve control over bladder urgency, prolong voiding intervals, increase bladder capacity, reduce incontinent episodes, and restore patient
confidence in controlling bladder function. The ideal form or intensity of a bladder training program for UI is unclear. It is also unclear whether bladder training can prevent the development of UI. The addition of bladder training to anticholinergic therapy did not improve UI compared to antimuscarinics alone, but it did improve frequency and nocturia [601]. In seven RCTs, BT was compared to drug therapy alone and showed only a benefit for oxybutynin in cure and improvement of UI [601].

5.6.3.2.3 Pelvic floor muscle training
A 2015 Cochrane review concluded that there was no overall benefit at twelve months post-surgery for men who received post-operative pelvic floor muscle training (PFMT) for the treatment of PPI and that the benefits of conservative treatment of PPI remain uncertain [602]. However, a subsequent SR and meta-analysis showed that PFMT either alone or in combination with biofeedback and/or electrical stimulation was effective for treating PPI, significantly reducing the time to continence recovery [603]. A further meta-analysis demonstrated that the addition of guided programs using biofeedback and/or pelvic floor muscle electric stimulation (PFES) significantly improved continence recovery rates at one- and three-month intervals post-surgery compared to PFMT alone [604].

Two subsequent SRs in patients who underwent robotic-assisted radical prostatectomy demonstrated that the addition of PFMT to the post-operative management plan shorten the time to continence recovery [605, 606].

Two RCTs have shown that written instructions alone offer similar levels of improvement to supervised PFMT [607, 608]. One RCT found that PFMT was helpful in men who had been incontinent for at least one year after prostatectomy, and who had had no previous therapy [609].

Other RCTs demonstrated that like PFMT, increased pelvic floor muscle strength and quicker return to continence may be achieved with the Pilates method [612], the oscillating rod [613], a combination of biofeedback with electrostimulation [614] and whole body vibration training [615]. Furthermore, quicker return to continence and improved QoL may be achieved, even with extended and continuing nursing care [616].

5.6.3.2.4 Electrical stimulation
The majority of evidence on electrical stimulation refers to women with SUI and many are of generally low quality, with a variety of stimulation parameters, treatment regimens and outcome parameters [610].

An RCT of 70 PPI men receiving surface or intra-anal electrostimulation reported a significant reduction in UI in terms of grams of urine loss and a significant improvement in QoL from baseline, but no statistically significant difference between treatment arms [617].

A Cochrane review of six RCTs on electrical stimulation in men with UI concluded that there was some evidence that electrical stimulation enhanced the effect of PFMT in the short-term but not after six months. Electrical stimulation was also more effective than sham stimulation at six, but not twelve months; however, there were more adverse effects including pain and discomfort with electrical stimulation [618].

Electromagnetic stimulation has been promoted as a treatment for UI, but only weak evidence of the short- and long-term effects has been reported in SRs [619, 620].

5.6.3.2.5 Posterior tibial nerve stimulation
Posterior tibial nerve stimulation (PTNS) has been studied as a treatment of UI, especially UUI. Electrical stimulation of the posterior tibial nerve delivers electrical stimuli to the sacral micturition centre via the S2-S4 sacral nerve plexus. Stimulation is done either percutaneously using a fine, 34-G, needle, inserted just above the medial aspect of the ankle (P-PTNS) or transcutaneously using surface electrodes (T-PTNS). Percutaneous PTNS treatment cycles typically consist of twelve weekly treatments of 30 minutes and T-PTNS treatment cycles typically consists of self-administered, twenty-minute daily sessions, after adequate education.

A female-predominant sham controlled RCT, assessed effectiveness of PTNS in OAB population. There were 22.8% and 20% males in the treatment and sham arms, respectively [621]. Overactive bladder symptoms improved significantly in 54.5% of patients in the PTNS arm compared to 20.9% in the sham arm. A non-inferiority RCT comparing P-PTNS compared to T-PTNS, reported significant improvements in daytime frequency, urgency and UUI episodes without significant difference between treatment arms after twelve weeks of therapy [622]. A SR on T-PTNS in idiopathic and neurogenic female-predominant (males < 10%) population, reported significant improvement in OAB symptoms in 48-93% of patients and cure of UUI episodes in 25-45% [623].
For PTNS, mild pain and discomfort at the puncture site is the most common adverse event [624]. Small haematomas, swelling, leg tingling and vasovagal reaction to needle placement have also been reported [621]. Treatment adherence is generally high at 89.7% [622]. Contra-indications include a cardiac pacemaker and skin disease at the site of stimulation.

There is some evidence that PTNS may benefit male patients with OAB, but due to too insufficient data, no recommendation on PTNS in males can be made at this time. However, considering the safety of this therapy, it can be offered to male patients as an alternative option prior to more invasive treatments.

### Recommendations

| Implement prompted voiding for patients with urinary incontinence (UI) where appropriate. | Strong |
| Offer bladder training as a complementary treatment for UI. | Weak |
| Offer pelvic floor muscle training alone or in combination with biofeedback and/or electrostimulation to men undergoing radical prostatectomy to speed recovery from UI. | Weak |

### Pharmacological management

#### 5.6.4 Drugs for urgency urinary incontinence

Muscarinic receptor antagonists [625-628] and beta-3 agonist [295-297, 629-632] are currently the first-line pharmacological treatments for UUI. The mechanism of action, efficacy, and safety and tolerability profiles of both classes of drugs are discussed in detail in sections 5.2.3 and 5.2.4, respectively.

#### 5.6.4.2 Drugs for stress urinary incontinence

A SR of eight studies evaluating the efficacy of duloxetine in postprostatectomy SUI reported that duloxetine resulted in a mean dry rate of 58% (25–89%), mean improvement in pad number of 61% (12–100%), and mean improvement in one-hour pad weight of 68% (53–90%), at short-term follow-up (mean one to nine months) [633]. However, mean adverse event rates were high, and treatment was discontinued in 38% of cases. The overall certainty of the evidence was low due to study heterogeneity and methodological limitations. Further RCTs with long-term follow-up are required.

### Summary of evidence

| Antimuscarinic monotherapy can significantly improve urgency, UUI, and increased daytime frequency. | 1b |
| Mirabegron is superior to placebo and as efficacious as antimuscarinics for improvement of UUI. | 1b |
| Duloxetine led to a short-term improvement in postprostatectomy SUI symptoms and QoL improvement; however, a significant proportion of men discontinued treatment. | 1b |

### Recommendations

| Offer antimuscarinic drugs or mirabegron to adults with urge urinary incontinence who failed conservative treatment. | Strong |
| Offer duloxetine to men with stress urinary incontinence. | Weak |
| Inform patients about the possible adverse events of duloxetine and that its use is off label for this indication in Europe. | Strong |
5.6.5  Surgical treatment for stress urinary incontinence

5.6.5.1  Bulking agents in men

Mechanism of Action: Urethral bulking agents work by adding bulk and improving the coaptation of a damaged sphincter zone. They represent a treatment option in men with either small volume leak or those unfit for more invasive treatment options [634].

Efficacy: A Cochrane review on surgical treatment of PPI identified only one RCT that fulfilled the inclusion criteria. This trial randomised 45 men to Macroplastique injection or artificial urinary sphincter (AUS) implantation and compared their outcomes at 48 months [634]. Significant improvement was reported in both groups for men with minimal incontinence, but in men with total incontinence there was a significant difference in continence rates favouring AUS implantation (72% vs. 23%) [635]. A SR of eight studies (n=142) in men using Macroplastique, Opsys, Durashape and Urolastic, showed short-term improvement, and reported dry rates between 0-83% [634]. A propensity score-matched analysis of 104 men with PPI, compared submucosal injection of Macroplastique to transobturator male sling (TILOOP male) [636]. At twelve months follow-up, the reported failure free rates were 15.4% and 76.9%, the daily use of 0-1 pads was 21.2% and 67.3% and the satisfaction rate was 3.8% and 71.2%, respectively. Several small cohort studies of several different bulking agents have not shown any benefit.

A narrative review including data from 25 articles, reports a success rate with all bulking procedures of 54.3%, with 37.5% of symptoms improvement and almost 30% of dryness [637].

In a SR and meta-analysis, three studies addressed bulking agents. Two of them, involving a total of 384 participants, showed a pooled short-term cure rate of 26.1% and a single study on 68 subjects reported a 10.3% long term cure rate. Short- and long-term reoperation rates were not described [638].

Tolerability and safety: Bulking agent associated dysuria and haematuria are frequently reported to be transient and self-resolving [634]. The risk of urinary retention requiring, clean intermittent self-catheterisation (CISC) or long-term catheter use is minimal [639]. However, they may provoke allergic reactions [640] and carry a potential risk for migration [641] to proximal and distal lymph nodes [642]. Overall, post procedural urinary retention rates range between 3-17%, with rare need for temporary catheterization, while post-operative urinary tract infections ranged from 6-7% [637].

Practical considerations: Bulking agents have shown low cure rates but remain an option for men unfit for more invasive treatment options.

Recommendation

Do not offer bulking agents to men with postprostatectomy incontinence.  

Strength rating: Weak

5.6.5.2  Male Slings

Male slings have been introduced to treat mild-to-moderate PPI. However, the definitions of mild and moderate UI are unclear. The majority of studies define cure as ‘no pad use’ or ‘one security pad per 24-hours’. Some authors used more strict criteria such as ‘urine loss of less than 2 g per 24-hour pad test’ [643].

5.6.5.2.1  Non-adjustable slings

Mechanism of Action: Non-adjustable male slings are positioned under the urethra and fixed by a retropubic or transobturator approach. The tension is adjusted during the surgery, and it cannot be re-adjusted post-operatively. Synthetic slings restore continence in males either by urethral compression and/or by repositioning the bulb of urethra [644, 645].

Efficacy: A SR and meta-analysis involving 33 prospective cohorts and one RCT comparing sling to AUS, reported that both options are effective in improving UI and QoL [646]. Following sling insertion, the overall cure rate was 60% (95% CI: 0.51-0.67) and 56% (95% CI: 0.44-0.68) for slings and AUS, respectively. The 24-hour pad use was -3.33 (95% CI: -4.33 to -2.34) and -3.75 (95% CI: -4.56 to -2.93) for slings and AUS, respectively. Similar findings were reported by a network meta-analysis that showed comparable efficacy between slings and AUS [647].

The MASTER Trial, a non-inferiority RCT comparing the outcomes of continence surgery in men with bothersome urodynamic SUI, using a very strict definition of UI after prostate surgery, reported that at twelve-
months incontinence rates were 87% for male sling vs. 84.2% for AUS (95% CI: -11.6-4.6, P_NI=0.003)], confirming non-inferiority [648]. The subgroup analysis suggested that male sling is inferior to AUS for men with greater incontinence at baseline (pad weight > 250g); however, the difference did not reach statistical significance.

For the re-positioning sling (Advance™ and AdvanceXP©), a mean subjective cure rate of 49% (8.6 - 73.7%) after mean follow-up of three years has been reported for 136 patients [649]. A prospective multicentre cohort study, with 60-month follow-up, in men with AdvanceXP© demonstrated a constant continence outcome over time with a 57.6% cure rate, 25.4% improvement rate and 16.9% failure rate. These findings were verified in an additional study which reported cure rates of 66.7% and 71.7%, improvement rates of 26.5% and 24.4% and failures rates of 6.9% and 13.3% at 24- and 48-months, respectively [650]. A retrospective comparative study showed that both options are safe and effective in the treatment of male SUI [651].

With the transobturator compressive I-Stop TOMS male sling, 38% of men were dry at twelve months, but this reduced to 23% and 15% after four and five years, respectively [652].

Tolerability and safety: A SR and meta-analysis of 1,170 men with SUI and male sling, reported that the predictors of failure are prior radiation, severity of incontinence and previous surgeries [653]. Pelvic radiotherapy has also been reported in other studies as a negative prognostic factor [654]. A comparison among radiated vs. non-radiated men who had AdvanceXP reported a greater degree of post-operative improvement in the non-radiated group (49.6% vs. 22.2%) as well as greater satisfaction rates (95% vs. 64%) [655]. The most common complication with male slings is pain and local superficial wound infection [656]. Chronic pain has been observed in 1.3% of men who had non-adjustable slings [656]. Post-operative transient voiding dysfunction occurred in 4.3-10.3%, mostly as de novo urgency or urinary retention, while erosions and chronic pain were uncommon (0-0.4%), as was explantation [649, 650, 657-659].

Practical considerations: Fixed male slings are considered safe and improve continence, but their efficacy is limited in men with severe incontinence or previous radiotherapy.

5.6.5.2.2 Adjustable slings in males
Mechanism of Action: Adjustable slings in males are those for which the tension of the sling can be adjusted post-operatively. Three main systems have been used in men: the Remeeex® system [660], the Argus® system [661] and the ATOMS® system [662].

Efficacy: There is one small RCT for adjustable slings in males [663]. Most studies consist of prospective or retrospective case series, with variable follow-up and different definitions of success [660, 662-666]. A SR reported objective cure rates varying between 17-92% after adjustable sling implantation [656].

For the Remeeex® system, only two studies, with conflicting findings, have been published. One study followed nineteen patients for nearly seven years and reported 70% success, with no explants, infections, or erosions [660]. The second study followed fourteen patients for 25 months. Only 36% of patients were satisfied and multiple re-adjustments were needed. Mechanical failure was reported in 21% [664].

