Adverse effects are common and have been summarised in a review with five to seventeen years follow-up of > 267 cases; 61 of which had non-neurogenic UUI [291]. Many patients may require CISC to obtain adequate bladder emptying (Table 2). It is unclear if mucolytic agents reduce mucus accumulation. The only RCT comparing various mucolytic agents did not find significant benefits with the use of N-acetylcysteine, aspirin, or ranitidine. In one small study (n = 40), subcutaneous octreotide immediately before, and for fifteen days after surgery yielded significant reductions in mucus production, the need for bladder irrigation to clear blockages, and mean duration of hospital stay [292]. Before cystoplasty, all potential complications should be outlined, and before and after surgery patients should be well supported by stoma/continence nurses.

Depending on the relative costs of onabotulinum toxin A and augmentation cystoplasty, the latter can be cost-effective within 5 years if the complication rate is low and duration of effect of onabotulinum toxin A is < 5 months [293].

4.1.4.3.4.2 Detrusor myectomy (bladder auto-augmentation)

Detrusor myectomy aims to increase bladder capacity and reduce storage pressure by incising or excising a portion of the detrusor muscle, to create a bladder mucosal bulge or pseudo-diverticulum. It was initially described as an alternative to bladder augmentation in children [294].

Two case series in adult patients with idiopathic and neurogenic bladder dysfunction demonstrated poor long-term results caused by fibrosis of the pseudo-diverticulum [295, 296]. This technique is rarely, if ever, used nowadays.

4.1.4.3.4.3 Urinary diversion

Urinary diversion remains a reconstructive option for patients with intractable UI after multiple pelvic procedures, radiotherapy or pelvic pathology leading to irreversible sphincteric incompetence or fistula formation. Patients may be offered irreversible urinary diversion surgery. Options include ileal conduit urinary diversion, orthotopic neobladder and heterotopic neobladder with Mitrofanoff continent catheterisable conduit. There is insufficient evidence to comment on which procedure leads to the most improved QoL.

A small study comparing ileal with colonic conduits concluded that there are no differences in the relative risks (RR) of UUT infection and uretero-intestinal stenosis. However, no studies that have specifically examined these techniques for treatment of intractable OAB/UUI [283]. Therefore, careful consideration of which operation is undertaken depends on thorough preoperative counselling, access to stoma/continence nurses, as well as patient factors to allow for fully informed patient choice.

4.2  **Stress urinary incontinence**

4.2.1  **Epidemiology, aetiology, pathophysiology**

Stress urinary incontinence is defined as the involuntary loss of urine on effort or physical exertion, is a significant health problem worldwide with social and economic impact on women and society. It is estimated that the number of women in the USA with UI will have increased from 18.3 million in 2010 to 28.4 million in 2050 [297]. The prevalence of SUI appears to peak between 45 and 59 years of age [298].

Data regarding the association of UI with ethnicity are conflicting. In several studies, SUI is more common in white women than in women of African–American or Asian–American origin [299, 300]. Other factors positively associated with SUI include parity, obesity, previous hysterectomy or pelvic surgery, diabetes mellitus [301] and pulmonary disease [302]. Physical activity level is another important factor that is positively correlated with SUI severity [303].

Two common, often overlapping, mechanisms for SUI have been described: (1) urethral hypermobility resulting from loss of support of the bladder neck and urethra; and (2) weakness of the urinary sphincter itself (intrinsic sphincter deficiency), which can result from trauma, radiotherapy, previous pelvic or uro-gynaecological surgery, neurological disease or ageing.

The mechanism behind urethral hypermobility as a cause of SUI is based on the “vaginal hammock” hypothesis [304]. The endopelvic fascia, which is attached to the upper (abdominal) side of the PFMs, links the muscles to the vagina and represents the “hammock”, which can compress the urethra during rest and activity. This compression, combined with intrinsic urethral sphincter pressure, supports and maintains the urethra in the correct and closed position, preventing involuntary loss of urine, despite any increases in intravesical pressure. Damage to the supporting tissues (particularly the arcus tendinous fasciae pelvis, the central part of the fascia) can result in urethral hypermobility. Consequently, rather than being compressed at times of increased intra-abdominal pressure, the urethra moves caudally, funnelling the bladder neck, and is no longer compressed, resulting in SUI [304, 305]. In general, almost all treatments are used for both subtypes of SUI, but in general most treatments are more successful in patients with some degree of urethral hypermobility than for isolated intrinsic weakness of the urinary sphincter [306].

4.2.2  **Classification**

Patients with SUI can be classified as uncomplicated and complicated [307]. The Panel has reached a consensus on the definition to be used throughout this guideline document:

- Women with uncomplicated SUI: no prior surgery for SUI, extensive pelvic surgery, or pelvic radiotherapy; no neurogenic LUT dysfunction; no bothersome genito-urinary prolapse; absence of voiding symptoms; and no medical conditions that affect the LUT. In cases where additional significant storage symptoms, especially OAB, are present, consider a possible diagnosis of MUI (see Section 4.3).
- Women with complicated SUI: previous surgery for incontinence or extensive pelvic surgery; history of pelvic irradiation; presence of anterior or apical POP; presence of voiding symptoms or neurogenic LUT dysfunction; and significant OAB/UUI. Neurogenic LUT dysfunction is reviewed in the EAU Guidelines on Neuro-Urology and will not be considered further in these guidelines [9]. The treatment of LUTS associated with genitourinary prolapse has been included in these guidelines (see Section 4.7).
4.2.3  **Diagnostic evaluation**

4.2.3.1  **History and physical examination**

There is universal agreement that taking a history should be the first step in the assessment of anyone with UI. When the history categorises UI as probable SUI the presence of complicated or uncomplicated SUI can also be determined. Those patients who require rapid referral to an appropriate specialist can also often be identified from the clinical history.

There is little evidence from clinical trials that carrying out a clinical examination improves clinical outcomes, but there is widespread consensus that it remains an essential part of the assessment of women with SUI. It should include abdominal examination, vaginal examination and careful assessment of any associated POP, examination of the perineum and evaluation of PFM strength, as well as a neuro-urological examination. An attempt to reproduce the SUI should be made. A standing cough test has greater sensitivity for diagnosis of SUI compared with a supine cough test [308]. Despite this, the ICS has proposed a standardisation of the female cough stress test that includes a supine/lithotomy position with 200–400 mL fluid in the bladder and one to four coughs [309].

4.2.3.2  **Patient questionnaires**

Although many studies have investigated the validity and reliability of urinary symptom questionnaires and PROMs, most of these studies did not include homogeneous populations of adult women diagnosed with SUI. This limits the extent to which results and conclusions from these studies can be specifically applied to women with SUI. Some questionnaires are used for prevalence studies; others are responsive to change and may be used to measure outcomes, although evidence on their sensitivity is inconsistent [26, 27]. There is no evidence to indicate whether use of QoL or condition-specific questionnaires has an impact on treatment outcome. To date, there is no one questionnaire that fulfils all requirements for the assessment of women with SUI.

4.2.3.3  **Post-void residual volume**

It is important to evaluate PVR volume in patients with SUI; particularly in those who also have voiding symptoms or POP. The prevalence of a significant PVR volume in patients with SUI is uncertain, partly because of the lack of a standard definition of an abnormal PVR volume. Most studies investigating PVR volume have not included patients with SUI. In general, the data on PVR volume can only be applied with caution to adults with non-neurogenic SUI. In a cohort study of > 900 women with SUI, there was good correlation between PVR volume estimated by US and measured by catheterisation. The mean PVR volume was 39 mL measured by catheterisation and 63 mL estimated by US, with only 16% of women having PVR > 100 mL [59].

4.2.3.4 Urodynamics

Urodynamic testing is widely used as an adjunct to clinical diagnosis, based on the assumption that it may help to provide or confirm diagnosis. The role of urodynamics in SUI evaluation remains poorly defined and is still under debate.

Invasive urodynamic tests are often performed prior to surgical treatment of SUI. Clinical diagnosis of incontinence and cystometric findings often do not correlate [67, 68]. The diagnostic accuracy of urethral pressure profilometry [69] and VLPP measurement in SUI is generally poor [310]. Measurement of MUCP correlates, albeit weakly, with incontinence severity [69], and there is conflicting evidence about its reproducibility [64, 65]. Methods of recording MUCP cannot be compared meaningfully [66]. Valsalva leak point pressures are not standardised and there is minimal evidence about reproducibility. Valsalva leak point pressure did not reliably assess incontinence severity in a cohort of women selected for surgical treatment of SUI [70]. The predictive value of the tests regarding treatment outcome remains unclear.

A Cochrane review including seven RCTs showed that urodynamic tests increased the likelihood of avoiding surgery for SUI. However, there is no evidence that this influence on decision-making alters the clinical outcome of treatment within trial populations [78].

A high-quality RCT (n = 630) compared office evaluation alone and combined with urodynamics in women with clinically demonstrable SUI about to undergo surgery. While urodynamics changed the clinical diagnosis in 56% of women [311], there was no difference in severity of SUI or any secondary outcome at twelve months' follow-up after SUI surgery [80]. A similar study also found that omission of urodynamics in the preoperative work-up of SUI did not lead to inferior results [312]. Patients in whom urodynamics were discordant with clinical assessment (n = 109) were randomly allocated to receive either immediate surgery or individually tailored therapy based on the urodynamic findings. In this trial, performing immediate surgery, irrespective of the result of urodynamics, did not result in inferior outcomes [313]. An RCT, in which 145 women were randomised to retropubic or trans-obturator MUS, concluded that when patients were stratified according to preoperative VLPP (≤ or > 60 cm H2O), it was not linked to outcome after both synthetic MUS procedures [314].

Another study reported conflicting evidence. Valsalva leak point pressure or MUCP in the lowest quartile was predictive in terms of synthetic MUS failure at twelve months [83].

The Panel recognises that it may be valuable to use urodynamic test results to help select the optimum surgical procedure, but the evidence outlined above suggests that performing urodynamics in patients with uncomplicated SUI, which can be diagnosed based on detailed clinical history and demonstrated at examination, is not necessary. The role of urodynamics in complicated SUI is still under debate [315]. However, the Panel consensus is that urodynamics should be carefully considered in cases of SUI with associated storage symptoms; cases in which the type of incontinence is unclear; cases in which voiding dysfunction is suspected; and cases with associated POP or prior surgery for SUI. This is in line with other guideline documents in this area [67].

4.2.3.5 Pad testing

Measurement of urine loss using an absorbent pad worn over a set period of time or during a protocol of physical exercise can be used to quantify the presence and severity of SUI, as well as a patient’s response to treatment.

The clinical utility of pad tests for people with UI has been assessed in two SRs [92, 93]. A one-hour pad test using a standardised exercise protocol and a diagnostic threshold of 1.4 g show good specificity but low sensitivity for diagnosis of SUI and MUI. A 24-hour pad test using a threshold of 4.4 g is more reproducible but is difficult to standardise with variation according to activity level [94]. A pad test with a specific short graded exercise protocol also has diagnostic value but a negative test should be repeated or the degree of provocation increased [95]. The usefulness of pad tests in quantifying severity and predicting treatment outcome is uncertain [92, 97]. Pad testing is responsive to change following successful treatment [98]. Pad testing using a standardised bladder volume (50% of cystometric capacity) has been suggested to allow for a more reliable assessment of UI in a small study of 25 women [99]. There is no evidence that one type of pad test is superior to another.

</tbody>
</table>

4.2.3.6 Imaging

The role of imaging in SUI patients is limited. Many studies have evaluated imaging of bladder neck mobility by US and MRI, and concluded that SUI cannot be identified by a particular pattern of urethro-vesical movement [316]. In addition, the generalised increase in urethral mobility after childbirth does not appear to be associated with *de novo* SUI [317]. Studies have assessed the use of imaging to investigate the mechanism of action of
MUS inserted for SUI. One study suggested that MUS placement decreased mobility of the mid-urethra but not mobility of the bladder neck [109]. Following MUS surgery, a wider gap between symphysis and sling (assessed by imaging) has been shown to correlate with a lower chance of cure of SUI [110]. One study of 72 women post-synthetic suburethral MUS surgery has investigated the usefulness of translabial US to assess tape functionality. In this study different parameters were measured (distance from tape to urethra, position and shape during Valsalva manoeuvre, etc.) and concluded that tape position relative to the patient’s urethra seems to play a role in treatment outcome [318]. The general role of US in the evaluation and follow-up of women with SUI is unclear, and further research is needed to establish its place in the clinical pathway.

Several imaging studies have investigated the relationship between sphincter volume and function [319] and sphincter volume and outcome of surgery [320] in women. However, no imaging test has been shown to predict the outcome of treatment for SUI. Imaging of the pelvic floor can identify levator ani detachment and hiatus size, although there is little evidence of a relationship to clinical benefit after treatment of SUI.

4.2.4 Disease management

4.2.4.1 Conservative management

4.2.4.1.1 Obesity and weight loss

Being overweight or obese has been identified as a risk factor for LUTS and SUI in many epidemiological studies [144, 145]. There is evidence that the prevalence of both UUI and SUI increases proportionately with body mass index (BMI) [321]. The proportion of patients who undergo surgery for incontinence who are overweight or obese is higher than that of the general population [145].

All the available evidence relates to women. Three SRs concluded that weight loss was beneficial in improving UI [143, 144, 322]. Five further RCTs reported a similar beneficial effect on incontinence following surgical weight reduction programmes [323-327]. Two large studies in women with diabetes mellitus, for whom weight loss was the main lifestyle intervention, showed UI did not improve but there was a lower subsequent incidence of UI among those who lost weight [323, 328]. There have been other cohort studies and case–control studies suggesting similar effects, including surgery for the morbidly obese [329-333].

In a prospective study in 160 consecutive women who underwent bariatric surgery, surgically induced weight loss was associated with a significant improvement in pelvic floor disorders, including UI [334]. Similar results reported by prospective single-centre studies investigating the effect of weight loss induced by bariatric surgery revealed that bariatric surgery was associated with substantially reduced UI at eleven months and three years [335, 336].

</tbody>
</table>

4.2.4.1.3 Pelvic floor muscle training

Pelvic floor muscle training is used to improve function of the pelvic floor, thus improving urethral stability. An immediate effect of a single PFM contraction is narrowing of the levator hiatus area, increase of urethral closure pressure, and lifting of the bladder and rectum thus preventing occurrence of SUI [337-339]. In an RCT comparing intensive PFMT over a six-month period with no treatment, there were increased muscle strength and endurance, narrowing of the levator hiatus, reduced PFM length, increased muscle volume, and lifting of the bladder neck and rectal ampulla [340]. Pelvic floor muscle training may be used to prevent SUI; e.g., in childbearing women before birth, or as part of a planned recovery programme after childbirth. Most often, PFMT is used to treat existing SUI; sometimes in combination with observation and/or palpation of the muscle contraction by the therapist, or biofeedback (using an apparatus measuring the contraction either by electromyography, manometry, dynamometry, US or MRI). Electrical stimulation and vaginal cones are also used in treatment of SUI based on an assumption of the same mechanism of action.

4.2.4.1.3.1 Efficacy of pelvic floor muscle training

A Cochrane review compared PFMT with no treatment or inactive control treatment and found that women with SUI in the PFMT groups were eight times more likely to report cure (56% vs. 6%; four trials including 165 women; high-quality evidence) [341]. The review also documented significant improvement in SUI (seven trials, 376 women; moderate-quality evidence), and improvement in UI QoL (seven trials, 348 women; low-quality evidence). Pelvic floor muscle training reduced leakage by one episode per day in women with SUI (seven trials, 432 women; moderate-quality evidence). Women with SUI in the PFMT groups lost significantly less urine in short (up to one-hour) pad tests. The comparison of short pad tests showed considerable heterogeneity but the findings still favoured PFMT when using a random-effects model (mean difference 9.71 g in four trials including 185 women; moderate-quality evidence). Women in the PFMT group were also more satisfied with treatment and their sexual outcomes were better. Adverse events were rare and minor.

A Cochrane review concluded that there may be some additional effect of adding biofeedback to PFMT. However, this was based on RCTs with training frequency and attention favouring biofeedback [342]. In a recent RCT (61.3% had MUI) comparing the exact same training dosage and attention between groups, use of biofeedback did not yield any additional effect [343]. Group training is cost-effective in treatment of SUI/UI compared to individual treatment [344]. Another Cochrane review concluded that combination of individual assessment/education and group training was equally effective compared to individual treatment, but again the dosage and attention differed between comparison groups [345]. In a more recent RCT with the exact same training dosage and attention in individual and group training, group training was not inferior to individual treatment [344]. It is worth noting that all of the PFMT interventions in these reviews follow individual assessment and teaching before starting PFMT, and most interventions use some sort of measurement tool (biofeedback) in the assessment.

Both the Cochrane review and the International Consultation on Incontinence (ICI) concluded that the use of vaginal cones to train the PFMs is more effective than no treatment, but it is inconclusive whether it is more or less effective than structured PFMT [341, 346, 347]. Some women are unable to maintain the cone inside, and some report discomfort and motivation problems and adherence may be low [346].
The Cochrane review [341], the ICI [347] and the National Institute for Health and Care Excellence (NICE) guidelines (2019) [67] all conclude that there is the highest level evidence (1a) to support PFMT in the treatment of SUI/MUI. All SRs conclude that PFMT is less effective if women with MUI and UUI are included in the studies and more effective with more intensive and supervised training. According to the NICE guidelines literature review, PFMT is as effective as surgery for around half of women with SUI, and due to the risks following surgery and absence of adverse effects of PFMT, they recommend three months of supervised PFMT as first-line treatment for SUI and MUI [67].

Pelvic floor muscle treatment was compared to synthetic MUS surgery in an RCT involving 460 women with moderate to severe SUI [348]. Crossover between treatment arms was allowed and 49.0% of women in the physiotherapy group and 11.2% of women in the surgery group crossed over to the alternative treatment. Subjective improvement was reported by 90.8% of women in the surgery group and 64.4% of women in the physiotherapy group at twelve months.

4.2.4.1.3.2 Efficacy of electrical stimulation
There is lack of consensus regarding the use of ES to treat SUI. For subjective cure of SUI, a Cochrane review found moderate-quality evidence that ES is probably better than no active treatment, risk ratio (RR): 2.31 [349]. Similar results were found for cure or improvement of SUI (RR: 1.73), but the quality of evidence was low. There is uncertainty as to whether there is a difference between ES and sham treatment in terms of subjective cure alone because of the very low quality of evidence (RR: 2.21). For subjective cure or improvement, ES may be better than sham treatment (RR: 2.03). Any comparison between ES and PFMT and other treatments is hampered by low-quality evidence. Adverse effects such as pain and discomfort have been reported, and ES is not tolerated by all women [349].

In an RCT, 132 women assessed by vaginal palpation to have 0–1 on the modified Oxford grading scale (unable to contract the PFM) were randomly assigned to an eight-week intervention of learning to contract via palpation, palpation with pelvic tilt, intravaginal ES, or verbal instruction [350]. The results showed that 63.6%, 69.7%, 33.3% and 18.2% in the four groups, respectively, scored two after the intervention. Palpation was significantly more effective that ES, but one third of the ES group had learned a correct PFM contraction [350]. The effect on UI measured by ICIQ-UI-SF was significantly better in the palpation group.

4.2.4.1.3.3 Long-term efficacy of pelvic floor muscle training
In a SR including nineteen studies, 1141 women were followed-up for one to fifteen years after PFMT for SUI [351]. Meta-analysis was not performed due to high heterogeneity of outcome measures and training dosage (frequency, intensity, duration and adherence). Only two studies provided interventions during follow-up. Losses to follow-up ranged between 0% and 39%. Long-term adherence to PFMT varied between 10% and 70%. Five studies reported that the initial success rate on SUI and MUI was maintained in the long term. Long-term success based on responders in the original trial varied between 41% and 85%. Surgery rates in the long term varied between 4.9% and 58%. It was concluded that short-term outcome of PFMT can be maintained at long-term follow-up without incentives for continued training, but there is a high heterogeneity in both interventional and methodological quality in short- and long-term PFMT studies [351].

4.2.4.1.3.4 Efficacy of pelvic floor muscle training in childbearing women
Pelvic floor muscle training to prevent SUI has been studied during pregnancy and in the postpartum period and the results are not reported separately for SUI and other subgroups of UI. A Cochrane review concluded that PFMT in women with and without UI (combined primary and secondary prevention) during pregnancy, produced a 26% reduced risk of UI during pregnancy and the mid-postnatal period [352]. Furthermore, pregnant continent women (primary prevention) who exercised the PFM during pregnancy were 62% less likely to experience UI in late pregnancy and had 29% lower risk of UI three to six months after giving birth. There is insufficient evidence for a long-term effect of antenatal PFMT beyond six to twelve months postpartum. Compared with usual care, there is no evidence that antenatal PFMT in continent women decreases incontinence in late pregnancy (very low-quality evidence), or in the mid- (low-quality evidence) or late postnatal periods (very low-quality evidence).

There have been fewer RCTs in the postpartum period than during pregnancy [352]. No primary prevention studies were found in women after birth. For PFMT started after delivery, in a mixed group of continent and incontinent women, there was uncertainty about the effect on UI risk in the late postnatal period (three trials, 826 women; moderate-quality evidence), and in postnatal women with persistent UI, there is no evidence that PFMT results in a difference in UI at more than six to twelve months postpartum (three trials; 696 women; low-quality evidence). However, another RCT found that UI was less frequent in the intervention group, with 57% of
4.2.4.1.3.5 Pelvic floor muscle training in elderly women
There have been few RCTs on conservative treatment of SUI in elderly women (> 65 years) and many of the studies combined different modalities, such as bladder training, lifestyle modifications and PFMT [354]. Some of the studies on PFMT and SUI in the general population have included women > 65 years and PFMT seems to be equally effective in elderly women. A SR on conservative management included 23 trials, with nine of moderate-to-high methodological quality, and concluded that PFMT in combination with physical training was effective in reducing UI and improving QoL [355]. Prompted voiding and toileting assistance with functional exercise reduced UI. Other behavioural interventions such as night-time prompted voiding and waking routine had no effect on UI reduction. The most recent ICI consensus publication stated that although there are limited studies of PFMT on UI in frail elderly populations, age and frailty alone should not preclude the use of PFMT in appropriate patients with sufficient cognition to participate [354]. More high-quality RCTs, both in frail and healthy older women (> 80 years of age) are needed.

A SR from the Cochrane Database found insufficient evidence to state whether or not there were additional effects by adding PFMT to other active treatments (including vaginal cones, electromagnetic stimulation, biofeedback, continence pessary, drugs) when compared with the same active treatment alone for female SUI or mixed UI. However, these results should be interpreted with caution as most of the comparisons were investigated in small, single trials. Also, none of the included trials reported data on adverse events associated with the PFMT regimen, thereby making it very difficult to evaluate the safety of PFMT [356].

4.2.4.1.4 Electromagnetic stimulation
Electromagnetic stimulation (EMS) has been evaluated for its role in SUI therapy. In a double-blind RCT of EMS including 70 women with SUI, no effect of EMS over sham in any outcome was recorded [357].
4.2.4.1.5 Electroacupuncture
A SR including fifteen RCTs and women with SUI treated by electroacupuncture (EA) demonstrated that EA for SUI was effective (odds ratio [OR]: 5.64; 95% CI: 4.19-7.59; I²: 22%). ICIQ-SF scores increased (SMD: -0.48; 95% CI: -0.62 to -0.33; I²: 32%) and 1-hour urine leakage decreased (OR: -4.14; 95% CI: -4.69 to -3.33; I²: 78%) in patients undergoing EA compared with those receiving sham EA, physical exercise or medication [358].

4.2.4.2 Pharmacological management
4.2.4.2.1 Oestrogen
Oestrogenic drugs including conjugated equine oestrogens, oestradiol, tibolone and raloxifene, are used as hormone replacement therapy (HRT) for women with natural or therapeutic menopause.

Oestrogen treatment for SUI has been tested using oral, transdermal and vaginal routes of administration. Available evidence suggests that vaginal oestrogen treatment with oestradiol and oestriol is not associated with the increased risk of thromboembolism, endometrial hypertrophy, and breast cancer seen with systemic administration [256-258]. Vaginal (local) treatment is primarily used to treat symptoms of vaginal atrophy in postmenopausal women.

A Cochrane review looked at the use of oestrogen therapy in postmenopausal women given local oestrogen therapy and seventeen studies focused on SUI [256]. There is also a narrative review of oestrogen therapy in urogenital diseases [359]. The Cochrane review found that vaginal oestrogen treatment improved symptoms of SUI in the short-term [256]. There were small, low-quality trials comparing vaginal oestrogen treatment with phenylpropanolamine, PFMT, ES and its use as an adjunct to surgery for SUI. Local oestrogen was less likely to improve UI than PFMT but no differences in UI outcomes were observed for the other comparisons. A single trial of local oestrogen treatment comparing a ring device to pessaries found no difference in UI outcomes, although more women preferred the ring device. In one trial, no significant adverse effects following vaginal administration of oestradiol for vulvovaginal atrophy over two years were reported [360].

Vaginal oestrogen therapy can be given as conjugated equine oestrogen, oestriol or oestradiol in vaginal pessaries, vaginal rings or creams. The ideal treatment duration and the long-term effects are uncertain. A review of local oestrogen treatment showed improvement of UI over placebo with vaginal rings, which were favoured subjectively over pessaries [361].

One RCT in postmenopausal women showed a benefit of adding intravaginal oestriol to vaginal ES and PFMT in female SUI [362].

Studies of systemic HRT with non-urogenital primary outcomes have looked for change in urinary continence in secondary analyses. Large trials using conjugated equine oestrogens showed a higher rate of development or worsening of UI compared to placebo and no SUI improvement [363-368]. In a single RCT, use of raloxifene was not associated with development or worsening of UI [369]. Three small RCTs using oral oestriol or oestradiol as HRT for vulvovaginal atrophy suggested that UI symptoms were improved although the evidence was unclear [67, 370, 371].

4.2.4.2.2 Duloxetine
Duloxetine inhibits the presynaptic reuptake of neurotransmitters, serotonin (5-hydroxytryptamine; 5-HT) and
noradrenaline (NE). In the sacral spinal cord, an increased concentration of 5-HT and NE in the synaptic cleft increases stimulation of 5-HT and NE receptors on the pudendal motor neurons, which in turn increases the resting tone and contraction strength of the urethral striated sphincter.

Duloxetine was evaluated as a treatment for female SUI or MUI in three SRs [170, 372, 373]. Improvement in UI compared to placebo was observed with no clear differences between SUI and MUI. One study reported cure for UI in about 10% of patients. An improvement in the Urinary Incontinence QoL questionnaire was not found in the study, which used this as a primary endpoint. In a further study comparing duloxetine, 80 mg daily, with PFMT alone, PFMT + duloxetine, and placebo [374], duloxetine reduced leakage compared to PFMT or no treatment. Global improvement and QoL were better for combined therapy than no treatment. There was no significant difference between PFMT and no treatment in this trial.

Two open-label studies with a follow-up of ≥ 1 year evaluated the long-term effect of duloxetine in controlling SUI [375, 376]. Both studies had a high patient withdrawal rate, due to lack of efficacy and a high incidence of adverse events, including nausea and vomiting (≥ 40% of patients), dry mouth, constipation, dizziness, insomnia, somnolence and fatigue.

A SR showed significant efficacy for duloxetine compared to placebo in women with SUI, but with increased risk of adverse events [373]. The adverse effects of duloxetine include mental health problems and suicidal ideation. A meta-analysis of four RCTs including 1910 women with SUI reported no suicidality, violence or akathisia events, but suggested that discontinuation rate due to adverse events was around one in seven and that the harm may outweigh the benefit of treatment [377]. A meta-analysis of twelve placebo-controlled trials involving almost 3000 patients showed that, in patients with major depressive disorders, there were no significant differences in the incidence of suicide-related events with duloxetine vs. placebo [378].

4.2.4.2.3 Adrenergic agonists

A SR from the Cochrane Database including 22 RCT involving 673 women and seven different adrenergic drugs (phenylpropanolamine in eleven trials, midodrine in two, norepinephrine in three, clenbuterol in another three, terbutaline in one, eskornade in one and Ro 115-1240 in one) found weak evidence that adrenergic agonists may improve SUI. Moreover, side effects did occur but were usually minor. More evidence is needed to compare adrenergic drugs with other drugs for SUI and also with PFMT [379].

4.2.4 Surgical management

4.2.4.3.1 General considerations

The use of polypropylene mesh as synthetic MUS for the treatment of SUI has recently come under scrutiny following concerns about long-term complications. In some European countries such as the UK, the use of synthetic MUS has been paused and pelvic mesh was the subject of a parliamentary review published in July 2020 [380]. This review concluded that "For many women mesh surgery is troublefree and leads to improvements in their condition. However, this is not the case for all. There is no reliable information on the true number of women who have suffered complications. While they may be in the minority, that does not diminish the catastrophic nature of their suffering or the importance of providing support to them and learning from what has happened to them".
The range of complications highlighted during the process of this parliamentary review included [380]:

- pain;
- recurrent infections;
- mobility issues;
- recurring or new incontinence/urinary frequency;
- recurring or new prolapse;
- haemorrhage;
- bowel issues;
- erosion of mesh; this can be into the vagina and/or other organs;
- sexual difficulties; including pain on intercourse and a loss of sex life;
- autoimmune issues;
- psychological impacts.

When considering the choice of surgical treatments for SUI the Panel advises individual clinicians to abide by any national or local rules that may be in place regarding mesh surgery. It is essential for clinicians to point out the deficiencies in the long-term evidence regarding mesh use in SUI with specific reference to the complications highlighted above.

In line with the recommendations from NICE [67] and the Scientific Committee on Emerging and Newly Identified Health Risks (SCENIHR) paper [381], the Panel agrees that surgeons and centres performing surgery should:

- be trained in the field of incontinence and for each surgical procedure they perform/offer;
- perform sufficient numbers of a procedure to maintain expertise of him/herself and the surgical team;
- be able to offer alternative surgical treatments;
- be able to deal with the complications of surgery;
- provide suitable arrangements for long-term follow-up.

The establishment of accurate and complete databases registering the interventions, patient profiles and surgical complications or all surgical treatments for SUI is recommended to allow the generation of robust long-term data.