Data on the Argus® system has been reported for 404 men, but only few series have reported on more than 40 patients, with the longest follow-up being 35-months. Success rates varied between 17-93%, with a mean of 73.0% reporting subjective cure [665, 666]. A head-to-head comparison between the two Argus systems reported similar efficacy outcomes at 44 months, but Argus T was associated with a higher inguinal pain and explantation rate [667]. A small study of 22 men with PPI randomised to Advance or Argus T reported superior 24-hour pad test results and of patient satisfaction levels for Argus T at eighteen-months follow-up [663].

A SR of the ATOMS system reported the pooled evidence from 1,393 patients with a 67% dryness, 90% improvement after adjustment and 16.4% complication rate [662]. The expulsion rate was 5.75%. Another SR and meta-analysis with 3,059 patients reported that ATOMS was superior to ProACT in mean dryness rate (68% vs. 55%), overall improvement (91% vs. 80%), satisfaction rate (87% vs. 56%), mean number of filing adjustments (2.4 vs. 3.5) and post-operative pad use per day (1.1 vs. 2.1) [668].

Tolerability and Safety: The most frequent complications in adjustable male slings are pain, erosions, and infections [656]. Pain at the implant site was usually only temporary, but chronic pain has been reported in 1.5% of men [665, 666]. The number of implants requiring re-adjustment is reported between 8-38.6% [666, 669, 670]. Explication rates range from 10-15.8% and erosion rate is estimated around 10% [653]. The most
common reasons for explantation are device infection (4.1-8%), erosions (4-12%), and urethral perforations (2.7-16%). A SR reported a device explantation rate of 5% vs. 25% and a major complication rate of 4.2% vs. 10.4% for ATOMS and ProACT, respectively [668].

Practical considerations: There is no evidence that adjustability offers additional benefit as RCTs are lacking; therefore, no recommendation can be made at this time. Explantation rate seems superior to fixed male sling based on external comparisons.

5.6.5.2.3 Autologous slings
The strategy of intra-operative placement of an autologous vas deferens sling below the vesico-urethral anastomosis during robotic-assisted radical prostatectomy (RARP) has been explored with the intention to improve early return of continence. Two RCTs [671, 672] showed an advantage of sling vs. no sling at one-month follow-up, and another study [673] showed an advantage of a 6-branch vs. a 2-branch sling at one month follow-up. However, a larger RCT (n=195), showed that continence rate and near-continence rate were similar between groups at six months with 66% vs. 65% and 86% vs. 88%, respectively [674].

* The terms "mild" and "moderate" PPI remain undefined.

5.6.5.3 Compression devices in males
5.6.5.3.1 Artificial urinary sphincter
**Mechanism of action:** The AUS is the standard treatment for moderate-to-severe male SUI. The AMS 800 three component system with inflatable cuff, control pump and pressure regulating balloon is the device with the longest follow-up and the greatest level of evidence [675]. The ZSI 375 is a two-component device, inflatable cuff, and control pump, allowing an easier implantation process [676]. Other AUS devices have been launched e.g., the Victo and Br-SL-AS 904 systems, but robust evidence regarding their efficacy and safety is pending [677].

**Efficacy** A meta-analysis of 33 cohort studies and one RCT, reported significant improvement after AUS implantation in overall cure rates (56%) and reductions in pad used per 24-hours (-3.75) [646]. Several observational studies reported on functional outcomes after AMS 800. Social continence rates (0-1 pads used daily) ranged from 55-76.8% [678-680]. A 77.2% continence rate and 89.5% subjective satisfaction rate have been reported after median follow-up of > 15 years in 57 men who had undergone AUS placement [681]. A prospective cohort study of 40 patients with a mean follow-up of 53 months, showed that from all urodynamic parameters only low bladder compliance had a negative impact on outcome [682]. However, another retrospective study showed that no urodynamic factors adversely altered the outcome of AUS implantation [683]. Some recent multicenter studies have confirmed older statements that surgeon's experience and higher surgical volume is associated with better outcomes and a lower revision rate after AUS implantation [684, 685].

The data regarding ZSI 375 is limited. A retrospective, non-randomised trial across several centres in Europe, reported an 84.4% success rate (19.3% dry rate and 65.1% improved 0-1 pads per day) after 43 months [676]. A 72% success rate was reported at seven years follow-up for 45 patients who underwent placement of the ZSI 375 device in France [686].

**Tolerability and safety:** Artificial urinary sphincter complications include device infection/erosion (8.5%), mechanical failure (6.2%) and urethral atrophy (7.9%) [687]. In multivariate analysis, radiation therapy was
independently associated with risk of urethral atrophy, as were older age and a longer time interval between prostate cancer treatment and AUS surgery [680]. Urethral erosion is associated with previous irradiation and penoscrotal approach [688]. The reported revision rates at three years for any reason were 10-29.1% [678, 688-690]. The risk of urethral erosion after ZSI 375 AUS is 8.2-13.3% and risk of mechanical failure is 2.2-2.5% [676].

**Practical Considerations:** Artificial urinary sphincter is efficacious and improves the QoL of men with PPI. To minimise complications, it is advised to refer patients to specialised centres experienced in AUS implementation. Men considering insertion of an AUS should be fully informed that the success of the intervention relies on their ability to operate the pump. Treating physicians should keep in mind that operating the AUS may become difficult in men who develop cognitive impairment or lose manual dexterity. Artificial urinary sphincter has a limited lifespan and ‘maintenance’ re-operations are common in the long-term. These re-interventions should not be classified as complications [675].

5.6.5.3.2 Non-circumferential compression device (ProACT®)

**Mechanism of action:** The ProACT® system consists of two devices. Each device includes the balloon, the bi-lumen tubing, and the volume-adjustment port. The devices are introduced by a trocar via two small perineal incisions and are placed under fluoroscopic guidance on each side of the bladder neck, close to the vesico-urethral anastomotic site. The balloons can be filled, and their volume can be adjusted post-operatively using a hypodermic needle injected through the intra-scrotal port.

**Efficacy:** A SR and meta-analysis of nineteen studies including 1,264 patients reported a 60.2% dry rate, significant reduction in number of pads used per day (-3.1) and greatly improved QoL scores for ProACT® [691]: however, the level of heterogeneity among the included studies was high. A comparison between ATOMS and ProACT®, showed that the former is associated with higher improvement and satisfaction rates and fewer complications [668]. A quasi-randomised trial comparing ProACT® with bone-anchored male slings found that both resulted in similar improvements in SUI (68% vs. 65%, respectively) [692]. A questionnaire study showed that 50% of patients were still significantly bothered by persistent incontinence following ProACT® [693]. A subgroup analysis of radiotherapy patients reported worst outcomes as compared to patients not receiving radiotherapy (46% vs. 68% success rate) as well as a higher percentage of urethral erosion for ProACT® [694].

**Tolerability and safety:** The most common intra-operative complication during ProACT® implantation is perforation of the bladder and/or urethra. A meta-analysis estimated a perforation rate of 5.3% [691]. The estimated overall revision rate is 22.2%, and the main causes are erosion (3.8%), device leaking (4.1%) and migration (6.5%) [691]. Other prospective series have shown that adverse events were frequent, leading to an explantation rate of 11-58% [692, 693, 695-697].

**Practical Considerations:** ProACT® has a satisfactory rate of success and seems to be a reasonable alternative for the treatment of male UI; however, it is associated with high complication rates.

5.6.6 Surgical treatment for urgency urinary incontinence

5.6.6.1 Bladder wall injection of botulinum Toxin A

**Mechanism of action:** The primary mechanism of action of BoNT-A is through the inhibition of neurotransmitter release from cholinergic neurons [541]. Onabotulinum toxin A (onabotA; BOTOX®) 100 U is licenced in Europe to treat OAB with persistent or refractory non-neurogenic UUI in adults [698, 699].

**Efficacy:** An RCT of OAB-wet patients whose symptoms were not adequately managed with anticholinergics and who receive either bladder wall injections of onabotA (100 U) or saline reported a 50% reduction in UUI episodes/day whilst the number of micturitions/day reduced by more than two in patients receiving onabotA [700]. A total of 22.9% of the patients in the onabotA arm were fully dry vs. 6.5% in the saline arm.

A SR and meta-analysis comparing the efficacy of onabotA, mirabegron and anticholinergics in adults with idiopathic OAB reported that patients who received onabotA (100U) achieved greater reduction in UI episodes, surgery, micturition frequency and the highest odds of achieving dryness as well as > 50% reduction from baseline UI episodes per day [701].

A randomised, placebo-controlled pilot study, assessing the effect of onabotA for the treatment of refractory OAB symptoms after prostatectomy reported significantly improved QoL and ICIQ scores and improvements in daily frequency in patients receiving onabotA compared to placebo [702]. A retrospective trial assessed onabotA efficacy in 65 non-obstructed men with refractory OAB and reported significant improvement in UDI-6 score (-4.2) and IQI-7 (-6.0) scores, compared to baseline [703].

In a retrospective, single-centre cohort study onabotA treatment for OAB in 120 patients lead to lower CISC rates in male patients after prior de-obstructive surgery than in surgery-naïve patients (28.6% CISC in the group without prior surgery, 7.5% in the TURP subgroup, and 4.2% in the radical prostatectomy subgroup) [704].

A phase IIIb trial randomised solifenacin-naive patients (10% males) with refractory OAB to onabotA, solifenacin or placebo, and showed that patients receiving onabotA had significantly greater changes in UI episodes (-3.19) compared to solifenacin (-2.6) and placebo (-1.33) [705].

A network meta-analysis (male population range 9.8-40.2%) which compared onabotA to mirabegron demonstrated that onabotA was associated with improved outcomes in frequency episodes per day (-0.43 [-1.22-0.37]) and in UI episodes per day (-0.46 [-1.46-0.53]) [706].

**Tolerability and safety:** Urinary retention and UTIs are the two most common adverse events after onabotA injection. Other reported adverse events include haematuria, dysuria and post-treatment pain [707]. Compared to mirabegron, onabotA is associated with higher risk for UTI and treatment emergent adverse events [706]. A retrospective analysis compared the use of CISC after onabotA injection, among men who had previous prostatectomy vs. those without prior surgery [704]. A 7.5% catheterisation rate after TURP, 4.2% rate after radical prostatectomy and 28.6% rate in men without prior prostate surgery was reported.

**Practical Considerations:** BoNT-A injections is a recommended treatment option for men with refractory UUI. Despite the lack of a universally accepted injection protocol, gender specific studies and absence of studies in BPO patients, BoNT-A seems superior to medical therapy. It is associated with a higher UTIs and urinary retention risk, coupled with the need for repeated injections. A dedicated series in male population, focused on treatment persistence, has shown a high discontinuation rate [708]. Patients treated for OAB with onabotA treatment that have not undergone prior de-obstruction are more likely to develop retention and subsequent CISC.

Recommendations | Strength rating
--- | ---
Offer bladder wall injections of onabotulinum toxin A (100 U) to patients with overactive bladder/urgency urinary incontinence refractory to medical therapy. | Weak
Warn patients of the limited duration of response, risk of urinary tract infection and the possible prolonged need for clean intermittent self-catheterisation (ensure that they are willing and able to do so). | Strong

### 5.6.6.2 Sacral nerve stimulation (neuromodulation)

**Mechanism of action:** Sacral nerve stimulation (SNS) delivers low amplitude electrical impulses to the sacral nerve roots via an electrode implanted adjacent to the third sacral nerve root and connected to an attached pulse generator implanted in the buttock. It works by modulating neural activity thus stabilising bladder electrical activity through an unknown mechanism. It is a two-stage process: in the first stage, a tined lead electrode is placed percutaneously near the S3 root and linked to an external stimulator to assess the response. If symptoms reduced more than 50%, patients are candidates for the second stage which is the full implant.

**Efficacy:** Several trials assess the clinical effectiveness of SNS. All RCTs suffer from the limitation that patients and assessors cannot be blinded to the treatment allocation since all recruited subjects had to respond to a test phase before randomisation. In addition, the percentage of male population in these trials is around 10%. A meta-analysis compared the effectiveness of SNS to onabotA and reported no significant difference in successfully treated cases at six-month follow-up (RR 0.93; 95% CI: 0.63-1.39) [709].

**Tolerability and safety:** Main complications after SNS are pain at the implant site (13-42%), lead migration (4.0-21%), leg or back pain (3.0-18%) and wound infection (5.7-6.7%). Surgical revision is required in 29-33% of patients due to device malfunction, battery or device replacement or lead migration [710].

**Practical Considerations:** SNS represents an alternative to onabotA in patients with refractory OAB, as it has shown good success rates and an acceptable safety profile.

### Summary of evidence LE

| Sacral nerve stimulation is effective after failed conservative treatment for OAB/UUI, but no sham controls have been used. | 2a |

### Recommendation | Strength rating
--- | ---
Offer sacral nerve stimulation to patients who have urgency urinary incontinence refractory to medical therapy and are willing to undergo surgical treatment. | Weak

### 5.6.6.3 Cystoplasty/urinary diversion

**Mechanism of action:** Augmentation cystoplasty involves the interposition of a detubularised segment of bowel into the bivalved bladder wall, aiming to increase bladder capacity and reduce OAB related symptoms. Urinary diversion remains a reconstructive option for patients with intractable UI after multiple pelvic procedures, radiotherapy or pelvic pathology leading to irreversible sphincteric incompetence or fistula formation.

**Efficacy:** There are no RCTs comparing bladder augmentation to other treatments for patients with refractory OAB/UUI. In a large study with three years follow-up augmentation cystoplasty resulted in a post-operative continence rate of 93% in idiopathic detrusor overactivity patients, 78% in neurogenic overactivity and up to 90% when an artificial urinary sphincter was implanted, respectively [711]. The largest case series of bladder augmentation in an idiopathic population included only women [712]. At an average follow up of 75.4 months only 53% were continent and satisfied with the surgery, whereas 25% had occasional leaks and 18% continued to have disabling UI. A small prospective mixed gender trial reported high patient satisfaction rates with augmentation cystoplasty vs. onabotA therapy [713]. A small study comparing ileal with colonic conduits concluded that there were no differences in the relative risks of UUT infection and uretero-intestinal stenosis [714]. However, there are no studies that have specifically examined these techniques in the treatment of intractable OAB/UUI [714]. Therefore, careful consideration on which operation is undertaken will depend on thorough pre-operative counselling, access to stoma/continence nurses as well as patient factors to allow for fully informed patient choice.

**Tolerability and safety:** Cystoplasty and urinary diversion are major urologic operations. The early post-operative complications include infection, bowel obstruction, bleeding, and cardiorespiratory complications.
Long-term complications include metabolic disturbances (hyperchloraemic metabolic acidosis), change in bowel habits, increased mucus production, stone formation, bladder perforation and rarely bladder cancer [715]. Following augmentation cystoplasty or diversion, the majority of patients will depend on self-catheterisation for bladder emptying. Patients with urinary conduit will depend on lifelong urine bags.

Practical Considerations: Augmentation cystoplasty and urinary diversion represent realistic treatment options for men with refractory OAB. However, both options involve a major operation, with a non-negligible long-term complication rate and a lifelong reliance on catheterisation or urine bags.

### Summary of evidence

<table>
<thead>
<tr>
<th>Statement</th>
<th>LE</th>
</tr>
</thead>
<tbody>
<tr>
<td>There is limited evidence of the effectiveness of augmentation cystoplasty and urinary diversion in treatment of idiopathic OAB.</td>
<td>3</td>
</tr>
<tr>
<td>The need to perform CISC following augmentation cystoplasty is high.</td>
<td>3</td>
</tr>
<tr>
<td>Augmentation cystoplasty and urinary diversion are associated with high risks of short- and long-term complications.</td>
<td>3</td>
</tr>
<tr>
<td>There is no evidence comparing the efficacy or adverse effects of augmentation cystoplasty to urinary diversion.</td>
<td>3</td>
</tr>
</tbody>
</table>

### Recommendations

<table>
<thead>
<tr>
<th>Recommendation</th>
<th>Strength rating</th>
</tr>
</thead>
<tbody>
<tr>
<td>Offer augmentation cystoplasty to patients with overactive bladder (OAB)/urgency urinary incontinence (UUI) who have failed all other treatment options and are able and willing to perform self-catheterisation.</td>
<td>Weak</td>
</tr>
<tr>
<td>Inform patients undergoing augmentation cystoplasty of the high risk of complications; the risk of having to perform clean intermittent self-catheterisation and the need for life-long surveillance.</td>
<td>Strong</td>
</tr>
<tr>
<td>Only offer urinary diversion to patients who have failed less invasive therapies for the treatment of OAB/UUI, who will accept a stoma.</td>
<td>Weak</td>
</tr>
</tbody>
</table>

6. **FOLLOW-UP**

6.1 Watchful waiting (behavioural)

Patients who elect to pursue a WW policy should be reviewed at six months and then annually, provided there is no deterioration of symptoms or development of absolute indications for surgical treatment. The following are recommended at follow-up visits: history, IPSS, uroflowmetry, and PVR volume.

6.2 Medical treatment

Patients receiving α1-blockers, muscarinic receptor antagonists, beta-3 agonists, PDE5Is or the combination of α1-blockers and 5-ARIs or muscarinic receptor antagonists should be reviewed four to six weeks after drug initiation to determine the treatment response. If patients gain symptomatic relief in the absence of troublesome adverse events, drug therapy may be continued. Patients should be reviewed at six months and then annually, provided there is no deterioration of symptoms or development of absolute indications for surgical treatment. The following are recommended at follow-up visits: history, IPSS, uroflowmetry, and PVR volume. Frequency volume charts or bladder diaries should be used to assess response to treatment for predominant storage symptoms or nocturnal polyuria.

Patients receiving 5-ARIs should be reviewed after twelve weeks and six months to determine their response and adverse events. The following are recommended at follow-up visits: history, IPSS, uroflowmetry and PVR volume. Men taking 5-ARIs should be followed up regularly using serial PSA testing if life expectancy is greater than ten years and if a diagnosis of PCa could alter management. A new baseline PSA should be determined at six months, and any confirmed increase in PSA while on 5-ARIs should be evaluated.

In patients receiving desmopressin, serum sodium concentration should be measured at day three and seven, one month after initiating therapy and periodically during treatment. If serum sodium concentration has remained normal during periodic screening follow-up screening can be carried out every three months subsequently. However, serum sodium concentration should be monitored more frequently in patients ≥ 65 years of age and in patients at increased risk of hyponatremia. The following tests are recommended at follow-up visits: serum-sodium concentration and FVC. The follow-up sequence should be restarted after dose escalation.
6.3 Surgical treatment
After prostate surgery, patients should be reviewed four to six weeks after catheter removal to evaluate treatment response and adverse events. If patients have symptomatic relief and are without adverse events, no further re-assessment is necessary. The following tests are recommended at follow-up visit after four to six weeks: IPSS, uroflowmetry and PVR volume.

7. CITATION INFORMATION 148
1. INTRODUCTION

Lower urinary tract symptoms (LUTS) encompass storage, voiding and post-micturition symptoms [1]. Storage symptoms include frequency, urgency, nocturia and urinary incontinence (UI) (stress UI [SUI], urgency UI [UUI] and mixed UI [MUI]). Voiding symptoms include hesitancy, intermittency, slow stream, straining, splitting or spraying of the urinary stream and terminal dribble. Post-micturition symptoms include post-void dribbling and feeling of incomplete bladder emptying. Lower urinary tract symptoms are often broadly classified into clinical syndromes/entities such as overactive bladder (OAB), underactive bladder (UAB), UI, nocturia, dysfunctional voiding, or genito-urinary fistulae.

LUTS are common in women [2-5] and cause a great deal of distress and embarrassment [6], as well as significant costs to both individuals and society [7]. Estimates of prevalence vary according to the definition and population studied. However, there is universal agreement about the importance of the problem in terms of human suffering and economic cost [7].

1.1 Aim and objectives

These Guidelines from the European Association of Urology (EAU) Working Panel on Non-neurogenic Female LUTS are written by a multidisciplinary group, primarily for urologists, but are likely to be referred to by other professional groups. The guidelines aim to provide sensible and practical evidence-based guidance on the clinical problems associated with female LUTS rather than an exhaustive narrative review. Such reviews for UI and other LUT syndromes are already available from the International Consultation on Incontinence [8] and other sources. Therefore, these EAU Guidelines do not describe the causation, basic science, epidemiology and psychology of LUTS/UI in detail. The focus of these guidelines is on assessment and treatment, reflecting clinical practice, and they do not consider women with LUTS caused by neurological disease, or LUTS occurring in children, as these are covered by complementary EAU Guidelines [9, 10].

The current guidelines provide:
- A clear description of the assessment and treatment of common clinical problems. This can provide the basis for both individual patient management and for planning and designing clinical services.
- A brief but authoritative summary of the current state of evidence on clinical topics, complete with references to the original sources.
- Clear guidance in those areas of practice for which there is little or no high-quality evidence.

The latest edition of the guideline has seen a significant expansion of scope from UI to non-neurogenic female LUTS. The primary consideration here is to include the significant population of women with functional urological conditions not necessarily associated with UI that were hitherto not accounted for in previous guidelines. Secondary considerations are to align more cohesively with the existing Non-neurogenic Male LUTS Guidelines. As a consequence of the anatomical and physiological differences between the male and female LUT, the prevalence, pathophysiology, diagnostic approach and management of male and female LUTS differ widely. For that reason, the EAU Guidelines Office decided to provide gender-specific guidelines on LUTS and UI.

1.2 Panel composition

The EAU Non-neurogenic Female LUTS Panel consists of a multidisciplinary group of experts, including urologists, a uro-gynaecologist, a urodynamic scientist, physiotherapists, a nurse practitioner continence care and patient advocates. All experts involved in the production of this document have submitted potential conflict of interest statements that can be viewed on the EAU website: https://uroweb.org/guideline/non-neurogenic-female-luts/.

1.3 Available publications

A quick reference document (Pocket Guidelines) is available, both in print and as an app for iOS and Android devices. These are abridged versions that require consideration together with the full-text versions. All documents are accessible through the EAU website: https://uroweb.org/guideline/non-neurogenic-female-luts/.

1.4 Publication history

The first EAU Urinary Incontinence Guidelines were published in 2001. The guidelines have been modified since to broaden its scope specifically to include other female LUTS as of 2021. Except for pelvic organ prolapse, all other sections of the 2022 Female LUTS Guidelines have been fully updated.
2. METHODS

2.1 Introduction
For the 2021 Non-neurogenic Female Lower Urinary Tract Symptoms Guidelines, the existing text of the 2018 Urinary Incontinence Guidelines was restructured and expanded. The Patient/Population, Intervention, Comparison and Outcome (PICO) question-based format of the text was modified to improve readability, although the underlying PICO structure still informs search strategies.

For the 2022 Non-neurogenic Female Lower Urinary Tract Symptoms Guidelines, databases searched included Medline, Embase, and the Cochrane Libraries, covering a time frame between 12 June 2020 and 07 September 2021 with a focus on high-level evidence only (systematic reviews and meta-analyses). A total of 187 unique records were identified, retrieved and screened for relevance. Detailed search strategies are available online: https://uroweb.org/guideline/non-neurogenic-female-luts/?type=appendices-publications.

For the 2022 edition of the guidelines a de novo systematic review (SR) was undertaken by the Panel on the subject of overactive bladder syndrome [11]. Full publication of the SR results are pending; however, the preliminary results have informed the corresponding sections of this guidelines update.

For each recommendation within the guidelines there is an accompanying online strength rating form, the basis of which is a modified Grading of Recommendations Assessment, Development and Evaluation (GRADE) methodology [12, 13]. Each strength rating form addresses a number of key elements, namely:

1. overall quality of the evidence which exists for the recommendation; references used in this text are graded according to a classification system modified from the Oxford Centre for Evidence-Based Medicine Levels of Evidence [14];
2. magnitude of the effect (individual or combined effects);
3. certainty of the results (precision, consistency, heterogeneity and other statistical or study-related factors);
4. balance between desirable and undesirable outcomes;
5. impact of patient values and preferences on the intervention;
6. certainty of those patient values and preferences.

These key elements are the basis that panels use to define the strength rating of each recommendation. The strength of each recommendation is represented by the words strong or weak [15]. The strength rating forms will be available online.

Additional information can be found in the general Methodology section of this print, and online at the EAU website: https://uroweb.org/guidelines/policies-and-methodological-documents/.

A list of Associations endorsing the EAU Guidelines can also be viewed online at the above address.

2.2 Review
The guidelines were extensively peer reviewed prior to publication in 2021.

2.3 Future goals
• Systematic review of pelvic organ prolapse;
• Systematic review of synthetic/mesh-related mid-urethral sling complications;
• Systematic review of the diagnosis and treatment of UAB in women.

3. DIAGNOSIS

3.1 History and physical examination
Taking a thorough clinical history is fundamental to the process of clinical evaluation. Despite the lack of high-level evidence to support taking a history, there is universal agreement that it should be the first step in the assessment of anyone with LUTS. The history should include a full evaluation of LUTS, as well as sexual, gastrointestinal and neurological symptoms. Details of urgency episodes, the type, timing and severity of UI, and some attempt to quantify symptoms should also be made. The history should help to categorise LUTS as storage, voiding and post-micturition symptoms, and classify UI as SUI, UUI, MUI or overflow incontinence; the
latter being defined as “the complaint of UI in the symptomatic presence of an excessively (over-) full bladder (no cause identified)” [16].

The history should also identify patients who need referral to an appropriate clinic/specialist. These may include patients with associated pain, haematuria, history of recurrent urinary tract infection (UTI), pelvic surgery or radiotherapy, constant leakage suggesting a fistula (see Section 4.8), new-onset enuresis or suspected neurological disease. A neurological, obstetric and gynaecological history may help to understand the underlying cause and identify factors that may affect treatment decisions. Guidance on history-taking and diagnosis in relation to UTIs, neuro-urological conditions and chronic pelvic pain (CPP) can be found in the relevant EAU Guidelines [9, 17, 18]. Patients should also be asked about other comorbidity as well as smoking status, previous surgical procedures and current medications, as these may affect LUTS.

There is little evidence from clinical trials that carrying out a clinical examination improves outcomes, but widespread consensus suggests that clinical examination remains an essential part of assessment of patients with LUTS. Examination should include abdominal examination, to detect an enlarged urinary bladder or other abdominal mass, and digital examination of the vagina and/or rectum. Pelvic examination in women includes assessment of oestrogen status, pelvic floor muscle (PFM) function and careful assessment of any associated pelvic organ prolapse (POP). A cough stress test is necessary to look for SUI. Among women with genital prolapse, the cough test was found to show good agreement with urodynamic studies (UDS) in the detection of SUI [19]. Urethral mobility can be assessed. Pelvic floor muscle contraction strength can also be assessed digitally. A focused neuro-urological examination should also be routinely undertaken.

3.2 Patient questionnaires

This section includes symptom scores, symptom questionnaires/scales/indices, patient-reported outcome measures (PROMs) and health-related quality of life (QoL) measures. The latter include generic or condition-specific measures. Questionnaires should have been validated for the language in which they are being used, and, if used for outcome evaluation, should have been shown to be sensitive to change. The US Food and Drug Administration (FDA) published guidance for industry on PROM instruments (questionnaires) in 2009 [20].