Many surgical procedures are available for uncomplicated SUI patients and the Panel analysed the results of the different procedures in terms of clinical effectiveness, safety and cost-effectiveness based on the recent ESTER SR and economic evaluation [382] and previous SRs including those from the Cochrane Collaboration [383-387].

The outcome parameters used to evaluate surgery for SUI have been limited to:

- continence rate;
- patient-reported outcome measures;
- general and procedure-specific complications;
- generic, specific (UI) and associated (sexual and bowel) QoL.

In this context, it has to be taken into account that a number of products may no longer be available and therefore the recommendations may not be transferable to current devices. The Panel makes a strong recommendation that new devices are only used as part of a structured research programme and their outcomes monitored in a registry, until there is adequate evidence of safety and efficacy.

<td>Strong</td>
</tr>
</tbody>
</table>

### 4.2.4.3.1.2 Shared decision making

The Panel recognises that a shared decision-making approach is paramount when any treatments are proposed but felt particular emphasis should be made for the topic area of surgical treatment for incontinence.
There are a number of different options available for patients which vary in both efficacy and safety profile. Consequently, the amount of information given to patients considering surgery for SUI is substantial. The Panel would unequivocally advise adherence to the fundamental principles of the shared decision-making process which include:

- full participation from the patient;
- delivery of factual information regarding benefits and risks of any particular treatment, if possible adapted to the specific situation of the patient;
- delivery of information about the experience and expertise of the HCP/institution delivering the treatment, especially for highly-specialised procedures such as complex SUI and mesh removal surgery;
- confirmation that the patient understands the information given;
- clinician understanding and documenting individual patient preferences;
- facilitation of deliberation and initial decision-making;
- patient opportunity to consider and confirm any decisions made;
- clinician assistance with implementation of the final decision.

4.2.4.3.2 Surgery for women with uncomplicated stress urinary incontinence

The principal procedures evaluated are:

- open and laparoscopic colposuspension;
- autologous “traditional” slings;
- bulking agents;
- synthetic MUS.

4.2.4.3.2.1 Open- and laparoscopic colposuspension surgery

Open colposuspension was previously considered the most appropriate surgical intervention for SUI, and was used as the comparator in RCTs of newer, less-invasive surgical techniques. These include laparoscopic techniques, which have enabled colposuspension to be performed with a minimally invasive approach.

Open colposuspension

A number of SRs have covered open surgery for SUI, with a large number of RCTs [382, 384-387]. The Cochrane review on open colposuspension [387] included 55 trials comprising 5417 women. In most of these trials, open colposuspension was used as the comparator to an experimental procedure. Within the first year, complete continence rates of 85–90% were achieved for open colposuspension, while failure rates in terms of recurrent UI were 17% up to five years and 21% at > 5 years. The risk of reoperation after Burch colposuspension is estimated at 6% within five years [78] and 10.8% within nine years [388]. The reoperation rate specifically for UI was only 2%. Colposuspension was associated with a higher rate of development of enterocoele/vault/cervical prolapse (42%) and rectocele (49%) at five years compared to tension-free vaginal tape (TVT) (23% and 32%, respectively). The rate of cystocele was similar after colposuspension (37%) and after TVT (41%). The Cochrane review concluded that open colposuspension is an effective treatment for SUI and around 70% of women can expect to be dry at five years after surgery.

Laparoscopic colposuspension

A Cochrane review reported on twelve trials comparing laparoscopic to open colposuspension [385]. Although these procedures had a similar subjective cure rate, there was limited evidence suggesting the objective outcomes were poorer for laparoscopic colposuspension. The ESTER SR [382] showed, based on a network meta-analysis, that at twelve months open colposuspension was more effective than laparoscopic colposuspension (nine trials) but these findings were based on low-quality evidence. The Surface Under the Cumulative Ranking (SUCRA) score, which is a numerical representation of the overall ranking and presents a single number associated with each intervention, was 76.7% after open colposuspension and 48.9% after laparoscopic colposuspension. Laparoscopic colposuspension had a shorter duration and subsequent hospital stay and may be slightly more cost-effective when compared with open colposuspension after 24 months’ follow-up. Single-port laparoscopic Burch can be an alternative treatment, although data confirming efficacy are limited [389].

Complications

Voiding difficulties are more common after laparoscopic colposuspension than after retropubic MUS (7.5% vs. 5.1%) [382]. There was no difference between open colposuspension and retropubic MUS (7.8% vs 7.5%; OR: 0.87) [382]. The results for the comparisons of de novo symptoms of urgency or UUI between open colposuspension and retropubic MUS (11% vs. 8%; OR: 1.49) did not favour either treatment and showed wide confidence intervals [382]. The rate of bladder or urethral perforation was higher for laparoscopic colposuspension compared with open colposuspension (3.7% vs. 0.7%; OR: 4.65) [382].

### 4.2.4.3.2.2 Autologous sling

In the past, autologous, cadaveric, xenograft, and synthetic materials have been used for bladder neck pubovaginal sling. Nowadays, use of autologous tissue, either rectus sheath or fascia lata, is the most studied material with the strongest evidence base to support its use [390]. The ESTER SR included three trials of autologous sling vs. open colposuspension, six trials of autologous sling vs. retropubic MUS and one trial of autologous sling vs. transobturator MUS. The quality of evidence was overall very low. The pooled estimate showed that fascial sling had a higher cure rate at one year than open colposuspension (OR: 1.24), retropubic MUS (OR: 1.06) and transobturator MUS (OR: 1.44) but without significance. The SUCRA score was 89.4% for women cured after autologous fascial sling. A sub-analysis from a Cochrane review showed autologous slings had better effectiveness compared to colposuspension at one to five years’ follow-up [387]. In an RCT of Burch colposuspension vs. autologous slings, complete continence rates decreased substantially over time in both arms. At five years, the continence rate of colposuspension was 24.1% compared to 30.8% for fascial slings. Satisfaction remained higher in the sling group (83% vs. 73%) and was directly related to continence status [391].

#### Complications

Adverse events rates were similar for the two treatment groups (Burch 10% and sling 9%) although postoperative obstruction was found exclusively in the sling group. Voiding difficulties appear to be more common after autologous sling (15.4% vs. 10.2%; OR: 1.46) than after retropubic MUS. Compared with open colposuspension, the rate of bladder or urethral perforation was lower for traditional sling (0.6% vs. 3.0%; OR: 0.20) [382].

4.2.4.3.2 Urethral bulking agents

The concept of this procedure originates from the idea that intra- or periurethral injection of an agent able to form artificial cushions under/around the urethra increases resistance at the bladder outlet and facilitates continence.

Two Cochrane reviews (2012 and updated in 2017) identified fourteen RCTs or quasi-RCTs of treatment for UI in which at least one management arm involved peri- or transurethral injection [392, 393]. Five additional reviews investigated the effect of injectables for the treatment of female SUI [394-398] independently of the injected material. One review included results from RCTs only [398]. In the most recent Cochrane review, 1814 patients were included from fourteen trials of seven different types of intraurethral injection: glutaraldehyde cross-linked collagen (Contigent©), a porcine dermal implant (Permacol©), solid silicone elastomer (Macroplastique©), autologous fat, pyrolytic carbon (Durasphere©), calcium hydroxylapatite (Coaptite©), hydrogel (Bulkamid®) and dextran polymer (Zuidex©). The conclusions state that the available evidence base remains insufficient to guide practice [393].

A SR of 23 studies using Macroplastique© including 958 patients showed a 75% improvement with 43% dry rate at < 6 months and a 64% improvement and 36% cure rate at > 18 months [395]. A review of 514 elderly women with SUI treated with various agents showed a reduced pad weight in 73% at one-year follow-up, independent of the material injected [399]. The heterogeneity of the populations, the variety of materials used and the lack of long-term follow-up limit guidance for practice. Most of the studies showed a tendency for short-term improvement in UI, with the exception of one RCT, which did not find a difference between saline and fat injection [400].

One trial of 30 women showed a weak, non-significant advantage in terms of patient satisfaction after mid-urethral injection in comparison to bladder neck injection but with no demonstrable difference in continence levels [393]. Two trials found a higher risk of urinary retention with intraurethral injections compared with transurethral injections, although the latter were associated with a higher risk of temporary urinary retention [392, 401]. A small RCT found no difference in efficacy between mid-urethral and bladder neck injection of collagen [402]. One study treated patients who had received radiotherapy with injection of Bulkamid® and reported ~25% cure at short-term follow-up [403].

Bulking agent injection is generally safe and the most frequent adverse event is UTI. However, autologous fat or hyaluronic acid should not be used due to the risk of fatal embolism and local abscess formation, respectively [392, 400].

Comparison with other surgical procedures

Two RCTs compared collagen injection to conventional surgery for SUI (silicon particles vs. autologous sling and collagen vs. other surgical procedures). The studies reported greater efficacy but higher complication rates for open surgery [404, 405].

In a recent non-inferiority clinical trial, women with primary SUI were randomised to TVT or polyacrylamide hydrogel urethral bulking agent injection (Bulkamid®) [406]. Mid-urethral TVT slings were associated with better satisfaction and cure rates than Bulkamid® in primary SUI. For objective cure rate, the cough stress test was negative in 95.0% of patients who underwent TVT vs. 66.4% who underwent Bulkamid®.

Another SR examining the relative efficacy of urethral bulking agents [407] included six studies in the quantitative synthesis for a total of 710 patients. The authors found that bulking agents are less effective than other surgical procedures according to subjective improvement after treatment (Relative risk [RR]: 0.70; 95% CI: 0.53-0.92, p = 0.01). However, the main limitation of this SR and meta-analysis was the absence of a common objective outcome measure to evaluate effectiveness.

4.2.4.3.2.3.1 Summary of evidence and recommendations for urethral bulking agents

### 4.2.4.3.2.4 Laser treatment

A SR including sixteen published studies, involving 899 patients with SUI, evaluated effects of laser treatment. The change in the ICIQ-SF score at one, two and sixth months was -5.49 (95% CI: -6.74 to -4.24; I²: 91%; p<0.01), -4.97 (95% CI: -6.24 to -3.71), and -5.48 (95% CI: -6.15 to -4.81), respectively. The improvement in an one-hour pad weight test results at one, three and twelve months post treatment was -5.59 (95% CI: -6.93 to -4.25), -4.96 (95% CI: -6.73 to -3.20), and -5.82 (95% CI: -6.77 to -4.87), respectively. The PISQ-12 score increased by 5.39 (95% CI: 1.20-9.58) following treatment. Subgroup analysis identified the type and severity of UI as the potential source of heterogeneity. Adverse effects were reported in sixth of the sixteen trials and affected only a small number of patients. Most adverse events were mild or moderate and required no medical intervention or resolved in a few days. According to this SR, vaginal laser therapy appears to be a safe, effective, and minimally invasive treatment option for SUI that can be well tolerated by patients [408].

Another SR including a total of 27 studies, evaluated the effects of Er:YAG and Fractional CO₂ lasers. The overall quality of studies was poor, and 23/27 studies were case series (LE:4). Er:YAGlaser showed a modest reduction in mild SUI cases, with benefits lasting a maximum of thirteen to sixteen months. Fractional CO₂ laser showed an improvement of mild SUI in few studies; however, no long-term data are available. When reported, adverse events were insignificant, however, they were not reported systematically [282].

Overall, SR have been noted in the current literature regarding vaginal lasers, including variation in laser settings and protocols, short-term follow-up, lack of urodynamic evaluation, and poor reporting of appropriate objective measures and adverse events. Based on the available literature, lasers cannot currently be recommended as a treatment option for SUI.

### 4.2.4.3.2.5 Mid-urethral slings

Early clinical studies identified that non-autologous synthetic slings should be made from monofilament, nonabsorbable material, typically polypropylene, constructed as a 1–2 cm-wide mesh with a large pore size (macroporous) and coloured to facilitate removal [409]. Mid-urethral slings are now the most frequently used surgical intervention in Europe for women with SUI.

**Transobturator route versus retropubic route**

A Cochrane meta-analysis of MUS procedures for SUI in women was performed in 2017, spanning January 1947 to June 2014 [410]. Moderate-quality evidence from 55 studies showed variable, but comparable,
subjective cure rates between retropubic (71–97%) and transobturator (62–98%) slings in the short term (up to one year). No difference in the objective cure rate in the short term was found. However, the ESTER SR [382], based on a network meta-analysis including 36 trials of overall moderate quality, showed that at twelve months retropubic MUS was more effective than transobturator MUS (OR: 0.74). The SUCRA scores for women cured after retropubic MUS were 89.1% vs. 64.1% after transobturator MUS. However, there was no significant difference in these cure rates between the two approaches. Similarly, based on 40 moderate-quality trials, retropubic MUS performed better than the transobturator approach in terms of symptom improvement (RR: 0.76) but the difference was again not significant.

Analysis of a randomised equivalence trial of retropubic vs. transobturator MUS for the treatment of SUI in women shows similar findings. This trial confirms equivalence of objective cure rates at twelve but not at 24 months (77.3% and 72.3% objective cure rate for retropubic and transobturator surgery). For both types of MUS, subjective and objective treatment success decreased over time and equivalence of the retropubic and the transobturator routes could not be confirmed at 24 and 60 months, with retropubic MUS demonstrating an increased benefit, despite satisfaction remaining high in both arms [411]. Five years after surgical treatment, objective success was 7.9% greater in women assigned to retropubic sling compared to transobturator sling (51.3% vs. 43.4%), not meeting prespecified criteria for equivalence. Patient satisfaction decreased over five years but remained high and similar between treatment arms (retropubic sling 79% vs. transobturator sling 85%) [412].

In terms of long-term complications, data are scant but in one study de novo OAB developed in 14% of patients at ten years, with no significant differences between groups (TOT vs. TVT) [413]. In a multicentre prospective study of women undergoing TOT, failure of previous anti-incontinence procedures was the only predictor of recurrence of SUI [413].

A long-term cohort study of retropubic TVT showed an 89.9% objective cure rate and a 76.1% subjective cure rate at ten years. Overall, 82.6% of patients reported high satisfaction with surgery [414]. A long-term prospective study on transobturator sling showed that, at 145 months, the objective and subjective cure rates were 78.9% and 62.6% respectively, with no significant deterioration in SUI cure rates over time [415]. Another long-term follow-up study of patients treated with TVT showed a sustained response with 95.3%, 97.6%, 97.0% and 87.2% of patients being cured or improved at five, seven, eleven and seventeen years, respectively [416]. The ESTER network meta-analysis based on cure and improvement suggested that, when comparing surgical treatments for SUI, retropubic MUS, transobturator MUS and traditional sling had the highest efficacy, but this ranking does not consider the complication profile of these techniques. The short- to medium-term adverse event data are sparse [382]. The nine procedures compared in ESTER with their associated SUCRA ratings are shown in Table 3.

*Adapted from ESTER [363].