Although many studies have investigated the validity and reliability of urinary symptom questionnaires and PROMs, most of these studies included mixed populations (men and women). This limits the extent to which results and conclusions from these studies can be applied to particular LUT syndromes in women. Some questionnaires (ICIQ-FLUTS, QUID, 3IQ, ICIQ-SF) have potential to discriminate UI types in women [21-23]. Others have been developed to measure symptoms and bother in OAB (OABQ-SF, B-DAQ) and other specific conditions. A newly developed patient assessment tool, the OAB-Bladder Assessment Tool (OAB-BAT), was found to be a valid and reliable OAB PROM that includes symptoms, bother, impacts and satisfaction with treatment [24]. A systematic review (SR) included 22 studies that assessed eleven case-finding tools for OAB. All tools were found to have good sensitivity and specificity for OAB or incontinence symptoms. The B-DAQ was the only tool in this SR to include screening for “red flag” symptoms such as haematuria and pain, and it has also been validated in a primary care setting [25]. Some questionnaires are responsive to change and may be used to measure outcomes, although evidence for this is inconsistent [26, 27].

A SR including 73 studies assessed 27 specific and six generic instruments that measure QoL in women with UI. In this review, IQoL was found to be the most psychometrically robust disease-specific tool for use in English-speaking women with UI. It had the highest level of evidence for sufficient internal consistency, test-retest reliability, measurement error and hypothesis testing for construct validity. It is also the most translated instrument. Evidence on the performance of generic QoL tools for this population is limited [28]. There is no evidence to indicate whether use of QoL or condition-specific questionnaires has an impact on outcome of treatment.
Detailed description of the different urinary symptoms questionnaires and PROMs is beyond the scope of these guidelines. For more information, we recommend the 6th International Consultation on Incontinence review on PRO assessment [29]. To date, there is not one questionnaire that fulfils all requirements for assessment of women with LUTS. Clinicians must evaluate the tools that exist, for use alone or in combination, for assessment and monitoring of treatment outcome [30]. The questionnaires can be found on the following websites: www.iciq.net, https://eprovide.mapi-trust.org, www.pfizerpcoa.com, www.ncbi.nlm.nih.gov.

3.3 Bladder diaries

Measurement of the frequency and severity of LUTS is an important step in the evaluation and management of LUT dysfunction. Bladder diaries are a semi-objective method of quantifying symptoms, such as frequency of UI events, number of nocturia episodes, etc. They also quantify urodynamic variables, such as voided volume, 24-hour urine volume or nocturnal total urine volume.

Discrepancy between diary recordings and the patient rating of symptoms, e.g., frequency of UI, can be useful for patient counselling. Fluid intake and voided volume measurement can be used to support diagnoses and management planning, for example in OAB, and for identifying 24-hour or nocturnal polyuria. Diaries can also be used to monitor treatment response and are widely used in clinical trials. In patients with severe UI, a bladder diary is unlikely to accurately report 24-hour urine output.

Consensus terminology is now well-defined and widely accepted [1, 31]. However, the terms micturition diary, frequency/volume chart, bladder diary and voiding diary, have been used interchangeably for many years, but only bladder diaries include information on fluid intake, times of voiding, voided volumes, UI episodes, pad usage, degree of urgency and severity of UI recorded for at least 24 hours. When reviewing the evidence, all synonymous search terms have been included.

Two studies have demonstrated the reproducibility of diaries in both men and women [32, 33]. Another two studies have shown the feasibility, reliability and validity of the bladder diary [34, 35]. Further studies have demonstrated variability of diary data within a 24-hour period and compared voided volumes recorded in diaries with those recorded by uroflowmetry [36, 37]. Another study found that keeping a bladder diary had a therapeutic benefit [38].

A number of observational studies have demonstrated a close correlation between data obtained from bladder diaries and standard symptom evaluation [39–42]. The optimum number of days required for bladder diaries appears to be based on a balance between accuracy and compliance [43, 44]. Diary durations between three and seven days are routinely reported in the literature.

3.4 Urinalysis and urinary tract infection

Reagent strip (dipstick) urinalysis may indicate proteinuria, haematuria or glycosuria, or suggest UTI requiring further assessment. Please refer to the Urological Infections Guidelines for diagnosis and treatment of UTI [17].

Urine dipstick testing is a useful adjunct to clinical evaluation in patients in whom urinary symptoms are suspected to be due to UTI. Urinalysis negative for nitrite and leukocyte esterase may exclude bacteriuria in women with LUTS [45], and should be included, with urine culture when necessary, in the evaluation of all patients with LUTS. Urinary incontinence or worsening of LUTS may occur during UTI [46] and existing UI may worsen [47]. The rate and severity of UI were unchanged after eradication of asymptomatic bacteriuria in nursing home residents [48].

3.5 Post-void residual volume

Post-void residual (PVR) volume is the amount of urine that remains in the bladder after voiding. It is a measure of voiding efficiency, and results from a number of contributing factors. The detection of significant PVR volume is important because it may worsen symptoms and, more rarely, may be associated with UTI, upper urinary tract (UUT) dilatation and renal insufficiency. Both BOO and/or detrusor underactivity (DU) can potentially contribute to the development of significant PVR volume. Post-void residual volume can be measured by catheterisation or ultrasound (US).

Most studies investigating PVR volume have assessed mixed populations including those with neurogenic UI. In general, the data on PVR volume can be applied with caution to women with non-neurogenic LUTS. The results of studies investigating the best method of measuring PVR volume [48-53] have led to the consensus that US measurement of PVR volume is preferable to catheterisation due to its favourable risk–benefit profile.

The prevalence of significant PVR volume among patients with LUTS is uncertain, partly because of the lack of a standard definition of an abnormal PVR volume. In peri- and postmenopausal women without significant LUTS or pelvic organ symptoms, 95% had a PVR volume < 100 mL [54]. In women with UUI, PVR volume > 100 mL was found in only 10% of cases [55]. Other research has found that a high PVR volume is associated with POP, voiding symptoms and an absence of SUI [54, 56-58]. In women with SUI, the mean PVR volume was 39 mL measured by catheterisation and 63 mL measured by US, with 16% of women having PVR volume > 100 mL [59]. Some authors have suggested that it is reasonable to consider a PVR volume > 100 mL to be significant, although many women may remain asymptomatic and hence it is imperative to consider the clinical context [55]. There is no consensus on what constitutes a significant PVR volume in women; therefore, the Panel suggests the additional use of bladder volume efficiency (BVE). Bladder volume efficiency is the proportion of the total bladder volume that is voided by the patient. Bladder volume efficiency can be calculated as a percentage: BVE = voided volume (VV)/(VV+PVR) × 100. This may be a more reliable parameter to evaluate poor voiding [46].

3.6 Urodynamics

Urodynamic testing is widely used as an adjunct to clinical diagnosis, in the belief that it may help to provide or confirm diagnosis, predict treatment outcome or facilitate discussion during counselling. The simplest form of urodynamic evaluation is uroflowmetry. The maximum flow rate ($Q_{\text{max}}$), the volume voided and the shape of the curve in addition to the PVR volume (see above) are the most important aspects to be assessed [29]. The bladder should be sufficiently full because of the volume dependency of $Q_{\text{max}}$ [60, 61]. A minimum voided volume of 150 mL is advised in men, but there is little evidence to suggest a volume threshold in women. It is relevant to ask the patient whether or not the voiding is representative.

Invasive urodynamic tests are sometimes performed prior to invasive treatment of LUTS. These tests include multichannel cystometry and pressure–flow studies, ambulatory monitoring and video-urodynamics, and different tests of urethral function, such as urethral pressure profilometry and Valsalva leak point pressure (VLPP). The International Continence Society (ICS) and the United Kingdom Continence Society (UKCS) provide standards to optimise urodynamic test performance and reporting [62, 63]. A characteristic of a good urodynamic study is that the patient's symptoms are replicated, recordings are checked for quality control, and results interpreted in the context of the clinical problem, remembering that there may be physiological variability within the same individual [62]. Non-invasive alternatives for measurement of detrusor pressure and BOO include transabdominal wall near-infrared spectroscopy and US detrusor wall thickness analysis, but as yet, these techniques have not been adopted into routine clinical practice [29].

Further condition-specific information regarding the role of urodynamic testing in OAB, SUI, BOO and UAB can be found in respective sections of these guidelines.

3.6.1 Variability

In common with most physiological tests there is variability in urodynamic results. This has consequences for the reproducibility, diagnostic accuracy and predictive value of urodynamic testing. It has been stated that, at least in the case of cystometry and pressure–flow studies, one set of measurements suffices, but only if the patient's symptoms have been replicated [62]. Contradictory findings have been reported in studies assessing same-session repeatability of cystometric and pressure–flow studies [64, 65]. There is also conflicting evidence about the reproducibility of maximum urethral closure pressure (MUCP) measurement [64, 65]. One method of recording MUCP cannot be compared meaningfully to another [65, 66]. Valsalva leak point pressure measurement is not standardised and there is minimal evidence about its reproducibility. No studies on the reproducibility of ambulatory monitoring in non-neurological patients have been published [29].

3.6.2 Diagnostic accuracy

Clinical diagnosis and cystometric findings sometimes do not correlate [67, 68] and asymptomatic women may have abnormalities on urodynamic testing. As the urodynamic diagnosis is often taken as the benchmark in the assessment of LUT function, this implies that other tests of LUT function may be biased. The diagnostic accuracy of urethral pressure profilometry [69] and urethral retro-resistance pressure measurement in SUI is poor [29]. Valsalva leak point pressure did not reliably assess UI severity in a cohort of women selected for surgical treatment of SUI [70]. Urethral pressure reflectometry may have greater diagnostic accuracy but its clinical role remains unclear [71]. Ambulatory urodynamics may detect unexpected physiological variance from normal more often than conventional cystometry does, but the clinical relevance of this is also uncertain [72, 73].

A pressure–flow study, that is, the simultaneous measurement of flow rate and detrusor pressure during voiding, can reveal whether a poor flow rate and PVR volume are due to BOO, poor bladder contraction...
strength/detrusor underactivity (DU), or a combination of both. Also, it may provide information on the degree of pelvic floor relaxation and thus diagnose dysfunctional voiding. Several proposals to define BOO in women have been made. These definitions are based on detrusor pressure, either P_{det,max}Q_{max} or the maximum value P_{det,max} and the Q_{max} value, either during the pressure–flow study or during uroflowmetry. These measures are sometimes combined with the findings during fluoroscopic imaging (see Section 4.5.4.8) [74, 75]. Unlike the situation in men, there is no widely accepted threshold for BOO diagnosis in women. Bladder contraction strength parameters are derived from detrusor pressure and flow rate during a pressure–flow study or from stop tests [75], but again, validation is poor. Although these parameters estimate the strength of the contraction, they ignore its speed and persistence (see Section 4.4.3.2) [76]. A video-urodynamic study can be useful to detect the site of obstructed voiding, which may be anatomical or functional [77]. Also, video-urodynamics may detect bladder diverticulum or gross reflux as a pressure-absorbing reservoir.

### 3.6.3 Predictive value

Performing urodynamic evaluation is only useful if it leads to more effective clinical care and better outcomes. A Cochrane review of eight randomised controlled trials (RCTs) showed that use of urodynamic tests in women with UI increased the likelihood of prescribing drugs and did not increase the likelihood of undergoing surgery. However, there was no evidence that this influence on decision-making altered the clinical outcome of treatment [78]. Most RCTs addressed the utility of urodynamic tests on SUI only, including women with uncomplicated SUI. A meta-analysis including four RCTs comparing surgical outcomes in women with self-reported SUI (or stress-predominant MUI) who were investigated via urodynamics with women who had office evaluation only, found that there was no difference in cure and complication rates [79]. In contrast, a large retrospective multicentre study found that only 36% of patients were defined as uncomplicated according to the definitions used in large RCTs [80]. The urodynamic observations were not consistent with the pre-urodynamic diagnosis in 1276 out of 2053 patients (62.2%). Voiding dysfunctions were urodynamically diagnosed in 394 patients (19.2%) and planned surgery was cancelled or modified in 304 of 1582 patients (19.2%) in whom data were available, due to the urodynamic findings [81].

The predictive value of urethral function tests remains unclear. In observational studies, there was no consistent correlation between the results of these tests and subsequent success or failure of SUI surgery [40-42, 82]. The same was true in a secondary analysis of an RCT [83].

The presence of preoperative detrusor overactivity (DO) in women with stress-predominant MUI has been associated with postoperative UUI but did not predict overall treatment failure following mid-urethral sling (MUS) surgery or colpop-suspension [83]. The urodynamic diagnosis of DO had no predictive value for treatment response in studies on antimuscarinics, onabotulinumtoxinA and sacral nerve stimulation in patients with OAB symptoms [84, 85]. Augmentation cystoplasty aims to abolish DO, improve bladder compliance and increase functional bladder capacity but there is no evidence to guide whether or not preoperative urodynamics are predictive of outcome. Most clinicians would, however, consider preoperative urodynamics as essential prior to contemplating augmentation cystoplasty.

A pressure–flow study is capable of discriminating BOO from DU as a cause of voiding dysfunction. The predictive value of parameters derived from such a study for voiding dysfunction after a surgical procedure for SUI is however low. A low preoperative flow rate and a low detrusor voiding pressure have been shown to correlate with voiding dysfunction after a tension-free vaginal tape (TVT) and an autologous fascial sling procedure, respectively [86-88]. Bladder contraction strength parameters combining flow rate and detrusor pressure only poorly predicted voiding dysfunction after autologous fascial sling [89]. Post hoc analysis of two high-quality surgical trials of TVT, Burch colpo-suspension and autologous fascial sling showed that no preoperative urodynamic parameter predicted postoperative voiding dysfunction in a selected population of women with low preoperative PVR volume [90, 91].