Several health economic analyses of MUS procedures have been published with conflicting results. In a review of 26 economic evaluations and on the basis of a cost-utility and value of information analysis over a ten-year period, the authors concluded that MUS remains among the most cost-effective approaches [383]. A primary economic evaluation of retropubic vs. transobturator tapes over a five-year time period suggested that the latter may be cost-effective and cost-saving compared to the standard TVT approach [417]. Conversely, the findings from the ESTER network meta-analysis stated that over a lifetime, retropubic MUS was, on average, the least costly and most effective surgery but the level of uncertainty in these analyses was high.
Complications of synthetic mid-urethral slings

The ESTER network meta-analysis noted that comparative assessment of adverse events between different procedures was not always possible due to the lack of available data [382]. Direct comparisons using head-to-head meta-analyses were mainly carried out for retropubic MUS, transobturator MUS or single-incision slings. The authors did, however, comment that “For other intervention comparisons, the number of studies was generally small and the CIs wide. However, there was some evidence to suggest that bladder perforation was more likely to occur after retropubic MUS than after transobturator MUS, open colposuspension or traditional sling”. In particular, the retropubic approach for MUS was associated with a significantly higher rate of bladder perforation than transobturator MUS was (5% vs. 0.2%). Regarding voiding dysfunction, 36 studies compared transobturator MUS with retropubic MUS, favouring the former (OR: 0.51). For pain, it is worth noting that it was defined and measured in many different ways across individual trials and across Cochrane reviews. Some pain outcomes were categorised by location (e.g., suprapubic) or time (e.g., short or long term). These discrepancies made it difficult to combine data from different studies. Data were available mainly for the comparison between retropubic and transobturator MUS and other surgical procedures. However, groin pain was more frequent after transobturator MUS than retropubic MUS (6.3% vs. 1.3%; OR: 3.80). Converse findings were reported for suprapubic pain, which was higher following TVT (1.2% vs. 4.0%; OR: 0.37). Visceral injury (0.5% vs. 2.4% OR: 0.36), mean operating time, intraoperative blood loss and hospital stay were lower in the transobturator than retropubic MUS groups. The overall vaginal erosion risk was low and comparable in both groups [382].

The rate of tape/mesh exposure or extrusion between retropubic and transobturator MUS was similar (2.1% vs. 2.4%; OR: 1.10). The exact time points at which measurements occurred could not be derived from the Cochrane reviews but most studies were reported to have a short follow-up period (≤ 12 months), with only a few studies having ≥ 2 years’ follow-up [382]. Repeat surgery for UI was more common in the transobturator group (RR = 8.79); however, the data are limited and of low quality.

A population-based study performed in Scotland in > 16,000 women with SUI showed a similar rate of complications between mesh and non-mesh surgery [422]. However, a recent study of > 92,000 patients followed in the UK National Health Service showed a significant (9.8%) rate of complications using a more broad definition, and following patients for a longer period [423]. The level of detail regarding the precise nature of complications in this paper was poor. These findings suggest that, as with any SUI surgery, MUS can be associated with complications and fully informed consent is mandatory.

In general, the available published evidence would suggest that MUS does not seem to be associated with significantly higher rates of morbidity and complications compared to other surgeries for SUI, such as open retropubic colposuspension. Pelvic organ prolapse is more common after colposuspension while voiding dysfunction occurs more often after MUS [387]. The ESTER review has commented that the level of detail regarding short-to-medium adverse event data is poor for all SUI surgeries [382] and the Panel is aware of the recent findings from the Independent Medicines and Medical Devices Safety Review in the UK that has raised the possibility that the level of complications from synthetic MUS may be higher than the medical literature would suggest [380].

The ESTER SR included seven studies comparing reintervention after transobturator and retropubic MUS [382]. Pooled analysis of these studies showed wide CIs and considerable uncertainty around the estimated OR (twelve-month post-surgery: 1.37). At one to five years after the procedure, rates of repeat continence...
surgery were higher in women undergoing transobturator MUS (18.3%) compared with retropubic MUS (0.5%), although only two studies were available for the analysis. A similar trend was observed in studies with a longer follow-up period (> 5 years) but the pooled analysis of these studies showed wide CIs. For retropubic MUS surgery, the bottom-to-top route was 10% more efficacious than top-to-bottom in terms of subjective cure and it was associated with less voiding dysfunction, bladder perforations and vaginal erosion [382].

**Single-incision mid-urethral slings**

Although there have been many studies published on single-incision devices, it should be noted that there are significant differences in technical design between devices and it may be misleading to make general statements about them as a class of operation. It should also be noted that some devices have been withdrawn from the market (e.g., TVT Secur®, Minitape, MiniArc®), and yet evidence relating to these devices may still be included in current meta-analyses. There is evidence to suggest that single-incision slings are quicker to perform and cause less postoperative thigh pain, but there is no difference in the rate of chronic pain. There is insufficient evidence for direct comparisons between single-incision slings, and no conclusions have been reached about differences between devices.

The ESTER SR showed, based on low-quality evidence, that at twelve months, retropubic and transobturator MUS were more effective than single-incision sling (TVT, OR: 0.50; TOT, OR: 0.68). The SUCRA score was 39.8% for women cured after single-incision slings. However, since not all single-incision devices have been assessed in a comparative RCT, it may be unsafe to assume that they are collectively technically similar or exhibit the same levels of efficacy.

Little data exists regarding the systematic reports of sling complications. When existing, the main limitations are heterogeneity of cohorts, poor long-term follow-up, and lack of evidence on the effective management of mesh-related complications [424]. A prospective registry will be required to generate meaningful outcome data and help in the complex management of patients who have mesh-related complications.

**Complications of single-incision slings**

Meta-analysis of comparison between single-incision sling and transobturator MUS showed similar rates of mesh erosion or extrusion between interventions (4.8% vs. 3.7%; OR: 1.23). Rates of postoperative pain were higher after retropubic MUS than after single-incision slings (19.2% vs. 6.8%; OR: 0.21).

The rate of unspecified pain was higher after transobturator MUS than after single-incision sling at twelve months (1.0% vs. 5.2%; OR: 0.24) and 24 months (1.4% vs. 10.4%; OR: 0.16). Single-incision sling was associated with more repeat surgery compared with transobturator MUS (5.1% vs. 2.9%; OR: 1.57). At > 3 years after the procedure, the repeat surgery rate was 10.3% for single-incision slings vs. 7.6% for transobturator MUS (OR: 1.42) [382].

**Sexual function after synthetic mid-urethral sling surgery**

A SR examining the effect of synthetic MUS on female sexual function suggested different and contradictory results between studies. More studies have shown an improvement, or no change, in sexual function because of a reduction in coital incontinence, anxiety and avoidance of sex. Dyspareunia was the most common cause of worsening of sexual function and the precise incidence is difficult to estimate as many studies did not report it [425]. A meta-analysis of outcome measures in trials of sling procedures suggests that single-incision slings are associated with a significantly higher improvement in sexual function compared to standard MUS procedures [426].

### 4.2.4.3.2.5.1 Summary of evidence and recommendations for mid-urethral slings

</tr>
<tr>
<td>The retropubic route of insertion, compared with the transobturator route, is associated with a higher intraoperative risk of bladder perforation and a higher rate of voiding dysfunction.</td>
<td>1a</td>
</tr>
<tr>
<td>The transobturator route of insertion is associated with a higher risk of groin pain than the retropubic route.</td>
<td>1a</td>
</tr>
</tbody>
</table>
Long-term analysis of MUS showed no difference in terms of efficacy for the skin-to-vagina (outside-in) compared to vagina-to-skin (inside-out) directions up to 9 years. 2a

The top-to-bottom (inside-out) direction in the retropubic approach is associated with a higher risk of postoperative voiding dysfunction. 1b

The comparative efficacy of single-incision slings against conventional MUS is uncertain. 1a

Operating times for insertion of single-incision MUSs are shorter than for standard retropubic slings. 1a

Blood loss and immediate postoperative pain are lower for insertion of single-incision slings compared with conventional MUS. 1b

There is no evidence that other adverse outcomes from surgery are more or less likely with single-incision slings than with conventional MUS. 1b

In women undergoing surgery for SUI, coital incontinence is likely to improve. 3

Overall, there is conflicting evidence regarding sexual function following SUI surgery. 2a

Improvement in sexual function appears higher with single-incision slings than with standard MUS. 1a

NB: Most evidence on single-incision slings is from studies using the tension-free vaginal tape secure device, and although this device is no longer available, it is, however, still included in many systematic reviews and meta-analyses.

4.2.4.3.2.6 Other treatments for uncomplicated stress urinary incontinence

Intravesical balloon treatment has been explored for women with SUI. The Vesair® gas-filled intravesical balloon differs from other treatment methods in that it is not intended to increase outlet resistance or minimise urethral hypermobility but to attenuate the fluctuation of intravesical pressure when the abdominal pressure increases [427, 428]. Two sham-controlled RCTs have evaluated the Vesair® intravesical balloon [427, 429]. Both reported significant reductions in incontinence symptoms and pad weight but QoL was not significantly different between study arms. High levels of adverse events were reported in both trials as well as significant numbers of withdrawals/device removals. The most common adverse events were dysuria, urgency, gross haematuria and UTIs.

Mechanical devices have been used to treat SUI for centuries. There are several devices available which act either by supporting the bladder neck or urethra to address urethral hypermobility, or by occluding the urethral lumen. A 2014 Cochrane review of eight RCTs that included three small trials comparing mechanical devices to no treatment found inconclusive evidence of benefit [430]. Another 2014 review of mechanical devices concluded that there was insufficient evidence to support their use in women [431]. The place of mechanical devices in the management of SUI remains in question. Currently, there is little evidence from controlled trials on which to judge whether their use is better than no treatment, and large well-conducted trials are required for clarification. There is also insufficient evidence in favour of one particular device and few comparisons of mechanical devices with other forms of treatment [430].

Systematic reviews support the use of compression devices such as the adjustable compression therapy and artificial urinary sphincter (AUS) devices [432, 433]. Although these procedures are largely reserved for those with recurrent or complicated SUI (see Section 4.2.4.3.3.3 External compression devices), these recent additions to the literature include the use of some compression devices for uncomplicated SUI.

4.2.4.3.3 Surgery for women with complicated stress urinary incontinence

This section addresses surgical treatment for women with complicated SUI as defined in Section 4.2.2.

Women with associated genitourinary prolapse are included in Section 4.7.

The principal procedures included are:
- Colposuspension or MUS (synthetic or autologous) following failed primary SUI surgery;
- External compression devices: adjustable compression therapy (ACT®) and AUS;
- Adjustable slings.

4.2.4.3.3.1 Colposuspension or mid-urethral sling (synthetic or autologous) following failed primary stress urinary incontinence surgery

Urinary incontinence following SUI surgery may indicate persistent or recurrent SUI, or the development of de novo UUI, or both. Careful evaluation including urodynamics is an essential part of the work-up of these patients.

Most of the data on surgery for SUI refer to primary operations. Even when secondary procedures have been included, it is unusual for the outcomes in this subgroup to be separately reported. When they are, the numbers of patients are usually too small to allow meaningful comparisons. This means that no firm recommendations can be made regarding which modality is best for the treatment of recurrent SUI, and previous SRs have commented that in view of the absence of any evidence, clinicians must rely largely on expert opinion or personal experience when advising patients about treatment options [434].

The ESTER network meta-analysis revealed that women with transobturator MUS were more likely to undergo repeat surgery than those who had retropubic MUS, and fewer repeat operations were observed after retropubic MUS compared with other interventions [382]. A recent update of two Urinary Incontinence Treatment Network trials [435] compared the retreatment-free survival rates by initial surgical procedure. Five-year retreatment-free survival rates were 87%, 96%, 97%, and 99% for Burch colposuspension, autologous fascial sling, transobturator, and retropubic MUS, respectively. Types of surgical retreatment included autologous fascial sling (19), bulking agent (18), and synthetic sling (1). This suggests that MUS may not be preferred in cases of recurrent SUI [435]. In these cohorts, 6% of women after standard anti-incontinence procedures were retreated within five years; mostly with injection therapy or autologous fascial sling. Not all women with recurrent SUI chose surgical retreatment.

A 2019 Cochrane review attempted to summarise the data regarding different types of MUS procedures for recurrent SUI after failure of primary surgical therapy [436]. The literature search identified 58 records but all were excluded from quantitative analysis because they did not meet eligibility criteria. Overall, there were no data to recommend or refuse any of the different management strategies for recurrent or persistent SUI after failed MUS surgery. Another SR looking at the effectiveness of MUS in recurrent SUI included twelve studies and reported an overall subjective cure rate following MUS for recurrent SUI after any previous surgery of 78.5% at an average 29 months' follow-up [437]. The subjective cure rate following MUS after previous failed MUS was 73.3% at follow-up of sixteen months. The authors commented that there was a lower cure rate with
transobturator compared to the retropubic tape for recurrent SUI after previous surgery. Conflicting evidence comes from a SR assessed the effectiveness and complications of various surgical procedures for female recurrent SUI and reported on data from 350 women in ten RCTs with a mean follow-up of 18.1 months [438]. The authors found no difference in patient-reported and objective cure/improvement rates between retropubic and transobturator MUS in the setting of recurrent SUI. There was also no significant difference between Burch colposuspension and retropubic MUS in terms of patient-reported improvement or objective cure/improvement.

A SR of older trials of open surgery for SUI suggested that the longer-term outcomes of repeat open Burch colposuspension may be poor compared to autologous fascial slings [439]. Similarly, one large non-randomised comparative series suggested that cure rates after more than two previous operations were 0% for open colposuspension and 38% for autologous fascial sling [440].

4.2.4.3.3.2 Adjustable slings

Although adjustable slings are most commonly used for treatment of complicated SUI, they may also be considered for uncomplicated SUI. There are no RCTs investigating outcome of adjustable sling insertion for women with SUI. There are limited data from cohort studies on adjustable tension slings with variable selection criteria and outcome definitions. Few studies have included sufficient numbers of patients or have long enough follow-up to provide useful evidence.

One adjustable sling is the Remeex system (Neomedic International®, Terrassa, Spain), which was investigated in a prospective study of 230 women with SUI [441]. After a mean follow-up of 89 months, 165 patients were cured of SUI (71.7% in the intention-to-treat [ITT] analysis, 80.5% in per protocol [PP] analysis). Forty patients remained incontinent (17.4% in ITT, 19.5% in PP). Eighty-eight patients required readjustment of the sling during follow-up.

The tension was increased in 82 cases due to recurrence of SUI and reduced in six due to outlet obstruction. The currently available adjustable sling devices have differing designs, making it difficult to draw general conclusions about them as a class of procedure.

</table>

4.2.4.3.3.3 External compression devices

External compression devices are usually used for treatment of recurrent SUI after failure of previous surgery but can be considered for primary treatment. Studies have largely included patients with profound intrinsic failure of the sphincter mechanism, characterised by low VLPP or urethral closure pressure [432, 433]. The two
intracorporeal external urethral compression devices available are the adjustable compression therapy (ACT®) device and AUS.

ACT®: Using US or fluoroscopic guidance, the ACT® device is inserted by placement of two inflatable spherical balloons; one on either side of the bladder neck. The volume of each balloon can be adjusted through a subcutaneous port placed within the labia majora. A SR including eight studies published between 2007 and 2013 with follow-up of one to six years revealed 15–44% of patients considered that their SUI had been cured and 66–78.4% were satisfied [432]. The explantation rate was 19–31%. In these studies, a significant reduction in the number of pads used daily was consistently observed after ACT® balloon placement and QoL was significantly improved. The authors concluded that ACT® balloons constitute a reasonable, minimally-invasive alternative for treatment of female SUI due to intrinsic sphincter deficiency, especially in patients who have already experienced failure of standard surgical treatment.

AUS: The major advantage of AUS over other anti-incontinence procedures is the perceived ability to be able to void normally [430]. There have been a few case series of AUS in women, with populations of 45–215 patients and follow-up of one month to 25 years [442-445]. Case series have been confounded by varying selection criteria, especially the proportion of women who have neurological dysfunction or who have had previous surgery. Most patients achieved an improvement in SUI, with reported subjective cure in 59–88%. Common adverse effects included mechanical failure requiring revision (≤ 42% at ten years) and explantation (5.9–15%). In a retrospective series of 215 women followed-up for a mean six years, the risk factors for failure were older age, previous Burch colposuspension and pelvic radiotherapy [445].

Early reports of laparoscopically implanted AUS do not have sufficient patient populations or sufficient follow-up to be able to draw any conclusions [446, 447].

A more recent SR included seventeen studies but all were retrospective or prospective non-comparative case series [433]. Most patients had undergone at least one anti-incontinence surgical procedure prior to AUS implantation (69.1–100%). Outcomes revealed that complete continence rates were 61–100%. The rates of explantation were 0–45%, erosion rates were 0–22% and mechanical failure rates were 0–44%. The authors concluded that AUS can provide excellent functional outcomes in women with SUI resulting from intrinsic urethral sphincter deficiency but at the cost of high morbidity.

<tr>
<td>4.2.4.3.4.1 Stress urinary incontinence surgery in obese women</td>
</tr>
<tr>
<td>There is no agreement about the outcome of incontinence surgery in obese women. Secondary analysis of an RCT on retropubic and transobturator tapes for treatment of women with SUI suggests that obese women experience inferior outcome compared to non-obese women. Stratification of patients according to BMI (&lt; 30 and ≥ 30) shows a significant difference in objective dry rates (negative pad test) at one year (85.6% vs. 67.8%) and five years (87.4% vs. 65.9%) and subjective cure (absence of SUI symptoms) at one year (85.8% vs. 70.7%) and five years (76.7% vs. 53.6%). At one and five years, 6.7% and 16.3% of patients who were initially dry (negative pad test) after surgery developed a positive pad test [448, 449].</td>
</tr>
<tr>
<td>Conversely, short-term outcome of single-incision MiniArc® sling showed comparable objective cure rates (negative cough stress test) at two years (86% and 81% in non-obese and obese women, respectively); similar improvement of the Urinary Distress Inventory 6 and Incontinence Impact Questionnaire seven was observed in non-obese and obese women [450].</td>
</tr>
<tr>
<td>4.2.4.3.4.2 Stress urinary incontinence surgery in elderly women</td>
</tr>
<tr>
<td>Age appears to be a significant factor in outcome from SUI surgery but there is conflicting evidence. An RCT of 537 women comparing retropubic to transobturator tape, showed that increasing age was an independent risk factor for failure of surgery over the age of 50 years [451]. An RCT assessing risk factors for the failure of TVT vs. transobturator tension-free vaginal tape (TVT-O) in 162 women also found that age was a specific risk factor for recurrence at one year [452]. In addition, based on a sub-analysis of a trial cohort of 655 women at two years’ follow-up, it was shown that elderly women were more likely to have a positive stress test at follow-up, were less likely to report objective or subjective improvement in stress and UUI, and were more likely to undergo retreatment for SUI. There was no difference in time to postoperative normal voiding [453].</td>
</tr>
<tr>
<td>Another RCT comparing immediate TVT vs. no surgery (or delayed TVT) in older women, confirmed efficacy of surgery in terms of QoL and satisfaction, but with more complications in the surgical arm [454]. Conversely, a cohort study of 181 women undergoing TVT-O found that women aged &gt; 70 years had similar outcomes when compared to women &lt; 70 years in terms of cure rates (92.5% vs. 88.3%), voiding dysfunction, vaginal erosion and groin pain at a median follow-up of two years [455].</td>
</tr>
<tr>
<td>Furthermore, a SR of the efficacy of treatments of UI in older patients suggests that MUS is successful in older patients (&gt; 65 years) with 5.2–17.6% reporting persistent SUI after surgery. No difference in the frequency of de novo UUI, persistent UUI or persistent SUI was found in older patients [384].</td>
</tr>
<tr>
<td>A cohort study of 256 women undergoing vagina-to-skin (inside-out) TOT reported similar efficacy in older vs. younger women, but there was a higher risk of de novo urgency in older patients [456].</td>
</tr>
</tbody>

4.2.5 **Follow-up**
The follow-up of patients with SUI is dependent on the treatment given. For conservative and physical therapies, sufficient time should be allowed for the demonstration of a therapeutic effect. For pharmacological treatment, early follow-up is recommended. For most surgical interventions, short-term follow-up should be arranged to assess efficacy and identify any early postoperative complications.

The Panel is supportive of long-term outcome assessment via registries and recognises the paucity of high-quality long-term data, specifically regarding complications from surgery.

4.3 **Mixed urinary incontinence**
The term MUI is broad because it may refer to equal stress and urgency symptoms, stress-predominant symptoms, urgency-predominant symptoms, urodynamic stress urinary incontinence (USUI or USI) with DO or USUI with clinical urgency symptoms, but no DO [457]. The challenge of this broad definition is that it leads to inconsistencies when evaluating treatment options and outcomes.

4.3.1 **Epidemiology, aetiology and pathophysiology**
The prevalence rates of MUI vary widely in the literature. Most epidemiological studies have either not considered subtypes of UI, or only reported on SUI, UUI and MUI. The current literature is unclear regarding the population prevalence and risks for the different UI subtypes [458]. There are many urinary symptom questionnaires used in epidemiological research, with varying evidence of validity. Caution is needed when comparing epidemiological studies that do or do not report a separate MUI subgroup, and when generalising from population level data to clinical practice. The problems arise from significant heterogeneity in terms of types of questionnaires/surveys used, population parameters, variable response rates, varying definitions of MUI, and outcome measures.

It seems apparent, however, that MUI is the second most common form of UI, after SUI, with most studies reporting a 7.5–25% prevalence [458]. One can extrapolate that among women with UI, approximately one-third have MUI [459]. In a secondary analysis of a large clinical trial, 655 women were evaluated for UI and their response to treatment [460]. It was found that 50–90% of women fell into the category of MUI based on patient-reported answers to the Medical Epidemiologic and Social Aspects of Aging and Urinary Distress Inventory (UDI) questionnaires. However, when objective criteria such as urodynamic findings were used, only 8% of women were categorised as having MUI.

Mixed urinary incontinence is usually caused by a combination of the same factors that cause SUI and UUI. Several factors may be responsible for its development, including oestrogen deficiency, abnormalities in histomorphology, and microstructural changes [461]. One report postulates that an incompetent sphincter and bladder neck allow urine to enter the proximal urethra during stress, causing a urethral-detrusor reflex that triggers involuntary detrusor contraction, which then causes urgency and UUI [462]. Another study has shown that urine flow across the urethral mucosa increases the excitability of the micturition reflex [463]. Ultimately, it is unlikely that one theory or risk factor can explain the development of MUI and its symptoms; it is more probable that disturbances in several elements and the lack of bladder compensation results in the development of MUI [461].

4.3.2 **Diagnostic evaluation**
Assessment of patients with MUI begins with a thorough history of the patient’s urinary symptoms and follows the recommendations set out in the general evaluation and diagnosis of LUTS section 3. It is conventional to try and categorise MUI as either stress or urge predominant.

Mixed urinary incontinence is difficult to diagnose, as the condition comprises many phenotypes. Some women exhibit detrusor contractions provoked by physical stressors, some have unprovoked detrusor contractions, and many have no abnormal detrusor contractions, but still report urine leakage with the sensation of urgency. Some women with urgency symptoms do not manifest UUI because their urethral sphincter is strong and often able to prevent urine leakage [464].

The role of urodynamics in MUI is unclear, but establishing objective degrees of SUI and DO incontinence may help in counselling patients about the most appropriate initial treatment option.

4.3.3 Disease Management

4.3.3.1 Conservative management

Women with MUI generally have more severe symptoms and respond less well to treatment than women with only SUI or UUI [465]. Clinicians are encouraged to begin treatment for MUI with conservative management directed toward the most bothersome component of the symptom spectrum and to reserve surgery as a last resort [464].

4.3.3.1.1 Pelvic floor muscle training

An RCT comparing PFMT with and without an audiotape for 71 women with UI did not find any difference between the two treatment arms [466]. Mean number of incontinent episodes per day decreased from 3.9 overall to 3.2 for participants with MUI. Six months after completing the course of exercises, approximately one third of all enrollees reported that they continued to note good or excellent improvement and desired no further treatment.

A small RCT including 34 women with SUI and MUI compared eight weeks of PFMT with no treatment and found that PFMT significantly increased PFM strength, improved QoL, and reduced the frequency of UI episodes compared to no treatment [467]. Another RCT including SUI and MUI confirmed these results [468].

A multicentre randomised controlled non-inferiority trial on 467 women with MUI was conducted in ten hospitals. Participants were randomised 1:1 to receive EA (36 sessions over twelve weeks with 24 weeks of follow-up) or PFMT–solifenacin (5 mg/day) over 36 weeks. In women with moderate-to-severe MUI, EA was not inferior to PFMT–solifenacin in decreasing the 72-h incontinence episodes (between-group difference, –1.34%) [469].

In a comparative study of the effectiveness of behavioural therapy and PFMT (combined with MUS vs. sling alone in women with MUI), 416 (86.7%) had post-baseline outcome data and were included in primary twelve-month analyses [470]. The UDI score in both groups significantly decreased (178.0 to 30.7 points in the combined group, 176.8 to 34.5 points in the sling-only group). The model-estimated between-group difference, did not meet the minimal clinically important difference threshold. Adherence to the behavioural therapy and PFMT regimes, which is a prerequisite for achieving a satisfactory outcome, was not reported in the study.

A Cochrane review comparing PFMT with no or sham treatment included 31 RCTs from fourteen countries, but there was only one study including women with MUI and one with UUI and none of them reported data on cure, improvement, or number of episodes of these subgroups [341].

Another Cochrane review comparing different approaches to delivery of PFMT (21 RCTs) concluded that increased intensity of delivery of the therapy improves response and that there is no consistent difference between group therapy and individualised treatment sessions [345]. This concurs with the latest ICI publication [347]. No other consistent differences between techniques were found.

The effect of combining biofeedback with PFMT has already been fully addressed in Section 4.2.4.1.3, and there was no evidence of any additional benefit in a population with predominantly MUI.

4.3.3.1.2 Bladder training

Details on BT programmes are given in Section 4.2.4. The ICI 2017 [347] concluded that for women with UUI or MUI, PFMT and BT are effective first-line conservative therapies. One RCT assigned 108 women with diagnoses of SUI (n = 50), UUI (n = 16), or MUI (n = 42) to sixth weeks of BT and PFMT or BT alone [471].
Overall, and in the SUI and MUI subgroups, significantly more patients in the BT and PFMT group reported cure and improved symptoms.

4.3.3.1.3 Electrical stimulation
A Cochrane review on ES for SUI included participants with SUI or stress-predominant MUI. Twenty-five percent of the included trials were deemed to have a high risk of bias due to a variety of factors, including baseline differences between groups and industry funding. For subjective cure or improvement of SUI, low-quality evidence indicated that ES was better than no active treatment or sham treatment. Electrical stimulation for OAB and SUI is covered in Sections 4.1.4.1.5.4 and 4.2.4.1.3.2.

4.3.3.3 Pharmacological management
Many RCTs include patients with MUI with predominant symptoms of either SUI or UUI but few report outcomes separately for those with MUI compared to pure SUI or UUI groups.

4.3.3.3.1 Tolterodine
In an RCT of 854 women with MUI, tolterodine ER was effective for improvement of UUI but not SUI, suggesting that the efficacy of tolterodine for UUI was not altered by the presence of SUI [472]. In another study (n = 1380) tolterodine was equally effective in reducing urgency and UUI symptoms, regardless of whether there was associated SUI [473]. Similar results were found for solifenacin [474, 475].

4.3.3.3.2 Duloxetine
In one RCT of duloxetine vs. placebo, 588 women were stratified into either stress-predominant, urgency-predominant or balanced MUI groups. Duloxetine was effective for improvement of incontinence and QoL in all subgroups, although results in the stress-predominant groups were better [476]. Treatment-emergent adverse event rate in the duloxetine group was 61.3% with discontinuation rates of 15.7%. Adverse event rates were higher in those participants taking other concomitant antidepressant agents.

Duloxetine was found to have equal efficacy for SUI and MUI in an RCT (n = 553) following secondary analysis of respective subpopulations but no adverse events data were reported [477].

Offer duloxetine (where licensed) to selected patients with stress-predominant MUI unresponsive to other conservative treatments and who want to avoid invasive treatment, counselling carefully about the risk of adverse events.  

### 4.3.3.4 Surgical management

The surgical treatment options for MUI, include all the anti-incontinence procedures are outlined in the SUI Section 4.2.4.3.

Many RCTs include patients with pure SUI or pure UUI as well as patients with MUI. However, few RCTs report separate outcomes for MUI subgroups.

*Post hoc* analysis of a large RCT showed that in women undergoing either autologous fascial sling or Burch colposuspension, the outcomes were poorer for women with a concomitant complaint of preoperative urgency [453]. A similar *post hoc* review of another RCT comparing transobturator and retropubic MUS showed that the greater the severity of preoperative urgency, the more likely that treatment would fail [97]. However, an earlier study had found that surgery provided similar outcomes, whether or not urgency was present prior to surgery (this study included only a few patients with urodynamic DO). Another RCT including 93 patients with MUI showed a significant improvement in continence and QoL in the group that had TVT and botulinum toxin A (Botox<sup>®</sup>) rather than with either treatment alone [478].

Case series tend to show poorer results in patients with MUI compared with those with pure SUI. In a case series of 192 women undergoing MUS insertion, overall satisfaction rates were lower for women with mixed symptoms and DO on preoperative urodynamics compared to those with pure SUI and normal urodynamics (75% vs. 98%, respectively) [479]. A comparison of two parallel cohorts of patients undergoing Burch colposuspension for SUI, with and without DO, found inferior outcomes in women with MUI [480].

One cohort of 450 women, showed that in urgency-predominant MUI, the success rate of TVT fell to 52% compared to 80% in stress-predominant MUI [481]. In a study of 1113 women treated with transobturator TVT, SUI was cured equally in stress- or urgency-predominant MUI. However, women with stress-predominant MUI had significantly better overall outcomes than women with urgency-predominant MUI [482].

In contrast to studies examining older surgical methods, more recent studies (generally small case series) have reported that UUI symptoms improve in 30–85% of women with MUI after MUS surgery [483].

In a prospective, multicentre, comparative trial, 42 women who had TVT for MUI had greater improvement in urgency and QoL scores than 90 women who had TOT. There were no significant differences in the cure and satisfaction rates between the two groups [484].

In a single-centre prospective study, 86 consecutive women underwent TOT for MUI. At a mean follow-up of 59 months, SUI was cured objectively in 83.7% and subjectively in 87.2% of the patients. The continence rates were 74.4% for UUI and 66.3% for MUI (cure of both components). The patient-reported success rate was 87.2% ("much better" or "very much better" on the Patient Global Impression of Improvement scale). There were significant improvements in all domains except general health. The univariate analysis found no significant risk factor for persistence of SUI. Median age > 60 years and menopause were predictive for persistence of UUI. Median and mean age > 60 years were predictive of persistence of overall incontinence [485]. Overall, the outcome for women with pre-existing UUI remains uncertain.