The Panel recognises that it may be valuable to use urodynamic test results to select the optimum management strategy; however, there is inconsistent evidence regarding the predictive value of such tests. When urodynamics and clinical assessment (i.e., by history and examination) are in disagreement, there needs to be a careful re-evaluation of the clinical symptoms and investigation results to ensure that the diagnosis is correct before invasive treatments are contemplated. Expert opinion recognises urodynamic testing as the most comprehensive analysis of LUT function. The primary aim of urodynamics includes reproduction of the patient's symptoms. The information one obtains from urodynamics may be very valuable to discuss and manage expectation regarding invasive treatment.

3.7 Pad testing

Measurement of urine loss using an absorbent pad worn over a set period of time or during a protocol of physical exercise can be used to quantify the presence and severity of UI, as well as provide an objective evidence of response to treatment.

The clinical utility of pad tests in women with UI has been assessed in two SRs [92, 93]. A 1-hour pad test using a standardised exercise protocol and a diagnostic threshold of 1.4 g shows good specificity but lower sensitivity for symptoms of SUI and MUI. A 24-hour pad test using a threshold of 4.4 g is more reproducible but is difficult to standardise, with variation according to activity level [94]. A pyridium pad test showed fair agreement with UDS in the detection of SUI among women with genital prolapse, particularly in identifying occult incontinence in up to 10% of prolapse patients [19]. A pyridium pad test involves patients taking pyridium 200 mg three times daily, for a day, recording if an orange stain is noted on the pad and qualifying the type of leakage associated with the staining as either stress or urgency.

A pad test with a specific short graded exercise protocol also has diagnostic value but a negative test should be repeated with the degree of provocation increased [95]. The usefulness of pad tests in quantifying severity and predicting outcome of treatment is uncertain [92, 96, 97]. Pad tests are responsive to change following successful treatment [98]. Pad testing using a standardised bladder volume (50% of cystometric capacity) was suggested to allow for a more reliable assessment of UI in a small study of 25 women [99]. There is no evidence that one type of pad test is superior to another.

### 3.8 Imaging

Imaging improves our understanding of the anatomical and functional abnormalities that may cause LUTS. In clinical practice, imaging is used to understand the relationship between anatomy and function. Ultrasound and magnetic resonance imaging (MRI) have largely replaced x-ray imaging in the evaluation of the pelvic floor. Ultrasound is sometimes preferred to MRI because of its ability to produce three-dimensional (3D) and 4D (dynamic) images at lower cost and wider availability.

There is no need for UUT imaging unless a high-pressure bladder, severe POP or chronic urinary retention is suspected or diagnosed, or abnormal renal function tests are observed. In cases of suspected UI caused by an UUT anomaly or uretero-vaginal fistula, UUT imaging (urography, computed tomography [CT]) may be indicated [100].

#### 3.8.1 Ultrasound

Ultrasonography of the LUT plays a role in the differential diagnosis of women with LUTS and in cases presenting with haematuria.

Ultrasonography has been used in the evaluation of UI and pelvic floor since the 1980s. Different imaging approaches, such as abdominal, transvaginal, transrectal, perineal and transurethral are described. The bladder neck and urethra are easily visible and measurements can be done at rest and during straining, coughing and pelvic floor contraction. The parameters assessed in the diagnosis of SUI, for example, include bladder neck mobility or descent, urethro-vesical angle and urethral rotation [101, 102]. Ultrasonography can be used to assess PFM s and their function. Contraction of PFM results in displacement of pelvic structures that can easily be imaged on US. Integrity of the levator ani muscle can be determined by 3D transperineal US. Ultrasound may also provide information on the anatomical changes of the LUT and pelvic floor associated with persistence of symptoms post-treatment [103]. The specific role of US is discussed in the condition-specific sections of these guidelines where applicable.

#### 3.8.2 Detrusor wall thickness

As OAB syndrome is linked to DO, it has been hypothesised that frequent detrusor contractions may increase detrusor/bladder wall thickness (DWT/BWT). Transvaginal US seems to be more accurate with less interobserver variability than transabdominal and transperineal approaches [104]. Several cut-off points have been suggested, from 4.4 to 6.5 mm. Other studies are contradictory and did not find this correlation. No consensus exists as to the relationship between OAB and increased BWT/DWT [105], and there is no evidence that BWT/DWT imaging improves management of OAB. There is no widely accepted, standardised bladder volume for bladder wall thickness measurement.

In a retrospective study including 227 women with symptoms of voiding difficulty (hesitancy, intermittency and poor stream), 74 (32.6%) were diagnosed with voiding dysfunction on the basis of free uroflowmetry and residual urine. While controlling for the effect of DO, the relationships between DWT and different parameters of voiding function in pressure–flow studies and free uroflowmetry were examined. The results indicated that DWT was not associated with any urodynamic parameters that may indicate BOO [106].

#### 3.8.3 Magnetic resonance imaging

There is a general consensus that MRI provides good global pelvic floor assessment, including POP, defecatory function and integrity of the pelvic floor support [107]. However, there is a large variation in MRI interpretation between observers [108] and little evidence to support its clinical usefulness in the management of LUTS/UI. There is no conclusive evidence that MRI evaluation of POP is more clinically useful than vaginal examination. Studies have assessed the use of imaging to assess the mechanism of MUS insertion for SUI. One study suggested that MUS placement decreased mobility of the mid-urethra but not of the bladder neck [109]. Following MUS, a wider gap between pubic symphysis and sling (assessed by imaging) has been shown to correlate with a lower chance of cure of SUI [110].

3.9 Urinary biomarkers and microbiome

Interest in the role of urinary biomarkers for the diagnosis of LUT dysfunction has increased in recent years. Nerve growth factor (NGF), brain derived neurotrophic factor (BDNF), prostaglandin E2, adenosin triphosphate (ATP) and purinergic receptors (P2X) in bladder tissue have been studied as biomarkers for OAB. Serum beta natriuretic peptide (BNP), urinary 6-sulfatoxymelatonin and C-reactive protein (CRP), melatonin, vasopressin levels have been studied in relation to nocturia. For SUI, urinary IL 12-70, urinary NGF, N-telopeptide of type I collagen (NTx) and urinary microbiome have been studied. Currently, studies investigating urinary biomarkers are methodologically limited often due to failing to control for confounding variables and results are conflicting [111].

Another area of discovery is the role of urinary microbiome in identifying and differentiating various types of UI and other LUT disease in women. A SR described studies showing differences in the types and relative proportions of bacteria such as Lactobacillus, Gardnerella, and Atopobium vaginae, among women with different types of UI compared with healthy controls. Urinary microbiome has also been shown to differ depending on women’s response to anticholinergic treatment response [112]. Further research is needed before the place of urine microbiome assessment in the clinical pathway for women with LUTS is fully defined.

Further information on the diagnostic efficacy of biomarkers in OAB can be found in section 4.1.3.3

4. DISEASE MANAGEMENT

4.1 Overactive bladder

4.1.1 Epidemiology, aetiology, pathophysiology

Overactive bladder is defined by the ICS as “urinary urgency, usually accompanied by frequency and nocturia, with or without UUI, in the absence of UTI or other obvious pathology” [113]. Overactive bladder is a chronic condition and can have debilitating effects on QoL. The hallmark urodynamic feature is DO, although this may not be demonstrated in a large proportion of OAB patients, which may partly be due to failure to reproduce symptoms during urodynamic assessment.

The EPidemiology of InContinence (EPiC) study was one of the largest population-based surveys of the prevalence of LUTS and OAB [114]. It was a cross-sectional telephone survey of adults aged > 18 years conducted in five countries, including Canada, Germany, Italy, Sweden and the UK. The study included > 19,000 participants.
participants and demonstrated an overall prevalence of OAB symptoms of 11.8% (10.8% in men and 12.8% in women). Other studies have reported prevalences of up to 30 to 40%, with rates generally increasing with age [5].

Various theories have been proposed to explain the pathophysiology of OAB, mainly relating to imbalances in inhibitory and excitatory neural pathways to the bladder and the urethra or sensitivity of bladder muscle receptors. However, no definite identifiable causes have been established.

4.1.2 Classification
Overactive bladder is generally classified into wet and dry, based on the presence or absence of associated UI.

4.1.3 Diagnostic evaluation
Evaluation of symptoms of OAB follows the general pathway of evaluation of women with LUTS.

4.1.3.1 Bladder diaries
Diaries are particularly helpful in establishing and quantifying symptoms of frequency, urgency and UI, and may be valuable in assessing change over time or response to treatment. Several observational studies have demonstrated a close correlation between data obtained from bladder diaries and standard symptom evaluation [39-42]. The optimum number of days required for bladder diaries appears to be based on a balance between accuracy and compliance. Diary duration of three to seven days is routinely used in the literature.

4.1.3.2 Urodynamics
Urodynamics is essential in establishing the presence of DO, but its absence does not preclude diagnosis of OAB, which is based on symptoms alone.

A Cochrane review of seven RCTs showed that use of urodynamic tests increased the likelihood of prescribing drugs or avoiding surgery. However, there was no evidence that this influence on decision-making altered the clinical outcome of treatment [78]. A sub-analysis of an RCT comparing fesoterodine to placebo [85] showed that the urodynamic diagnosis of DO had no predictive value for treatment response.

4.1.3.4 Urinary biomarkers
A SR and meta-analysis indicated that urinary NGF (standard mean difference [SMD]: 1.45; 95% confidence interval [CI]: 0.53-2.36), NGF/Cr ratio (SMD: 1.23; 95% CI: 0.67-1.78), BDNF/Cr ratio (SMD: 0.78; 95% CI: 0.006-1.50), and BDNF/Cr ratio (Risk ratio [RR]: 0.78; 95% CI: 0.006-1.50) were increased in female OAB patients compared to healthy controls, whereas no difference was found for the PGE2/Cr and ATP/Cr ratios [115]. The current data is inadequate to assess any other potential biomarkers, such as urinary malondialdehyde (UMDA), ATP, and cytokines, in the management of OAB in female patients. Further studies are needed to establish their potential as diagnostic and management tools in OAB women.

4.1.4 Disease management
4.1.4.1 Conservative management
In clinical practice, it has long been the convention that non-surgical therapies are recommended first because they usually carry the lowest risk of harm. While this remains true for non-pharmacological conservative treatments [e.g., pelvic floor muscle training (PFMT)], increasing concerns regarding the adverse events of some pharmacological treatments used to treat LUTS (e.g., anticholinergic drugs), particularly regarding cognitive function, have emerged and patients should be fully counselled regarding this potential risk.
4.1.4.1.1 Addressing underlying disease

LUTS, especially in elderly patients, are associated with multiple comorbid conditions including:

- cardiac failure;
- chronic renal failure;
- diabetes;
- chronic obstructive pulmonary disease;
- neurological disease;
- general cognitive impairment;
- sleep disturbances, e.g., sleep apnoea;
- depression;
- metabolic syndrome.

It is possible that improvement of associated disease may reduce the severity of urinary symptoms. However, this is often difficult to assess as patients frequently have more than one condition. However, if new treatment for any associated comorbidity has been linked (usually by the patient or carer) to a deterioration in LUTS then this should be reviewed by a health care practitioner (HCP).

One study involving middle-aged women with type 1 diabetes mellitus showed that 10% had UUI. The study showed no correlation between early intensive insulin treatment of type 1 diabetes mellitus vs. conventional insulin treatment and found no difference in the prevalence of UI in these patients later in their lives [113].

### 4.1.4.1.2 Adjustment of other medication

Although LUTS are listed as adverse effects of many drugs, this mainly derives from uncontrolled individual patient reports and post-marketing surveillance. Few controlled studies have used the occurrence of LUTS as a primary outcome, or were powered to assess the occurrence of statistically significant LUTS or worsening rates against placebo. In most cases, it is therefore not possible to be sure that any drug causes OAB/LUTS.

A structured scoping review failed to identify any studies addressing whether adjustment of specific medications could alter existing symptoms of OAB.

### 4.1.4.1.3 Urinary containment

Urinary containment is important for people with OAB wet or UUI when active treatment does not cure the problem, is delayed, or when it is not available or not possible. Some individuals may prefer urinary containment rather than active treatment with its associated risks. Containment includes the use of absorbent pads, urinary catheters, external collection devices and intravaginal devices. Detailed literature summaries can be found in the current International Consultation on Urological Diseases (ICUD) monograph [8] and in a European Association of Urology Nurses guidance document [116].
A SR of six RCTs comparing different types of pads found that pads filled with superabsorbent material were better than standard pads, while evidence that disposable pads were better than washable pads was inconsistent [117]. A series of three crossover RCTs examined performance of different pad designs for differing populations [118, 119]. For women with light UI, disposable insert pads (within washable pouch pants) were most effective. In adults with moderate/severe UI, disposable pull-up pants were more effective for women.

A Cochrane review summarised three RCTs comparing different types of long-term indwelling catheters and found no evidence that one catheter material or type of catheter was superior to another [120]. A SR of non-randomised studies found no differences in UTI outcome or UUT changes between use of suprapubic or urethral catheter drainage; however, patients with suprapubic catheters were less likely to have urethral complications [121].