In a secondary analysis of a study of transobturator TVTs in the treatment of women with urodynamic MUI, no difference in patient-reported success rates was found between the vagina-to-skin (inside-out) and the skin-to-vagina (outside-in) groups (63.2% and 65.5%, respectively) at nine years’ follow-up [421].

Analysis of the trial populations included in the meta-analysis on single-incision slings suggests that the evidence can be generalised to women who have predominantly SUI, and no other clinically severe LUT dysfunction. The evidence is not adequate to guide choice of surgical treatment for those women with MUI, severe POP, or a history of previous surgery for SUI.

Research trials should define accurately what is meant by MUI. There is a need for well-designed trials comparing treatments in populations with MUI, and in which the type of MUI has been accurately defined.

4.4 Underactive bladder

Underactive bladder is a common clinical entity, defined by the ICS as “a symptom complex characterised by a slow urinary stream, hesitancy, and straining to void, with or without a feeling of incomplete bladder emptying sometimes with storage symptoms” [486]. Diagnosis of UAB is based on clinical symptoms and the presentation and aetiology can be variable.

This differs from DU, which is a diagnosis based on urodynamic studies. Detrusor underactivity is defined by the ICS as “a detrusor contraction of reduced strength and/or duration, resulting in prolonged bladder emptying and/or failure to achieve complete bladder emptying within a normal time span” [1]. Acontractile detrusor is specified when there is no detrusor contraction.

Female voiding dysfunction is defined by the ICS as a diagnosis based on symptoms and urodynamic investigations characterised by abnormally slow and/or incomplete micturition, based on abnormally slow urine flow rates and/or abnormally high PVR volume; ideally on repeated measurement to confirm abnormality. Pressure-flow studies may be required to determine the cause of the voiding dysfunction [31].

4.4.1 Epidemiology, aetiology, pathophysiology

4.4.1.1 Epidemiology

Underactive bladder as an entity remains difficult to study, partly because its corresponding urodynamic correlate, DU, remains loosely defined, leading to significant variability in diagnostic criteria across research studies and significant overlap of symptoms with other conditions. As a consequence of the variable definition, reported prevalence also varies and ranges from 12% to 45% in women, with increased prevalence seen with age [76] and in institutionalised elderly women [487]. Several studies have demonstrated similar prevalence rates for DU in the ambulatory setting of around 12–19.4% [488-490]. As would be expected, voiding symptoms consistent with UAB are higher. A Detroit population study surveyed 291 women, with 20% reporting difficulty with bladder emptying [491]. In a large cross-sectional, population-based internet survey conducted in the USA, UK and Sweden including 15,861 women aged ≥ 40 years, 20.1% referred to weak flow, 27.4% to incomplete bladder emptying and 38.3% to terminal dribbling [5].

Some studies have identified the coexistence of DO during filling and DU in the voiding phase of urodynamic studies (formerly known as detrusor hyperactivity with impaired contractility; DHIC) as a common finding in elderly women. Up to 38.1% of incontinent institutionalised women showed DHIC in urodynamic studies [492, 493].

4.4.1.2 Aetiology

The presence of DU in diverse clinical groups suggests multifactorial aetiology [494]. Idiopathic DU is probably partly an age-dependent decrease in detrusor contractility with no other identifiable causes, but young women can also have DU. There are many secondary causes of DU, including neurogenic (e.g., multiple sclerosis, multiple systemic atrophy, spinal cord injury, spina bifida, Parkinson’s disease, hydrocephalus, transverse myelitis, stroke, Guillain–Barré syndrome, diabetes mellitus, and pelvic nerve injury), myogenic (acute prolonged bladder overdistension, diabetes mellitus, and BOO) and iatrogenic (pelvic surgery) causes [495].
4.4.1.3 Pathophysiology

There are many pathways involved in normal detrusor contraction, and there are different possible sites of dysfunction [76] with a variety of mechanisms involved in UAB:

- Central circuits and centres (prefrontal cortex, periaqueductal gray, pontine micturition centre and hypothalamus): failure of integration or processing;
- Efferent pathways (sacral cord, sacral nerves, pelvic nerves and postganglionic neurons): impaired detrusor activation;
- Afferent pathways (peripheral afferent nerves, anterolateral white column and posterior column): early termination of voiding reflex;
- Muscle (detrusor myocytes and extracellular matrix): loss of intrinsic contractility.

Different aetiologies can share common pathophysiological mechanisms: for example, diabetes mellitus affects mainly afferent pathways and the detrusor muscle; and neurogenic diseases affect central circuits and efferent/afferent pathways.

One study suggests that in patients with DU, there is significant urothelial dysfunction, increased sub-urothelial inflammation and apoptosis, and altered sensory protein expression [496]. Impaired urothelial signalling and sensory transduction pathways may reflect part of the pathophysiology of DU. Pelvic ischaemia is another proposed mechanism of DU in ageing patients [496] (Figure 1).

4.4.2 Classification

There is no current classification system of UAB. Patients can be classified according to presumed aetiology or pathogenic mechanism, but without sufficient longitudinal data or high-level evidence to establish prognostic factors, the classification of UAB patients in terms of relevant clinical characteristics or risk of complications is not possible.

4.4.3 Diagnostic evaluation

4.4.3.1 Symptoms associated with detrusor underactivity

A retrospective study correlated LUTS with urodynamic findings in 1788 patients (1281 women). Women with DU, defined as detrusor pressure at maximum flow rate ($P_{detQ_{max}}$) < 20 cmH₂O, maximum flow rate ($Q_{max}$) < 15 mL/s, BVE < 90% and excluding obstruction on video-urodynamic studies, had a significantly higher
occurrence of reduced and/or interrupted stream, hesitancy, feeling of incomplete bladder emptying, palpable bladder, and absent and/or decreased sensation compared with women with normal pressure and flow [497]. A qualitative study on a small sample of male and female patients diagnosed with DU reported a variety of LUTS and associated impact on QoL. Storage symptoms of nocturia, increased daytime frequency, and urgency, and the voiding symptoms of slow stream, hesitancy, and straining were reported by over half of the patients. A sensation of incomplete emptying and post-micturition dribble were also frequently described. The impact of their symptoms on QoL was variable, but in general, storage symptoms were more bothersome [498].

Based on current data, it is not possible to find a pivotal symptom or collection of symptoms to identify DU patients. The ICI Questionnaire Underactive Bladder (ICIQ UAB) has been developed as a research PROM tool, that needs validation before use in common clinical practice [499].

4.4.3.2 Urodynamic studies

Non-invasive studies like uroflowmetry, PVR volume measurement and BVE determination are potentially useful to identify women who might have DU. There is considerable symptomatic overlap with BOO, and uroflowmetry and PVR volume findings may also be similar. Only invasive urodynamics with pressure–flow studies can reliably distinguish DU from BOO and these urodynamic diagnoses can coexist. Diagnosis in women is particularly difficult as they can void by relaxing the pelvic floor, that is, without detectable detrusor contraction during pressure–flow study and without increased abdominal pressure [500]. The simplest methods to define and diagnose DU are based on the use of cut-off values of $Q_{\text{max}}$ and $P_{\text{det}}Q_{\text{max}}$, possibly combined with cut-off values of PVR volume and BVE. However, there is no consensus on which cut-off values should be used [501]. It is obvious that the prevalence of DU depends on the criteria used. In a retrospective study of 1015 women, DU was found in 14.9% when using $Q_{\text{max}} < 12 \text{ mL/s}$ or PVR volume $> 150 \text{ mL}$; in 9.6% when using $P_{\text{det}}Q_{\text{max}} < 30 \text{ cm H}_2\text{O}$ and $Q_{\text{max}} < 10 \text{ mL/s}$; and in 6.4% when using $P_{\text{det}}Q_{\text{max}} < 20 \text{ cm H}_2\text{O}$, $Q_{\text{max}} < 15 \text{ mL/s}$ and BVE $< 90\%$ [502].

More elaborate methods combine urodynamic data into an index or a physical quantity that reflects bladder contraction strength. A value below a certain threshold would thus diagnose DU. Again, there is no consensus regarding what is normal/abnormal. Table 4 provides an overview of the best-known parameters, their background, and typical values. Watt’s factor (WF) estimates the power generated by the detrusor per unit area of bladder surface [503] and it varies during voiding. Usually, $WF_{\text{max}}$ is considered. Alternatively, its value at $Q_{\text{max}}$ can be used. Projected isovolumetric pressure (PIP) is a gross simplification of the bladder output relation and estimates the maximum detrusor pressure that can be generated by the bladder when the outlet is closed; the isovolumetric detrusor pressure. The bladder contractility index (BCI) is simply a reduction of PIP to an index [504]. The population in which PIP and BCI were developed mainly consisted of men. Projected isovolumetric pressure one, is similar to PIP and also estimates the isovolumetric detrusor pressure, but was developed in an entirely female population via an experimental method [505].

A third method of quantifying bladder contraction strength involves stop tests. One study compared three types of direct measurement of isovolumetric pressure: (1) the voluntary stop test, in which the patient voluntarily interrupted flow; (2) the mechanical stop test, in which flow was interrupted by a balloon catheter; and (3) the continuous occlusion test, in which the subject tried to void against a blocked outlet. The latter had the best reliability and best detected drug-induced changes, though the results of the mechanical stop tests were similar [506].

All parameters discussed above give some information about the strength of detrusor contraction in a given void. They do not necessarily reflect what the detrusor might potentially achieve under optimum conditions [507]. Also, they give no information on the important aspect of voiding duration. No parameters for this are available. Finally, abnormally low bladder contraction strength does not necessarily imply insufficient bladder contraction strength to achieve optimal voiding. Table 4 summarises different parameters to measure detrusor contraction in female patients.

BPO = benign prostatic obstruction; BCI = Bladder contractility index; PIP = Projected isovolumetric pressure; UUI = urgency urinary incontinence; WF = Watt’s factor.

4.4.4 Disease management
As there are so many different possible causes and pathogenic mechanisms involved in female UAB, preventive and therapeutic strategies are difficult to define. Among preventive strategies, early recognition after major surgery or labour might prevent long-term problems associated with prolonged bladder over-distension. Nerve-sparing techniques for radical pelvic surgery are more favourable in terms of early recovery of bladder function [510, 511].

Treatment of female DU includes strategies to ensure bladder drainage, increase bladder contraction, decrease urethral resistance, or a combination [508]. The management goals for UAB are to improve symptoms and QoL, to reduce the risk of complications for impaired bladder emptying, and to identify situations where interventions may not be appropriate.

4.4.4.1 Conservative management
4.4.4.1.1 Behavioural interventions
Regular or timed voiding to avoid bladder over-distension should be encouraged in women with impaired bladder sensations. Assisted voiding by abdominal straining with adequate relaxation of the PFM has been recommended, as well as double or triple voiding in an attempt to improve bladder emptying. None of these manoeuvres has proven its efficacy in a randomised study. There is a possible association between voiding by excessive abdominal straining and the risk of pelvic organ prolapse [512]. A small retrospective study in women with neurogenic acontractile detrusor secondary to spina bifida showed that Valsalva voiding may increase the risk of rectal prolapse compared with CISC [513].

4.4.4.1.2 Pelvic floor muscle relaxation training with biofeedback
There are no RCTs on PFM relaxation training in adult women with UAB. Contradictory to common beliefs, one study found significant relaxation of the PFMs after contraction [514] and another study found that PFM relaxation training over time increased the speed of relaxation after a single contraction [515]. However, muscle contraction is known to be followed by relaxation. There is some evidence from the paediatric literature, including one RCT that compared efficacy of PFM relaxation with biofeedback plus combined therapy (including hydration, scheduled voiding, toilet training and diet) vs. combined therapy alone in children with non-neuropathic UAB and voiding dysfunction. Mean number of voiding episodes was significantly increased in the relaxation training group compared with the group with only combined treatment (6.6 ± 1.6 vs. 4.5 ± 1
times a day). Postvoid residual urine volume and voiding time decreased considerably, whereas maximum urine flow increased significantly in the relaxation group compared with the combined treatment group (17.2 ± 4.7 vs. 12.9 ± 4.6 mL/s) [516].

4.4.4.1.3 Clean intermittent self-catheterisation
See Section 4.1.4.1.3 for details on CISC.

4.4.4.1.4 Indwelling catheter
Indwelling urinary catheter may be an option for some women who have failed all other treatments and are unable to perform CISC. Complications include UTI, stone formation and urethral damage. Suprapubic catheterisation may be preferable over urethral catheterisation to minimise the risk of urethral trauma and pain [517].

4.4.4.1.5 Intravesical electrical stimulation
Intravesical electrical stimulation (IVES) can be used to improve bladder dysfunction by stimulating A-delta mechanoreceptor afferents, but requires preservation of afferent circuits and healthy detrusor muscle. One retrospective study in sixteen patients (eleven females) found that two-thirds of patients with a weak detrusor after prolonged bladder over-distension regained balanced voiding after IVES due to detrusor reinforcement [518].

4.4.4.1.6 Intravaginal insert
The intravaginal insert, or prosthesis, is a short silicone catheter containing an internal valve and pump mechanism positioned in the female urethra. A narrative review [519] that evaluated the InFlow™ intravaginal valve pump and activator identified seven studies of which six were industry sponsored. The studies reported a high drop-out rate (12–50%), mainly due to tolerability issues (leakage and discomfort), but discontinuation rates were found to be reduced with careful patient education and counselling prior to commencement. Amongst participants who did tolerate the device, QoL rates improved by 60% and UTI rates were marginally lower than for the standard comparator (CISC). The studies reported equivalent efficacy for the insert in terms of reducing PVR compared to CISC. The certainty of evidence from this review remains low due to clinical heterogeneity and publication bias.

4.4.4.2 Pharmacological management

4.4.4.2.1 Parasympathomimetics
Theoretical approaches to UAB pharmacological treatment include direct stimulation of detrusor cell muscarinic receptors using agonists like carbachol or bethanechol, or inhibiting acetylcholinesterase (enzyme that inhibits the endogenous muscarinic agonist acetylcholine) using agents such as distigmine, pyridostigmine or neostigmine.

A SR on the use of parasympathomimetics in patients with UAB included ten RCTs (controls typically received placebo or no treatment). Three studies reported significant improvements relative to the control group, but six did not and one even reported significant worsening of symptoms. There was no evidence for differences between individual drugs, specific uses of such drugs, or in outcome measures [520]. The review concluded that the available studies do not support the use of parasympathomimetics for treating UAB, especially when frequent and/or serious adverse effects (gastrointestinal upset, blurred vision, bronchospasm and bradycardia) are taken into account.

4.4.4.2.2 Alpha-adrenergic blockers
In order to improve bladder emptying, decreasing outlet resistance through sympathetic blockade at the bladder neck/urethra has been investigated. One prospective study with tamsulosin showed similar improvement in terms of uroflowmetry parameters (specifically in the percentage of patients who had a good therapeutic response) in women with BOO (39.4%) or DU (32.7%) [521]. Another longitudinal study including fourteen women with DU showed clinical and urodynamic improvements after tamsulosin [522]. A prospective single-blind RCT in female patients with DU compared efficacy of alpha-blocker, cholinergic drugs or combination therapy, with the latter exhibiting the best results [523].

4.4.4.2.3 Prostaglandins
Prostaglandins are prokinetic agents that promote smooth muscle contraction. Prostaglandins E2 and F2 have been used intravesically to treat urinary retention after surgery. A Cochrane review showed a significant association between intravesically administered prostaglandin and successful voiding among postoperative patients with urinary retention. However, the success rate was low (32%) compared to placebo. It should also be noted that the 95% CI was wide, RCTs included in the pooled analysis were underpowered with
methodological limitations, and the event rate was very low, indicating a very low certainty of the evidence [524]. Intravesical prostaglandin treatment is rarely used and further research is necessary before it can be taken up more widely.

4.4.4.3 Surgical management
4.4.4.3.1 Sacral nerve stimulation
Sacral nerve stimulation is approved by the US FDA for therapy of non-obstructive urinary retention. The mechanism of action has not been fully elucidated, but activation ofafferent sensory pathways, modulation–activation of the central nervous system, and inhibition of inappropriate activation of the guarding reflex are some of the mechanisms proposed.

An RCT included 37 patients in the implantation arm and 31 in the standard medical therapy arm, showing a mean decrease in PVR volume in the implantation group compared with a control of 270 mL and a mean increase in voided PVR volume of 104 mL [525]. A meta-analysis of seven studies showed a mean difference in PVR volume reduction of 236 mL and a mean voided volume increase of 299 mL [526]. The response rate during the trial phase ranged from 33 to 90% (mean 54.2%) and the success rate of permanent implantation ranged from 55 to 100% (mean 73.9%), highlighting that patient selection is crucial [527]. A subgroup of women with idiopathic urinary retention (Fowler’s syndrome) had a higher response rate of 68–77% [528].

In conclusion, SNS is a valid option for female patients with DU, with proper patient selection. Women should have preserved bladder contractility on urodynamic tests and mechanical/anatomical BOO should be excluded. Patients with evidence of anatomical BOO, suspected loss of intrinsic detrusor contractility or neurogenic bladder dysfunction show lower response rates [529].

4.4.4.3.2 Onabotulinumtoxin A
Onabotulinumtoxin A injections in external striated urethral sphincter may improve voiding in patients with DU by reducing outlet resistance and reducing the guarding reflex. Some retrospective case studies have shown improvement in voiding symptoms, recovery of spontaneous voiding, and improvement in urodynamic parameters (reduction of voiding pressure and/or urethral closure pressures, reduced PVR volume) [530, 531]. The duration of symptomatic relief is short; typically three months.

4.4.4.3.3 Transurethral incision of the bladder neck
Transurethral incision of the bladder neck has been described in short series of women with refractory DU. In a retrospective case study, 40/82 (48.8%) women achieved satisfactory outcomes (spontaneous voiding with voiding efficiency ≥ 50%), but five (6.1%) patients developed SUI and two (2.4%) developed a vesico-vaginal fistula [532].

4.4.4.3.4 Reduction cystoplasty
This is an uncommon procedure with a few case reports described only in men [533].

4.4.4.3.5 Myoplasty
One retrospective multicentre study reported the long-term results of latissimus dorsi detrusor myoplasty in patients with bladder acontractility, with 71% recovering complete spontaneous voiding, with a mean PVR volume of 25 mL [534]. No other groups have published their experience to reproduce these findings.

4.4.4.4 Summary of therapeutic evidence on detrusor underactivity
The level of evidence for most therapeutic interventions for DU is low. Only CISC remains as a gold standard to reduce the adverse consequences of a high PVR volume and incomplete voiding, in spite of the low level of evidence that supports this statement.

4.4.4.4.1 Summary of evidence and recommendations for underactive bladder

<table>

4.4.5 Follow-up

Natural history and clinical evolution at long-term follow-up of women with DU is not well known. No longitudinal cohort studies with long-term follow-up are described in the literature. The interval between follow-up visits depends on patient characteristics, treatments given and the frequency of urinary complications.

4.5 Bladder outlet obstruction

4.5.1 Introduction

Bladder outlet obstruction is defined by the ICS as “obstruction during voiding, characterised by increased detrusor pressure and reduced urine flow rate” [1]. Its precise diagnosis requires urodynamic evaluation including an assessment of pressure and flow.

Voiding dysfunction is a broad term defined by the ICS as “a diagnosis made by symptoms and urodynamic investigations characterised by abnormally slow and/or incomplete micturition, based on abnormally slow urine flow rates and/or raised PVRs, ideally on repeated measurement to confirm abnormality” [113]. Pressure–flow studies are required to determine the precise cause of the voiding dysfunction. In women, voiding dysfunction can be caused by BOO or DU [1]. There are also non-obstructive causes and therefore voiding dysfunction and BOO should not be used interchangeably. Another term that must be differentiated from BOO and voiding dysfunction is dysfunctional voiding, which is a specific and discrete form of voiding dysfunction characterised by an intermittent and/or fluctuating flow rate due to involuntary intermittent contractions of the periurethral striated muscle during voiding in neurologically normal individuals [113].

4.5.2 Epidemiology, aetiology, pathophysiology

4.5.2.1 Epidemiology

Estimates of prevalence of BOO among women vary from 2.7% to 29% [535]. One large series of women undergoing urodynamic evaluation for LUTS found that ~20% are diagnosed with BOO. The wide variance is due to several factors, including differences in definitions and diagnostic criteria for female BOO, differences in study populations, and variation in study methods. The estimated prevalence rates of LUTS due to BOO in women are lower than those reported in men (18.7–18.9% vs. 24.3–24.7%) [536].
Prevalence of voiding LUTS is associated with age [55, 537, 538], parity [55, 539], prolapse [55, 539] and prior continence surgery [55, 539]. Bladder outlet obstruction has long been postulated to cause mainly voiding symptoms [540] but recent data from a series of 1142 consecutive women referred for evaluation of LUTS suggest that storage symptoms may be predominant in women diagnosed with BOO, and excess daytime urinary frequency was the most common symptom reported by 69% [535].

4.5.2.2 Pathophysiology
Bladder outlet obstruction is one of multiple causes of voiding dysfunction in women. The obstruction can be either anatomical (mechanical) or functional. In anatomical BOO, there is a physical or mechanical obstruction to the outflow of urine, whereas in functional BOO there is a non-anatomical, non-neurogenic obstruction of the outlet usually resulting from non-relaxation of the bladder neck, sphincter or PFM, or increased urethral sphincter tone or PFM contraction during voiding, as observed in patients with dysfunctional voiding.

Mechanisms for anatomical (mechanical) obstruction include external compression, fibrosis, stricture or injury to the urethra and kinking of the urethra due to POP. Progressive fibroblastic reaction around the urethra induced by mesh tapes or slings used in incontinence surgery may also cause anatomical (mechanical) obstruction [495]. In a retrospective review of 192 women diagnosed with BOO, 64% had mechanical obstruction [535].

Functional obstruction may be caused by failure of relaxation, or contraction, of the bladder neck and/or urethral sphincter complex or the PFMs during sustained detrusor contraction [540]. The exact causes of this lack of relaxation, or contraction, are often elusive but might be due to sympathetic hyperactivity or hypertrophy of the bladder neck smooth muscle for primary bladder neck obstruction [541], or may be mostly behavioural for dysfunctional voiding [542].

4.5.2.3 Aetiology
Conditions associated with anatomical BOO include POP, incontinence surgery, urethral stricture, urethral stenosis, urethral diverticulum, urethral caruncle, urethral malignancies and paraurethral masses.

Conditions associated with functional BOO include primary bladder neck obstruction, dysfunctional voiding, and idiopathic urinary retention (Fowler’s syndrome).

In primary bladder neck obstruction, the bladder neck fails to open adequately during voiding, in the absence of an anatomical obstruction [543]. It is estimated that 4.6–16% of women presenting with voiding symptoms have primary bladder neck obstruction [541].

Dysfunctional voiding is due to involuntary intermittent contractions of the periurethral striated or levator muscles during voiding in neurologically normal women, and is thought to be caused by faulty learned toileting behaviour [495]. There is also some evidence of a link between dysfunctional voiding and a history of sexual abuse [544].

Idiopathic urinary retention, also known as Fowler’s syndrome, is a primary disorder of the external urethral sphincter with hypertrophy of the muscle fibres, which fail to relax during micturition. It is associated with decreased detrusor contractility via enhancement of the guarding reflex. It is seen most often, but not exclusively, in young women with urinary retention and is characterised by increased urinary sphincter volume and activity/tone, which may be hormonally triggered [545].

Alpha-adrenergic agonists, such as pseudoephedrine commonly contained in decongestants, can lead to some form of functional obstruction due to their stimulatory effects, which may contract the bladder neck and lead to urinary retention [546].

Neurological conditions can also bring about functional BOO in women. These conditions are not considered in these guidelines and are covered elsewhere [9].

4.5.3 Classification
4.5.3.1 Anatomic bladder outlet obstruction
Anatomical BOO involves a physical or mechanical obstruction of the outflow of urine.

4.5.3.2 Functional bladder outlet obstruction
Functional BOO involves a non-anatomical, non-neurogenic obstruction of the outflow of urine resulting from non-relaxation or increased tone in the bladder neck and/or urethral sphincter complex or the PFMs (Table 5). Neurological causes of functional BOO are not considered in these guidelines and are covered elsewhere [9].

4.5.4 Diagnostic evaluation

Diagnosis of BOO in women, although dependent on formal pressure–flow studies, may be suggested by several clinical and other non-invasive assessments.

4.5.4.1 Clinical history

In terms of clinical history, a range of LUTS may be elicited and these may not be confined to voiding LUTS. Women may not present until they have the possible complications of BOO, such as recurrent UTI, chronic urinary retention or acute/chronic kidney disease [535]. The evidence regarding clinical utility of symptoms for the diagnosis of BOO is inconclusive. In a single-centre retrospective study involving 587 women, 38 of whom were diagnosed with BOO, the authors concluded that symptom assessment alone was insufficient for diagnosis and a full urodynamic evaluation was essential [547]. A smaller retrospective study of 57 premenopausal women with bothersome LUTS found a significantly higher proportion of women with bladder dysfunction presenting with UUI. Patients with voiding phase dysfunction have higher total scores and voiding symptom subscores in the American Urological Association (AUA) symptom index [548]. Perhaps some of the difficulty in evaluating the diagnostic accuracy of urinary symptoms comes from the observation that a significant proportion of women presenting with obstruction also have concomitant urodynamic abnormalities. In a large study of > 5000 women with urinary symptoms including 163 with BOO, additional urodynamic diagnoses were noted in 54% [549]. Similarly, in a study involving 101 women with a primary diagnosis of SUI, the prevalence of BOO (based on maximum urine flow \( Q_{\text{max}} \) < 12 mL/s and maximum detrusor pressure at \( Q_{\text{max}} \) > 25 cm H\(_2\)O) was 16% [550]. Symptoms alone were not sufficient to discriminate between the various different diagnostic groups of women in these two studies. LUTS appear to be fairly sensitive to change following intervention for BOO. A prospective study in 53 women with clinically suspected voiding dysfunction describes significant symptom improvement in twelve of sixteen patients who underwent surgical intervention [551].

4.5.4.2 Clinical examination

There are no studies evaluating the clinical utility of physical examination in women with suspected BOO; nevertheless, it is widely considered as a key part of the medical assessment. It allows for visual inspection of the urethra and vagina for possible causes of mechanical obstruction as well as an assessment of the pelvic floor, which may be the cause of functional obstruction.

4.5.4.3 Uroflowmetry and post-void residual volume

Reduced \( Q_{\text{max}} \) and incomplete bladder emptying can result from weakness in the contractile strength of the detrusor muscle, or increased outlet resistance due to functional or anatomical/mechanical BOO. The use of uroflowmetry to differentiate between anatomical and functional BOO was explored in a retrospective study of 157 women [542], which concluded that \( Q_{\text{max}} \) was significantly lower in patients with anatomical obstruction, but a large degree of overlap was noted. The largest evaluation of the diagnostic utility of urine flow studies and PVR volume estimation was a retrospective analysis of > 1900 patients with symptoms of voiding dysfunction, of whom, > 800 were diagnosed with BOO based on urodynamic assessment [552]. Functional BOO was > 6 times more common than anatomical/mechanical obstruction, which does not agree with most of the other epidemiological literature for female BOO. The authors found that although urine flow rate alone was
not accurate enough to diagnose BOO, PVR of ≥ 200 mL could differentiate bladder neck dysfunction from the other causes of BOO, with a receiver-operator characteristics (ROC) area under the curve (AUC) of 0.69. Conversely, in a retrospective study involving 101 women primarily presenting with SUI, a good correlation between abnormal uroflowmetry and urodynamic obstruction (phi = 0.718, p < 0.0001) was found [550]. In a prospective study of > 50 women with a clinical diagnosis of voiding dysfunction, abnormal uroflow curves were observed in ~40% of women, but BOO based on pressure–flow results was confirmed in only 52% of these women [551].

4.5.4.4 Ultrasound
The major utility of US scanning in women with BOO is to detect possible complications such as bladder wall thickening or upper tract dilatation/hydronephrosis. However, the diagnostic capabilities of US have been investigated in a prospective case–control study of 27 patients with cystoscopically confirmed bladder neck obstruction [553]. The diagnostic value of shear wave elastography (SWE) and acoustic radiation force impulse imaging (ARFI) for female BOO was compared and the authors concluded that ARFI was more accurate than SWE, but a combination of the techniques was superior to both alone. Ultrasound scanning was further evaluated in a small study of fifteen women with BOO diagnosed urodynamically [554]. The authors proposed that transvaginal ultrasonography was able to demonstrate a closed bladder neck during attempts at micturition and concluded that this modality was useful for evaluation of the possible causal factors of female BOO, such as primary bladder neck obstruction.

4.5.4.5 Magnetic resonance imaging
The role of MRI in the diagnostic evaluation of female patients with suspected BOO is poorly defined. Although MRI allows for precise anatomical evaluation of pelvic structures, there are no reports of its clinical utility in the diagnosis of female BOO. Magnetic resonance imaging in patients with pathological urethral stricture can determine the degree of periurethral fibrosis, although the prognostic and clinical significance of such a finding has not been established [555].

4.5.4.6 Electromyography
Electromyography (EMG) has been most extensively studied in the subgroup of women with BOO due to idiopathic urinary retention caused by a high-tone non-relaxing sphincter (Fowler’s syndrome). Abnormal urethral EMG activity may be associated with non-relaxation of the striated sphincter, abnormally high urethral pressure, and, through an exaggerated guarding reflex, poor bladder sensation and reduced detrusor contractile strength [544, 556]. Complex repetitive discharges and decelerating bursts are specific urethral EMG abnormalities that have been described in patients with high-tone non-relaxing sphincter, although these abnormalities have also been noted in asymptomatic volunteers [557, 558]. A review of voiding dysfunction in women included 65 studies with only a small number addressing the diagnostic utility of PFM EMG [495]. The authors commented that increased EMG activity of the PFM can be seen during voiding or non-relaxation, and when this is coupled with pressure–flow information from urodynamics, it may be useful to differentiate between functional and anatomical obstruction. Further evidence for this comes from a retrospective study of 157 women with roughly equal numbers of women with functional and anatomical obstruction, which concluded that a low level of PFM EMG activity is characteristic of anatomical obstruction [542]. Additional neurophysiological tests, such as anal sphincter EMG, bulbocavernosus reflex, and pudendal sensory evoked potentials can assess the integrity of the somatic S2–4 nerve roots; however, their clinical utility in the context of non-neurogenic female BOO needs to be better defined [544].