Catheter-related bladder discomfort may be significant in women. Anticholinergics have been proposed to prevent or reduce this issue, but most of the evidence comes from clinical trials in the postoperative period, and the results are controversial [122-125]. One retrospective study including 40 women (most of them neurogenic) with long-term bladder catheters found intravesical botulinum toxin injections helped to prevent bladder pain and discomfort and catheter bypass/leakage. Patients reported an improvement in QoL and a significant 83% reduction in urine leakage [126].

Clean intermittent self-catheterisation (CISC) is the most commonly used therapy to manage high PVR volume and urinary retention [116]. It reduces the risk of complications such as UTI, UUT deterioration, bladder stones and overflow UI etc. It has not yet been established whether the incidence of UTI, other complications and user satisfaction are affected by either sterile or clean intermittent catheterisation (IC), coated or uncoated catheters or by any other strategy [127]. The use of hydrophilic catheters may be associated with a lower rate of UTI, but further evidence is needed, as current data comes from neurogenic patients [128]. The average frequency of catheterisation is four to six times per day [129] and the catheter sizes most often used are 12–16 Fr. In aseptic IC, an optimum frequency of five times showed a reduction of UTI [129]. Frequency of catheterisation needs to be based on individual need and capability, to prevent chronic and repeated over-filling of the bladder [130]. Thorough counselling regarding techniques, frequency, equipment and adverse effects of CISC should be given to all potential patients in line with good medical practice.

For people using CISC, a Cochrane review found no evidence that one type of catheter or regimen of catheterisation was better than another [131]. However, a recent narrative review suggests that, in certain populations, single-use catheters may reduce urethral trauma and UTI [132]. A Cochrane review summarising five trials comparing bladder washout policies in adults with indwelling urinary catheters found inconsistent evidence of benefit [133].

A further Cochrane review summarising eight trials of whether antibiotic prophylaxis was beneficial for adults using CISC or indwelling catheterisation found it reduced incidence of symptomatic UTI but possible harms were not assessed [134]. A multicentre RCT from the UK reported that prophylaxis was well-tolerated but development of antibiotic resistance was a concern [135].

### 4.1.4.1.4 Lifestyle interventions

Examples of lifestyle factors that may be associated with UI include obesity, smoking, level of physical activity, regulation of bowel habit and fluid intake. Modification of these factors may improve symptoms of OAB.
4.1.4.1.4 Caffeine intake
Many drinks contain caffeine, particularly coffee, tea and cola. Conflicting epidemiological evidence of urinary symptoms being aggravated by caffeine intake has focused on whether caffeine reduction improves LUTS [136, 137]. A scoping review of fourteen interventional and twelve observational studies reported that reduction in caffeine intake may reduce symptoms of urgency, but the certainty of evidence was low, with significant heterogeneity in study populations [138].

4.1.4.1.4.2 Fluid intake
Modification of fluid intake, particularly restriction, is a strategy commonly used by people with OAB to relieve symptoms. Any advice on fluid intake given by HCPs should be based on 24-hour fluid intake and urine output measurements as retrieved from the bladder diary. From a general health point of view, it should be advised that fluid intake should be sufficient to avoid thirst and that an abnormally low or high 24-hour urine output should be investigated. The few RCTs that have been published provide inconsistent evidence [139-141]. In most studies, the instructions for fluid intake were individualised and it was difficult to assess participant adherence. All available studies were in women. An RCT showed that a reduction in fluid intake by 25% improved symptoms in patients with OAB but not UI [141]. Personalised fluid advice compared to generic advice made no difference to continence outcomes in people receiving anticholinergics for OAB, according to an RCT comparing drug therapy alone to drug therapy with behavioural advice [142]. Patients should be warned of the potential consequences of fluid restriction such as worsening of constipation or development of UTI.

4.1.4.1.4.3 Obesity and weight loss
Being overweight or obese has been identified as a risk factor for LUTS in many epidemiological studies [143, 144]. There is evidence that the prevalence of both UUI and SUI increases proportionately with body mass index [145]. However, the evidence base largely relates to obesity and SUI rather than UUI and OAB. Therefore, no definite inference can be drawn between obesity and the prevalence of OAB.

4.1.4.1.4.4 Smoking
Smoking cessation is a general public health measure and has been shown to be weakly associated with improving urgency, frequency and UI [146, 147]. The effect of smoking cessation on LUTS was described as uncertain in a health technology assessment review [148].

4.1.4.1.5 Behavioural and physical therapies
Approaches include bladder training (BT) and PFMT. Almost always in clinical practice, these are introduced as part of a package of care including lifestyle changes, patient education and possibly some cognitive therapy. The extent to which individual therapists motivate, supervise and monitor these interventions is likely to vary but it is recognised that these influences are important components of the whole treatment package, especially for adherence to training.

A SR on cognitive components of behavioural therapies for OAB concluded that they were neither well described nor rationalized. Behavioural therapy that includes a cognitive component shows promise for OAB
treatment, but its relative importance has not been evaluated nor rigorously studied. Cognitive strategies include mental distraction (the most common), relaxation and mindfulness practices [149].

4.1.4.1.5.1 Prompted voiding and timed voiding
The term ‘prompted voiding’ implies that carers, rather than the patient, initiate the patient going to void with the aim of preventing or reducing UI. This applies largely to an assisted care setting. One SR (including nine RCTs), comparing prompted voiding in comparison to standard care, suggested evidence of short-term benefit for management of UI, but longer-term effects are unknown [150].

Timed voiding is defined as fixed, predetermined, time intervals between toileting, applicable for those with or without cognitive impairment. A Cochrane review of timed voiding reviewed two RCTs, finding inconsistent improvement in continence compared with standard care in cognitively impaired adults [151].

4.1.4.1.5.2 Bladder training
Bladder training is a programme of patient education along with a scheduled voiding regimen with gradually increasing intervals. Specific goals are to correct faulty patterns of frequent urination, improve control over bladder urgency, prolong voiding intervals, increase bladder capacity, reduce incontinent episodes and restore patient confidence in controlling bladder function. The ideal form or intensity of a BT programme for OAB/UI is unclear. It is also unclear whether or not BT can prevent development of OAB/UI.

There have been three SRs on the effect of BT compared to standard care confirming that BT is more effective than no treatment in improving UUI [67, 148, 152]. The addition of BT to anticholinergic therapy did not improve UUI compared to anticholinergics alone but it did improve frequency and nocturia [153]. A review identified seven RCTs in which BT was compared to drug therapy alone and only showed a benefit for oxybutynin for cure or improvement of UUI [153].

4.1.4.1.5.3 Pelvic floor muscle training
An immediate effect of PFM contraction is simultaneous inhibition of urgency, detrusor contraction and incontinence [154]. Intensive and regular strength training of the PFMs over time increases both PFM contraction strength and endurance, and changes the morphology of the pelvic floor, which may yield more effective inhibition of the detrusor and help to stabilize the proximal urethra and improve urethral function. There is a lack of basic and mechanistic studies to confirm that change in pelvic floor morphology improves OAB symptoms.

A SR of eleven RCTs [155] including women with OAB compared the efficacy of PFMT vs. inactive control, usual care, other lifestyle modification or other intervention. Pelvic floor muscle training significantly reduced OAB symptoms (frequency and UUI) in five RCTs, while the remaining six reported no significant difference. Significant heterogeneity in protocols precluded meaningful comparisons.

4.1.4.1.5.4 Electrical stimulation
The methods of delivery of electrical stimulation (ES) vary considerably. Electrical stimulation of the PFM can also be combined with other forms of conservative therapy; e.g., PFMT with and without biofeedback. Electrical stimulation is often used to assist women who cannot initiate contractions to identify their PFMs and in patients with OAB and UUI with the aim of inhibiting detrusor contraction. There is, however, a lack of basic and mechanistic studies to confirm this theory.

A SR of the effect of ES included 51 trials with 3,443 adults with OAB symptoms [156], with quality of evidence ranging from very low to moderate. Moderate-quality evidence suggests that ES is more likely to improve OAB symptoms compared to sham control, no treatment or placebo. Moderate-quality evidence suggests that ES is more likely to improve OAB symptoms compared to anticholinergic therapy. There is insufficient evidence for comparisons with PFMT and between different types of ES.

4.1.4.1.5.5 Acupuncture
A SR with meta-analysis of ten RCTs including 794 patients (590 women) reported that acupuncture might have an effect in reducing OAB symptoms compared to sham treatment [157]. The studies were of low quality and compared electro-acupuncture vs. sham acupuncture, or electro-acupuncture plus tolterodine vs. tolterodine alone. An up-to date SR from the Cochrane collaboration is planned for 2022 [158].

4.1.4.1.5.6 Posterior tibial nerve stimulation
Electrical stimulation of the posterior tibial nerve (PTNS) delivers electrical stimuli to the sacral micturition centre via the S2–S4 sacral plexus. Stimulation is percutaneous with a fine (34-G) needle, inserted just above the medial aspect of the ankle (P-PTNS). Transcutaneous stimulation is also available (T-PTNS) that delivers
stimulation via surface electrodes that do not penetrate the skin. Treatment cycles typically consist of twelve weekly treatments of 30 minutes.

4.1.4.1.5.6.1 Percutaneous posterior tibial nerve stimulation
The reviewed studies included a SR, two twelve-week RCTs of P-PTNS compared with sham treatment [159-161], one comparing PTNS to tolterodine, and a three-year extension trial utilising a maintenance protocol in patients with UUI [162, 163]. The results of studies of PTNS in women with refractory UUI are consistent. These results suggest that PTNS improves UUI in women who do not have adequate improvement or cannot tolerate anti-muscarinic therapy. Improvements in voiding frequency, nocturia, urgency, incontinence episodes, cystometric capacity and compliance were described in the SR [161]. The major complication was pain at the puncture site, but the incidence was low. However, there was no good evidence that PTNS cures UUI in women. In addition, PTNS is no more effective than tolterodine for improvement of UUI in women.

4.1.4.1.5.6.2 Transcutaneous posterior tibial nerve stimulation
A small RCT compared T-PTNS plus standard treatment (PFMT and BT) with PFMT and BT alone in older women [164]. Women in the T-TPNS group were more likely to achieve improvement at the end of therapy. A SR of thirteen trials (ten RCTs and three cohort studies) compared the efficacy of T-PTNS (duration four to twelve weeks) with sham treatment, anticholinergics, and exercise in treatment of adults with OAB symptoms [165]. Of note, the populations were adult women and men, and some studies included patients with neurogenic OAB. Meta-analysis was possible in two RCTs comparing T-PTNS with sham treatment, and revealed mean reduction in total international consultation on incontinence modular questionnaire (ICIQ) Urinary Incontinence Short Form (ICIQ-UI SF) associated with T-PTNS of −3.79 points.

A SR with meta-analysis including three RCTs (two RCTs comparing P-PTNS with solifenacin and one RCT comparing T-PTNS with oxybutynin) found PTNS to be more effective than anticholinergics in improving UUI in women with OAB on short-term follow-up of ≤ 12 weeks (mean difference [MD]: -0.67; 95% CI: -1.31 to -0.02). The certainty of evidence was low to moderate. However, the meta-analysis revealed no statistically significant difference between PTNS and anticholinergics in improvement of mean symptoms scores on validated questionnaires, frequency, or urgency episodes [11]. Adding anticholinergics to PTNS added no statistically significant value to improvement of any of OAB symptoms than PTNS alone [166].

A small RCT compared BT alone, BT plus P-PTNS and BT plus T-PTNS in women with idiopathic OAB. Both P-PTNS and T-PTNS were more effective than BT alone. These two tibial nerve stimulation methods had similar clinical efficacy but with slight differences: TTNS had shorter preparation time, less discomfort level and higher patient satisfaction than PTNS [166].

4.1.4.2 Pharmacological management

4.1.4.2.1 Anticholinergic drugs

Anticholinergic (antimuscarinic) drugs are currently the mainstay of treatment for OAB. They differ in their pharmacological profiles, such as muscarinic receptor affinity and other modes of action and in their pharmacokinetic properties, such as lipid solubility and half-life.

The evaluation of cure or improvement of OAB is made harder by the lack of standard definitions. In general, a SR noted that the overall treatment effect of drugs is usually small but larger than that of placebo. Some RCTs have UI as an outcome rather than UUI. Dry mouth is the commonest adverse effect, although constipation, blurred vision, fatigue and cognitive dysfunction may occur with anticholinergic drugs [152].

Immediate-release (IR) anticholinergic preparations provide maximum dosage flexibility, including an off-label on-demand use. Immediate-release drugs have a greater risk of adverse effects than extended release (ER) formulations because of differing pharmacokinetics. A transdermal delivery system and gel developed for oxybutynin provide alternative formulations.

Seven SRs of individual anticholinergic drugs vs. placebo have been reviewed [152, 167-172]. Most studies included patients with a mean age of 55–60 years. The evidence reviewed was consistent, indicating that ER and IR formulations of anticholinergics offer clinically significant short-term improvement of OAB compared to placebo. On balance, IR formulations tend to be associated with more adverse effects compared to ER formulations [171].

A network meta-analysis of 128 RCTs comparing anticholinergics with placebo or other anticholinergics revealed that all anticholinergics, except imidafenacin, showed significant cure or improvement rates for OAB symptoms in both sexes [173].

Cure of UUI is deemed to be the most important outcome measure. Table 1 shows a summary of the findings from SRs [152]. Every drug for which cure of UUI was available showed superiority compared to placebo, but the absolute size of the effect was small. There is limited evidence that patients who do not respond to first-line anticholinergic treatment respond to a higher dose or a different anticholinergic agent [174, 175]. Risk of adverse events is often represented by trial withdrawal, although this does not reflect clinical practice. The cure rates for darifenacin were not included in the US Agency for Healthcare Research and Quality (AHRQ) review. Continence rates were 29–33% for darifenacin compared to 17–18% for placebo [152]. Transdermal oxybutynin showed a significant improvement compared with placebo and other oral formulations in the number of incontinence episodes and micturitions per day but cure of UI was not reported as an outcome [152].

Oxybutynin topical gel was superior to placebo for improvement of UUI, with a higher proportion of participants being cured [152, 176].

4.1.4.2.1.1 Comparison of different anticholinergic agents

Head-to-head comparison trials of the efficacy and adverse effects of different anticholinergic agents are of interest for decision-making.

A network meta-analysis revealed no clear best anticholinergic preparation for cure or improvement [173]. Darifenacin (40%), tolterodine IR and oxybutynin ER (13% each) appeared to score highest in indirect comparisons. Fesoterodine and oxybutynin IR were more effective than oxybutynin (transdermal) and tolterodine ER. There were no clinically significant differences between anticholinergics for voiding and UI outcomes.

Another network meta-analysis of 53 RCTs compared the efficacy and tolerability of solifenacin 5 mg with other oral anticholinergics in the treatment of adults with OAB symptoms [177]. Solifenacin 5 mg/day was significantly more effective than tolterodine 4 mg/day for reducing UUI episodes, but significantly less effective than solifenacin 10 mg/day for reducing micturition episodes. Solifenacin 5 mg/day showed significantly lower risk of dry mouth compared with other anticholinergics. There were no significant differences for the risk of blurred vision or constipation.

It is notable that nearly all the primary studies in this category were industry sponsored. Upward dose titration is often included in the protocol for the experimental arm but not for the comparator arm. In general, these studies have been designed to achieve regulatory approval. They have short treatment durations (twelve weeks) and a primary outcome of a change in OAB symptoms rather than a cure of, or an improvement in, UUI, which were generally analysed as secondary outcomes. The clinical utility of these trials in real-life practice is therefore debatable. Most trials were of low or moderate quality [169]. The 2012 AHRQ review included a specific section addressing comparisons of anticholinergic drugs (Table 1).

No single anticholinergic agent improved QoL more than another [169]. Dry mouth is the most prevalent adverse effect. Extended release formulations of short- and longer-acting drugs are associated with lower rates of dry mouth than IR preparations are [169, 178]. Oxybutynin IR shows higher rates of dry mouth than tolterodine IR and trospium IR show, but lower rates of dry mouth than darifenacin, 15 mg daily [169, 178]. Overall, oxybutynin ER causes higher rates of dry mouth than tolterodine ER does, although the incidence of moderate or severe dry mouth is similar. Transdermal oxybutynin has a lower rate of dry mouth than oxybutynin IR and tolterodine ER have, but an overall higher rate of withdrawal due to adverse skin reactions [169]. Solifenacin 10 mg daily has higher rates of dry mouth than tolterodine ER [169]. Fesoterodine 8 mg daily has a higher rate of dry mouth than tolterodine 4 mg daily [179-181]. Similar discontinuation rates have been observed, irrespective of differences in the occurrence of dry mouth.

4.1.4.2.1.2 Anticholinergic drugs versus conservative treatment

The choice of pharmacologic vs. conservative treatment of OAB patients is an important question. More than 100 RCTs and high-quality reviews are available [153, 169, 170, 182-184]. Most of these were independent studies. The main focus of the reviews was to compare the different drugs used to treat UUI. A U.S. health technology assessment [182] found that trials were of a low or moderate quality.

The combination of BT and solifenacin in female patients with OAB confers no additional benefit in terms of continence compared with solifenacin monotherapy [185]. A recent Cochrane review on the benefit of adding PFMT to other active treatments of UI in women showed insufficient evidence of any benefit in adding PFMT to drug treatment [186].

One RCT reported a similar improvement in subjective parameters with T-PTNS or oxybutynin [187]. One study compared tolterodine ER to transvaginal/anal ES in women with OAB symptoms and/or UUI without demonstrating any differences in UI outcomes [188].

A SR with meta-analysis included RCTs combining anticholinergics with various non-invasive modalities including pregabalin, topical estrogenic, and physiotherapy. The review showed that these combinations were associated with significantly higher improvement in mean symptoms score on validated questionnaires.
(6 RCTs, MD: 0.55; 95% CI: 0.16-0.95), urgency episodes (4 RCTs, MD: 0.68; 95% CI: 0.04-1.32) and UUI episodes (5 RCTs, MD: 1.18; 95% CI 0.18-2.17). The quality of evidence was low to moderate [11].

A SR with meta-analysis of 57 RCTs assessed the role of placebo in patients with OAB, it showed that placebo had age-dependent statistically significant effect on improvement of OAB symptoms including urgency daily episodes (MD: -0.51; 95% CI: -0.60 to -0.43) and UUI episodes (MD: -0.05; 95% CI: -0.61 to -0.39) [189]. The authors concluded that placebo response is non-negligible and is of importance in RCTs as a control arm. The same group published a SR with meta-analysis of data retrieved from 57 RCTs on the nocebo effect of pharmacotherapy in patients with OAB (up to 80% females). They reported dry mouth as the most common reported adverse event with mean rate of 4.9% (95% CI: 0.042 to -0.057) followed by constipation 2.6%, (95% CI: 0.022 to 0.031), the authors concluded that HCPs should appreciate the possible positive and negative patient expectation regarding pharmacotherapy for OAB in order to optimise the individual outcomes [190].

4.1.4.2.1.3 Anticholinergic drugs: adherence and persistence
Most studies on anticholinergic medication are short-term (twelve weeks). Adherence in clinical trials is considered to be higher than in clinical practice [191]. This topic has been reviewed for the development of a previous version of these guidelines [192]. The main drugs studied were oxybutynin and tolterodine IR and ER. Non-persistence rates were high for tolterodine at twelve months, and particularly high (68–95%) for oxybutynin. Two open-label extensions of RCTs of fesoterodine 8 mg showed adherence rates at two years of 49–84% [193, 194].

Five articles reported median days to discontinuation, but follow-up periods varied from < 30 up to 50 days [195-199]. In a military health system where free medication was provided, the median time to discontinuation extended to 273 days [196].

Data on adherence/persistence from open-label extension populations are questionable as it could be argued that these patients are self-selected on the basis of their compliance. A longitudinal disease analyser database study has indicated an increasing discontinuation rate, following treatment with anticholinergics, from 74.8% at one year to 87% at three years [200].

Several of the RCTs tried to identify the factors associated with low/lower adherence or persistence of anticholinergics. These were identified as:
• low level of efficacy (41.3%);
• adverse events (22.4%);
• cost (18.7%), although higher adherence rates were observed when drugs were provided at no cost to patients [196].

Other reasons for poor adherence included:
• immediate release formulations (lower persistence compared with ER formulations);
• age (lower persistence among younger adults);
• unrealistic expectations of treatment;
• gender distribution (better adherence/persistence in female patients);
• ethnic group (African–Americans and other ethnic minorities are more likely to discontinue or switch treatment).

4.1.4.2.2 Beta-3 agonists

Beta-3 adrenoceptors are the predominant beta receptors expressed on detrusor smooth muscle cells and their stimulation is thought to induce detrusor relaxation. Mirabegron was the first clinically available beta-3 agonist. Vibegron is another beta-3 agonist commercially available in some countries.

Mirabegron has undergone evaluation in industry-sponsored phase II and III trials [201-204]. Three SRs assessing the clinical effectiveness of mirabegron [201, 202, 205] reported that mirabegron at doses of 25, 50 and 100 mg results in significantly greater reduction in UI episodes, urgency episodes and micturition frequency than placebo, with no difference in the rate of common adverse events [202]. The dry rates in most of these trials are 35–40% for placebo and 43–50% for mirabegron. In all trials the significant differences were consistent only for improvement but not for cure of UI. Similar improvements in the frequency of UI episodes and micturition frequency were found whether or not patients had previously tried anticholinergic agents.

One SR showed that mirabegron is as efficacious as most anticholinergics in reducing UUI episodes [206]. One SR [207] assessed the outcomes of mirabegron in women with OAB. It included seven RCTs, three non-RCTs and eleven observational studies. The review reported no statistical difference between mirabegron and anticholinergics in decreasing OAB symptoms on voiding diaries and symptom questionnaires on short-term follow-up (up to twelve weeks). However, at one year follow-up, there was statistically significant decrease in OAB symptoms (MD: -0.35; 95% CI: -0.51 to -0.19) in favour of mirabegron.

The most common adverse events in the mirabegron groups were hypertension (7.3%), nasopharyngitis (3.4%) and UTI (3%), with the overall rate similar to that with placebo [201, 204, 208].

A SR with meta-analysis of data pooled from three RCTs comparing vibegron (75 mg or 100 mg) with placebo in 2120 patients with OAB revealed significant improvement of urgency episodes (MD: -0.77; 95% CI: -1.03 to -0.52) and UUI episodes (MD: -0.45; 95% CI: -0.64 to -0.34) and mean voided volume (MD: 22.2; 95% CI: 17.36 to 27.7) associated with vibegron [209]. The review also reported that vibegron showed a favourable safety profile. Another SR that included three high-quality RCTs compared vibegron with anticholinergic monotherapy (imidacine and tolterodine) concluding similar efficacy in terms of improvements in mean number of micturitions, urgency and UUI episodes, but with less dry mouth in vibegron groups [210].

In a twelve-month, active-controlled RCT of mirabegron 50/100 mg vs. tolterodine ER 4 mg, improvement in efficacy at twelve weeks was sustained at twelve months in all groups. The reported dry rates at twelve months were 43%, 45% and 45% for mirabegron 50 mg, 100 mg and tolterodine 4 mg respectively [208]. Post hoc analyses of RCTs showed that clinical improvement in OAB severity translates into improvement in health-related quality of life (HRQoL), and efficacy is maintained in patients with more severe UI [211, 212]. No risk of QTc prolongation [213] and no raised intraocular pressure [214] were observed up to the 100 mg dose; however, patients with uncontrolled hypertension or cardiac arrhythmia were excluded from these trials.

There is no significant difference in the rate of adverse effects at different doses of mirabegron [208]. Patients on concurrent medication (e.g., metoprolol) should be counselled that, due to common metabolic pathways, their drug dose may need to be adjusted. In the case of patients taking metoprolol, blood pressure should be monitored after starting mirabegron and, if necessary, the metoprolol dose may need to be changed.

Equivalent adherence was observed for tolterodine and mirabegron at twelve months (5.5% and 3.6%), although the incidence of dry mouth was significantly higher in the tolterodine group [208]. In mirabegron-treated patients, improvement in objective outcome measures correlates directly with clinically relevant
PROMs (Overactive Bladder questionnaire and Patient Perception of Bladder Condition) [211, 215]. Data from a large Canadian Private Drug Plan database suggest a higher adherence rate for mirabegron compared to anticholinergics [216].

An RCT in patients who had inadequate response to solifenacin monotherapy 5 mg demonstrated that combination treatment with mirabegron 50 mg had a higher chance of achieving clinically meaningful improvement in UI as compared to dose escalation of solifenacin [217].

4.1.4.2.3 Anticholinergics and beta-3 agonists: elderly patients and cognition

Trials have been conducted in elderly patients with OAB. Considerations in this patient group include the multifactorial aetiology of OAB, comorbidities such as cognitive impairment, the effect of concomitant medications, and the risk of adverse events. The effects of anticholinergic agents on cognition have been studied in more detail.

Systematic reviews have included sections on the efficacy and safety of anticholinergics in elderly patients [152, 169]. A 2012 SR found inconclusive evidence of the impact of anticholinergics on cognition [218].

Two recent longitudinal cohort studies in patients using anticholinergic drugs showed deterioration in cognitive function, alteration in central nervous system metabolism and an association with brain atrophy [219, 220]. As most of the study periods are short (four to twelve weeks), the long-term impact of anticholinergic agents specifically approved for OAB treatment on specific patient cohorts are poorly understood [221-224].

- **Oxybutynin:** There is evidence that oxybutynin IR may cause/worsen cognitive dysfunction in adults [221, 223, 225, 226]. One RCT with oxybutynin topical gel focused on cognitive and psychomotor function after one week of treatment showed no clinically meaningful effect on recent memory or other cognitive functions in healthy elderly adults [226]. Another retrospective study did not show cognitive impairment after four weeks of treatment with transdermal oxybutynin [223]. Recent evidence has emerged from a prospective cohort study showing cumulative cognitive deterioration associated with prolonged use (mean follow-up 7.3 years) of anticholinergic medication including oxybutynin [219]. Another prospective cohort study including 376 nursing residents aged 65 and older taking oxybutynin and tolterodine showed a decline in activity of daily living after a median follow-up of 141 days, in spite of concomitant treatment with cholinesterase inhibitors [227].

- **Solifenacin:** One pooled analysis [228] showed that solifenacin did not increase cognitive impairment in elderly patients. No age-related differences in the pharmacokinetics of solifenacin in different age groups were found, although more frequent adverse events in patients aged > 80 years were observed. No cognitive effect on healthy elderly volunteers was shown [229]. In a sub-analysis of a large trial, solifenacin 5–10 mg improved symptoms and QoL in people aged ≥ 75 years who had not responded to tolterodine [230]. In patients with mild cognitive impairment, aged ≥ 65 years, solifenacin showed no difference in efficacy between age groups and a lower incidence of most adverse effects compared to oxybutynin IR [226, 231].

- **Tolterodine:** No change in efficacy or adverse effects related to age has been reported, although a higher discontinuation rate was found for both tolterodine and placebo in elderly patients [221]. Two RCTs in elderly patients found similar efficacy and adverse effect profile to those in younger patients [232-235].
Post hoc analysis has shown little effect on cognition. One non-randomised comparison showed lower rates of depression in elderly participants treated with tolterodine ER compared to oxybutynin IR [236]. Duration of the RCTs was short (twelve weeks).

- **Darifenacin**: Two RCTs in the elderly population (one in patients with UUI and the other in volunteers) concluded that, compared with placebo, darifenacin was effective with no risk of cognitive change, measured as memory scanning tests [237, 238]. Another study on darifenacin and oxybutynin ER in elderly people concluded that the two agents had similar efficacy, but that cognitive function was more often affected in the oxybutynin ER arm [223].

- **Trospium chloride**: Trospium does not appear to cross the blood–brain barrier in healthy individuals due to its molecular characteristics (quaternary amine structure and hydrophilic properties). Two studies in healthy volunteers using electroencephalography showed no effect from trospium, while tolterodine caused occasional changes and oxybutynin caused consistent changes [239, 240]. No evidence as to the comparative efficacy and adverse effect profiles of trospium in different age groups are available. However, there is some evidence that trospium does not impair cognitive function in Alzheimer’s disease patients if combined with cholinesterase inhibitors in a six month period [224], or in non-cognitively impaired patients over shorter periods (twelve weeks) [241] and that it is effective compared to placebo in the elderly [242].

- **Fesoterodine**: Pooled analyses of the RCTs of fesoterodine confirmed the efficacy of 8 mg but not 4 mg dose in patients aged > 75 years [193]. Adherence was lower in patients aged > 75 years but effects on mental status were not reported [181, 193, 243]. A more recent RCT showed efficacy of fesoterodine in vulnerable elderly people with no differences in cognitive function at twelve weeks [244].

- **Mirabegron**: Analysis of pooled data from three RCTs showed efficacy and safety of mirabegron in elderly patients [245].

4.1.4.2.3.1 Applicability of evidence to the general elderly population

It is not clear how much the data from pooled and subgroup analyses from large RCTs can be extrapolated to a general ageing population. Community-based studies of the prevalence of anticholinergic adverse effects may be the most helpful [246]. When starting anticholinergics in elderly patients, mental function should be assessed objectively and monitored [247]. No consensus exists as to the best mental function test to detect changes in cognition [227, 248].

4.1.4.2.3.2 Anticholinergic burden

Several drugs have anticholinergic effects and, if another anticholinergic drugs are prescribed, possible cumulative effects on cognition should be considered. Lists of drugs with anticholinergic properties are available from several sources [249].

No studies were identified specifically in older people with LUTS, but evidence is available from observational cohort studies relating to the risk in a general population of older people.

Two SRs of largely retrospective cohort studies showed a consistent association between long-term anticholinergic use and cognitive dysfunction [250, 251]. Longitudinal studies in older people over two to four years have found increased rates of cognitive decline in patients on anticholinergics or drugs with anticholinergic effects [219, 220, 252, 253]. It is unclear whether there is a direct correlation between cognitive dysfunction caused by medication and the long-term risk of development of dementia.

#### 4.1.4.2.4 Oestrogens

Oestrogen treatment for UI has been tested using oral, transdermal and vaginal routes of administration. Vaginal (local) treatment is primarily used to treat symptoms of vaginal atrophy in postmenopausal women. Available evidence is related mainly to SUI, and although some reviews include participants with predominantly OAB/UUI, it is difficult to generalise the results to women with predominantly OAB/UUI.

The association of LUTS with genitourinary syndrome of menopause (GSM) should be considered [254]. Genitourinary syndrome of menopause (GSM) is a new term that describes various menopausal symptoms and signs associated with physical changes of the vulva, vagina and LUT. These include mucosal pallor/erythema, loss of vaginal rugae, tissue fragility/fissures, vaginal petechiae, urethral mucosal prolapse, introital retraction and vaginal dryness. There is evidence from a SR to suggest benefit from vaginal oestrogen therapy in GSM [255]. All vaginal oestrogens demonstrated superiority in objective and subjective end points of GSM compared with placebo. Only some trials demonstrated superiority vs. placebo in urogenital symptoms (UI, recurrent UTI, urgency and frequency). No significant difference was observed between various doses and dosage forms of vaginal oestrogen products. Vaginal oestrogen showed superiority over vaginal lubricants and moisturisers for the improvement of objective clinical end points of vulvovaginal atrophy but not for subjective end points [255].

Available evidence suggests that vaginal treatment with oestradiol and oestriol is not associated with increased risk of thromboembolism, endometrial hypertrophy, and breast cancer that is seen with systemic administration [256-258].

#### 4.1.4.2.5 Placebo

Placebo has a clear effect on the improvement of OAB signs and symptoms, and the overall placebo responses in various outcomes studied are statistically significant and, for some of the outcomes, possibly clinically significant. A recent SR including 57 studies with 12901 patients showed a standardised MD of -0.45 (95% CI: -0.51 to -0.40; p < 0.001) for daily micturition episodes, -0.33 (95% CI: -0.42 to -0.24; p < 0.001) for daily nocturia episodes, -0.46 (95% CI: -0.55 to -0.37; p < 0.001) for UUI episodes, -0.50 (95% CI: -0.61 to -0.39; p < 0.001) for daily urgency episodes, -0.51 (95% CI: -0.60 to -0.43; p < 0.001) for daily incontinence episodes, and 0.25 (95% CI: 0.211–0.290; p < 0.001) for volume voided per micturition [189]. The placebo response seems to be non-negligible in OAB, supporting the requirement for placebo control in RCTs.

#### 4.1.4.3 Surgical management

##### 4.1.4.3.1 Bladder wall injection of botulinum toxin A

Onabotulinum toxin A (onabotA; BOTOX®) 100 U is licenced in Europe to treat OAB with persistent or refractory UUI in adults of both sexes [259, 260]. Surgeons should be aware that other doses of onabotA and other formulations of botulinumtoxin A, abobotulinumtoxin A and incobotulinumtoxin A, are not licensed for use in OAB/UUI. Doses for onabotA are not transposable to the other brands of botulinumtoxin A. The continued efficacy of repeat injections is usual, but discontinuation rates may be high [261, 262]. The most important adverse events related to onabotA 100U injection detected in the regulatory trials were UTI and an increase in PVR volume that may require CISC [263].
Following a dose-ranging study in which 100 U onabotA was established as the optimum dose, a phase III trial randomised (1:1) the same group of 557 OAB-wet patients whose symptoms were not adequately managed with anticholinergics to receive bladder wall injections of onabotA (100 U) or saline. At baseline, the population had on average > 5 episodes of UUI, ~12 micturitions per day and a small PVR volume. At week twelve, in patients treated with onabotA, UUI episodes/day were halved and the number of micturitions/day reduced by > 2. A total of 22.9% of the patients in the onabotA arm were fully dry, against 6.5% in the saline arm [263]. Rates of urinary retention were not reported in SRs, and a Cochrane review reported no significant difference in PVR volume between the onabotA and placebo groups [264].

Quality of life was substantially improved in the onabotA arm, as shown by the > 2.5 times improvement in Incontinence Quality of Life Questionaire (I-QOL) scores compared to baseline. Cohort studies have shown the effectiveness of bladder wall injections of onabotA in elderly and frail elderly people [265], although the success rate might be lower and the PVR volume (> 150 ml) higher in this group.

The median time to request retreatment in the pooled analysis of the two RCTs was 24 weeks [260, 263]. Follow-up over 3.5 years showed consistent or increasing duration of effect for each subsequent treatment, with a median of 7.5 months. Considerable differences were noted in patient outcomes on secondary analysis [266].

An RCT compared onabotA injection 100 U to solifenacin (with dose escalation or switch to trospium possible in the solifenacin group) and showed similar rates of improvement in UUI over the course of 6 months [267]. However, patients receiving onabotA were not only more likely to have cure of UUI (27% vs. 13%), but also had higher rates of urinary retention during the initial 2 months (5% vs. 0%) and of UTIs (33% vs. 13%). Patients taking anticholinergics were more likely to have dry mouth. These results are further strengthened by a 2017 SR and network meta-analysis including 65 RCTs of onabotulinum toxin A vs. oral therapies (anticholinergics and mirabegron) for OAB at twelve weeks [268]. This review reported that patients receiving onabotulinum toxin A had the greatest reduction in UUI episodes, urgency episodes, micturition frequency and the highest odds of achieving dryness, as well as ≥ 50% reduction from baseline UI episodes/day (type not specified). However, adverse events were not reported in this network meta-analysis.

Identification of DO in urodynamics does not appear to influence the outcome of onabotulinum toxin A injections in patients with UUI [269].

### 4.1.4.3.2 Sacral nerve stimulation

Sacral nerve stimulation involves placing electrodes adjacent to the sacral nerve roots and delivering an electric current to the area via an attached battery implanted in the buttock, which delivers low-amplitude stimulation resulting in modulation of neural activity and stabilisation of bladder electrical activity through a mechanism that is, as yet, not fully understood. In most centres, test stimulation with a temporary or permanent electrode is performed to assess response, before undertaking permanent stimulator implantation. Currently, the only
reliable predictor for treatment success in SNS is test stimulation. A SR did not find predictive factors of success due to low level of evidence of included studies (small, retrospective and heterogeneous populations) [270].

All randomised studies suffer from the limitation that patients cannot be blinded to the treatment allocation since all recruited patients have to respond to a test phase before randomisation. A Cochrane review in March 2008 [271] identified three RCTs that investigated SNS in patients with refractory UUI. The majority of studies compared a strategy of immediate implantation with delayed implantation.

One study compared implantation to controls who stayed on medical treatment and received delayed implantation at six months. Fifty percent of the immediately implanted group had > 90% improvement in UUI at six months compared with 1.6% of the control group [272]. The effect on QoL measured by the SF-36, was unclear as it differed between the groups in only one of the eight dimensions. The other RCT achieved similar results, although these patients had already been included in the first report [273].

The results of seventeen case series of patients with UUI, who were treated early with SNS, were reviewed [274]. After follow-up of one to three years, ~50% of patients with UUI demonstrated > 90% reduction in UI, 25% demonstrated 50-90% improvement, and 25% demonstrated < 50% improvement. Two case series describing the outcome of SNS, with a mean or median follow-up of ≥ 4 years [275, 276] reported continued success (> 50% improvement of original symptoms) in patients available for follow-up. Cure rates for UUI were 15% [276].

A more recent RCT comparing a strategy of onabotulinum toxin A injection (200 IU), repeated as required, against a strategy of test and, if indicated, subsequent permanent SNS, showed lower cure rates with SNS at six months: 20% in the onabotulinum toxin A group and 4% in the SNS group had complete resolution of UUI [277]. Forty-six per cent in the onabotulinum toxin A group and 26% in the SNS group had ≥ 75% reduction in the number of episodes of UUI [278]. Two-year follow-up data from 87% of participants in this trial suggest no significant differences in treatment outcomes over 2 years, although satisfaction rates and treatment endorsement remain higher with onabotulinum toxin. The rates of complete resolution of UI (5% for both) as well as ≥ 75% reduction in UI episodes (22% onabotulinum toxin A vs. 21% SNS) were equivalent at the 2-year mark [279]. Sacral nerve stimulation revision and removal occurred in 3% and 9% of this cohort, respectively.

A 2018 review of studies including SNS with ≥ 6 months follow-up reported dry rates of 43–56% [280]. Adverse events occurred in 50% of implanted cases, with surgical revision necessary in 33–41% [276, 277]. In a sub-analysis of the RCT similar success rates were found in patients with or without urodynamic DO [281].

### 4.1.4.3.3 Laser treatment

A recent SR evaluated the use of vaginal lasers in the treatment of OAB and evaluated short-term studies detailing minimal improvement [282]. In general the quality of reported studies were weak and long-term safety data were lacking. Before considering widespread use of laser for the treatment of SUI and OAB, additional good-quality studies with extended follow-up, systematic reporting of adverse events, and objective measures of outcomes (urodynamic, 24-hour pad test, voiding diaries) are required.

4.1.4.3.4 Cystoplasty/urinary diversion
4.1.4.3.4.1 Augmentation cystoplasty
In augmentation cystoplasty (also known as clam cystoplasty), a detubularised segment of bowel is inserted into the bivalved bladder wall. The distal ileum is the bowel segment most often used but any segment can be utilised if it has the appropriate mesenteric length. Most of the evidence pertaining to cystoplasty comes from patients with neuropathic bladder dysfunction. One study did not find any difference between bivalving the bladder in the sagittal or coronal plane [283, 284]. The procedure can be done, with equal success by open or robotic techniques, although the latter takes more time [285].

There are no RCTs comparing bladder augmentation to other treatments for patients with OAB/UUI. Most often, bladder augmentation is used to correct neurogenic DO, small capacity or low-compliant bladders caused by fibrosis, chronic infection such as tuberculosis, radiation, or chronic inflammation from interstitial cystitis.

The largest case series of bladder augmentation in a mixed population of idiopathic and neurogenic UUI included 51 women [286]. At an average follow-up of 74.5 months, only 53% were continent and satisfied with the surgery, whereas 25% had occasional leaks and 18% continued to have disabling UUI. The results for idiopathic DO (58%) were less satisfactory than for neurogenic UUI (90%). Malignant transformation was not reported in this series; however, it has been documented in other series and a SR [287-289]. Fewer than 60 cases have been reported worldwide, and almost all are exclusively beyond 10 years after the original cystoplasty [290].