4.5.4.7 Cystourethroscopy
Cystourethroscopy can be useful to visualise any anatomical/mechanical obstruction and provide information regarding its nature, location and calibre. Given that pelvic malignancy may cause anatomical BOO, cystourethroscopy is considered an essential part of the diagnostic pathway. Formal urethral calibration may be useful for women with BOO secondary to pathological urethral stricture and various different urethral calibre thresholds have been used, from 14 to 20 Fr [559].

4.5.4.8 Urodynamics and video-urodynamics
Pressure–flow studies are the mainstay of BOO diagnosis and the characteristic abnormalities are a combination of low flow and concomitant high detrusor pressure [543]. However, while the general definition of BOO is well established, with some data supporting its clinical validity in male patients [560], the urodynamic definition of female BOO remains controversial [540]. Several urodynamic criteria have been introduced during the past twenty years but none has been established as a standard due to lack of clinical validation [540, 561]. The Blaivas and Groutz nomogram, which plots free $Q_{\text{max}}$ and maximum detrusor pressure (P$_{\text{det,max}}$) measured during urodynamic studies, is one of the most popular [562] but has been suggested to overestimate
obstruction [563]. The addition of fluoroscopic imaging suggested by Nitti and colleagues introduces a video-urodynamic criterion for obstruction and has found popularity [77]. However, both methods lack data supporting their clinical validity, especially regarding their predictive value for therapeutic intervention outcomes [75].

In a large retrospective study of 1914 patients, 810 of whom were diagnosed with BOO, several urodynamic cut-off values were determined by ROC curve analysis to optimise the diagnostic accuracy of video-urodynamic studies [552]:

- \( P_{\text{det}Q_{\text{max}}} \geq 30 \) cm H2O for differentiating BOO from bladder dysfunction and normal studies (ROC AUC = 0.78);
- the Abrams-Griffiths number > 30 for differentiating anatomical from functional BOO (ROC AUC = 0.66);
- \( P_{\text{det}Q_{\text{max}}} \geq 30 \) cm H2O for differentiating dysfunctional voiding from poor relaxation of the external sphincter (ROC AUC = 0.93).

Other smaller studies with a similar methodology of utilising ROC curve analysis have concluded that neither pressure–flow data only, nor clinical symptoms alone, may be sufficient for diagnosing obstruction in women [564], therefore independent validation of any suggested thresholds is necessary.

More recently, Solomon and Greenwell devised a female BOO nomogram that parallels the ICS nomogram used for male BOO [565]. It allows the calculation of an alternative BOO female index (BOOIf), using a formula closely aligned to its male counterpart:

\[ \text{BOOIf} = P_{\text{det}Q_{\text{max}}} - 2.2Q_{\text{max}}. \]

It is interpreted with a different algorithm however:

- BOOIf < 0: < 10% probability of obstruction;
- 5 < BOOIf < 18: equivocal, > 50% likelihood of obstruction;
- BOOIf > 18: 90% likelihood of obstruction.

The Solomon–Greenwell nomogram was the first to be tested for clinical validity. In a recent series of 21 unselected consecutive women treated for BOO, the authors observed significant improvement of all urodynamic parameters \(Q_{\text{max}}, P_{\text{det}Q_{\text{max}}} \) and BOOIf in female patients who became asymptomatic postoperatively [566].

An alternative urodynamic parameter of area under the detrusor pressure curve during voiding (corrected for voided volume) has been proposed following a prospective study of 103 women [567]. The authors concluded that this variable appears to be the most discriminating urodynamic parameter for the diagnosis of female BOO. This suggested diagnostic method has not been independently validated.

Voiding cystourethrography (VCUG) alone or in conjunction with concomitant pressure–flow studies may be useful in delineating the site of obstruction. Characteristic features include:

- radiographic evidence of obstruction between the bladder neck and distal urethra in the presence of sustained detrusor contraction [77];
- lack of funnelling appearance of the bladder neck/tight bladder neck in primary bladder neck obstruction;
- proximal dilatation of the urethra with distal narrowing in women with urethral stricture disease or pelvic-floor hypertonicity.

It is not uncommon for women with a voiding dysfunction, specifically functional BOO, to be unable to provide a flow during (video)urodynamic testing. Failure to relax the PFM can enhance the guarding reflex, limiting detrusor contractility.

4.5.5 Disease management

Therapeutic interventions for BOO aim to decrease outlet resistance in order to increase urinary flow, improve bladder emptying and thus reduce voiding and storage LUTS [75, 540, 561]. Treatment choice is commonly dictated by the nature of the underlying cause of the obstruction.

4.5.5.1 Conservative management

4.5.5.1.1 Behavioural modification

Behavioural modification aims to improve or correct maladaptive voiding patterns through analysis and alteration of the relationship between the patients’ symptoms and their environment, lifestyle and habits. Behavioural modification interventions are often tailored to individual patients’ needs, symptoms and circumstances and can include elements such as education regarding normal voiding function, self-monitoring of symptoms, changes in lifestyle factors that may affect symptoms, avoidance of constipation, and alteration of voiding technique. Ultimately, techniques aim to improve the coordination between the detrusor and sphincter, resulting in their synergistic action [75, 540, 561].

The vast majority of individual components of self-management have not been critically evaluated and most recommendations are traditionally derived from consensus methodology. General interventions such as those listed above may help with symptoms resulting from BOO but no quantification of their effect is possible.

4.5.5.1.2 Pelvic floor muscle training +/− biofeedback

Pelvic floor muscle training aims to improve pelvic floor function and urethral stability. In the context of BOO, physiotherapy aims to teach patients to relax their PFMs and striated urethral sphincter during voiding. Pelvic floor muscle contraction, particularly in women with pelvic floor dysfunction, has been shown to significantly reduce vaginal resting pressure and surface EMG activity [514]. A twelve-week PFMT programme in postmenopausal women demonstrated significant improvement in the speed of relaxation after PFM contraction and a decrease in PFM tone [515].

As mentioned in the section discussing UAB (Section 4.4.4.1.2), most of the evidence supporting PFMT in dysfunctional voiding is from paediatric studies.

A case-series reported improved PFM relaxation and voiding function following PFMT with biofeedback in fifteen women with dysfunctional voiding based on a dilated proximal urethra on voiding cysto-urethrography and hyperactivity of the pelvic muscles or external urethral sphincter on EMG during voiding. No clinical outcomes were reported by this series [568].

4.5.5.1.3 Electrical stimulation

Application of electrodes that allow for controlled contraction and relaxation of the PFMs may theoretically facilitate the relaxation of the external sphincter and pelvic floor but no critical evaluation of this intervention in women with BOO has been published.

4.5.5.1.4 Use of vaginal pessary

Intravaginal devices such as pessaries aim to relieve voiding symptoms and improve bladder emptying by physical correction of the obstruction caused by a POP. In a prospective study of eighteen women with grade three or four cystoceles and diagnosed with BOO by urodynamics (defined as \( P_{det}Q_{max} > 25 \text{ cm H}_2\text{O}, Q_{max} < 15 \text{ mL/s} \)), normal voiding was noted in seventeen (94%) immediately after placement of a vaginal pessary. No other outcomes were available in this series [569]. No long-term data are available on the use of vaginal pessary for BOO.

4.5.5.1.5 Urinary containment

Urinary containment devices include body-worn absorbent products. Their use in BOO is to achieve social continence in patients with urinary retention and associated overflow UI and they are often only a temporary measure. There are no published studies on the outcomes or adverse events associated with the use of urinary containment devices for the management of female BOO. While there may be no studies exclusively involving women with BOO, there are many involving women with UI who may have BOO as an underlying cause.
4.5.5.1.6 Urinary catheterisation

Significant urinary retention from BOO may be addressed by actively bypassing the obstruction and draining the residual urine. Catheterisation may be used as a treatment itself or as an adjunct to an initial treatment of urethral dilatation or urethrotomy or bladder neck incision. There are two ways of using a catheter: CISC or indwelling catheterisation [116].

After UI surgery, BOO may be managed by short-term catheterisation in most patients who have transient postoperative voiding difficulty. For a few women who develop chronic urinary retention, CISC or indwelling catheterisation may be offered [495].

A small RCT investigated the effectiveness of CISC to prevent recurrence after internal optical urethrotomy for urethral stricture disease. In the treatment group, CISC was done twice a day for one week, and once a day for four weeks, then once weekly for seven weeks post-urethrotomy. Freedom from stricture recurrence, determined by urography and uroflowmetry performed twelve weeks postoperatively, was higher in the catheterisation group compared to the group with no catheterisation (78.5% vs. 55.4%) [570]. This finding mirrors the Cochrane review on self-dilatation for urethral stricture among men that showed less recurrence with the performance of self-dilatation [571].

In a series of 20 patients with voiding dysfunction after TVT who were put on a CISC programme, overall cure rate was 59%, with cure defined as consistent residual volume < 100 mL. Half of these patients were voiding normally within twelve weeks [572].

A patient satisfaction survey involving 188 patients on CISC/self-dilatation, which included 38 patients with urethral stricture, showed positive (pleased or satisfied) outcomes in 54.3% of patients, while 28.2% had mixed feelings and 9.6% were unhappy. No rates were given specifically for the BOO group [573].

4.5.5.1.7 Intraurethral inserts

An intraurethral insert is a short silicone catheter containing an internal valve and pump mechanism positioned in the female urethra. The valve-pump mechanism is operated by an external control unit, which activates to open the valve and the pump to draw urine from the bladder and allow voiding. At the end of urination, the pump ceases to rotate and the valve closes to regain continence. The insert is routinely replaced once a month.

Only one study reported the use of this device in 92 women with voiding dysfunction of various aetiologies including multiple sclerosis, prior pelvic surgery, pelvic radiation, diabetes mellitus, and spinal stenosis and injury. The device was removed within seven days of insertion in 60% of the cases due to discomfort, pericatheter leakage or technical difficulty. An additional 20% of patients had late discontinuation. All those who continued to use the device were satisfied, with PVR volumes remaining < 100 mL. Adverse events included migration into the bladder in six cases and symptomatic UTI in four cases [574, 575]. Extended, long-term data on the use of urethral inserts are not available.

4.5.5.1.8 Extracorporeal magnetic stimulation

Extracorporeal magnetic stimulation involves the patient sitting on a device that induces consistent PFM contraction and relaxation by repeated magnetic stimulation of motor nerve fibres. Extracorporeal magnetic stimulation contracts and then relaxes the PFM following a set frequency and interval. It is postulated that patients could therefore learn to spontaneously contract or relax the PFM, which may enhance their ability to relax their pelvic floor while voiding [576].

In a small (n = 60) prospective non-randomised trial, alfuzosin was compared to EMS and to the combination of alfuzosin + EMS in women with functional BOO. They observed significant increase of $Q_{\text{max}}$ and significant decrease of International Prostate Symptom Score (IPSS) in all groups and significantly greater improvement in the QoL question of the IPSS in the combination therapy group [576].

76 MANAGEMENT OF NON-NEUROGENIC FEMALE LOWER URINARY TRACT SYMPTOMS (LUTS) - limited update March 2022
In women with large (grade three or four) cystoceles causing bladder outlet obstruction (BOO), placement of a vaginal pessary may improve voiding efficiency.

Regular CISC after urethrotomy is better than no catheterisation to prevent recurrence of urethral strictures. Regular CISC after urethrotomy is better than no catheterisation to prevent recurrence of urethral strictures.

A CISC programme in women with voiding dysfunction after TVT has a cure rate of 59%.

Women who use an intraurethral device have lower PVR volume but most require its removal due to complications.

Extracorporeal magnetic stimulation combined with alfuzosin may be more effective than either of these therapies alone in women with functional BOO.

### 4.5.6 Pharmacological management

#### 4.5.6.1 Alpha-adrenergic blockers

Alpha-adrenergic blockers are postulated to relieve LUTS caused by BOO in women via smooth muscle relaxation in the bladder neck, thus decreasing bladder outlet resistance [577].

Systematic reviews on the use of alpha-blockers in women generally involve studies with a population that includes women complaining of LUTS and voiding dysfunction. Confirmation of BOO is often not required in the trials included [578, 579]. These reviews showed significant improvements in symptoms and urodynamic parameters associated with their use [578-580]. A meta-analysis of fourteen RCTs comparing alpha-blockers and placebo in women with LUTS showed significant symptom relief after alpha-blocker treatment relative to placebo, but no significant difference in Q-max, PVR and adverse event rates [578]. This is in contrast to prospective non-comparative trials that consistently showed improvements in voiding and storage symptoms, bother scores, and urodynamic parameters [Q-max, PVR, P-det, MUCP after alpha-blocker use compared to baseline [521, 522, 581-583].

A SR performed by the Panel of studies on alpha-blockers used specifically for women with BOO included one placebo-controlled RCT, one RCT comparing two types of alpha-blockers, and six prospective non-comparative studies. In the only placebo-controlled RCT reporting subgroup analyses in women with urodynamically proven BOO (based on the Bladder and Groutz nomogram) no significant difference was observed in the changes of IPSS, IPSS sub scores, Q-max, PVR volume and bladder diary after eight weeks of alfuzosin (n = 58) vs. placebo (n = 59). Of note, no EMG and/or voiding cysto-urethrography was used to distinguish between dysfunctional voiding and primary bladder neck obstruction [584].

Information on the comparative effectiveness of the different types of alpha-blockers was limited to one RCT. A small trial of 37 women with IPSS > 8, Q-max < 12 mL/s and PVR volume > 50 mL, compared tamsulosin and prazosin over a three-month treatment period. More patients treated with tamsulosin were completely satisfied with their treatment (16/20 vs. 9/20). Both treatment groups showed significant improvement in symptom scores from baseline but no further statistical comparison between the groups was done. However, a larger decrease in the AUA Symptom Index was seen in the tamsulosin group compared with the prazosin group. More adverse events were reported with prazosin (thirteen vs. one case) [585].

A small three-arm non-RCT in women with functional BOO compared alfuzosin monotherapy and EMS. The combination of alfuzosin and EMS showed greater improvement in storage symptoms and QoL than alfuzosin monotherapy alone [576].

#### 4.5.6.2 Striated muscle relaxants

Baclofen is a gamma-aminobutyric acid (GABA) agonist that exerts its effect on the GABAergic interneurons in
the sacral inter-medialateral cell column responsible for the relaxation of the striated urinary sphincter during voiding. Intrathecal administration has been shown to improve voiding in a trial among patients with spinal cord injury. Oral baclofen has also been widely studied [561].

A randomised placebo-controlled crossover trial investigated the efficacy and safety of a four-week course of oral baclofen 10 mg three times/day in 60 women diagnosed with BOO, based on increased EMG activity with sustained detrusor contraction during voiding. It showed a lower number of voids, significant improvements in \(Q_{\text{max}}\) and \(P_{\text{det}Q_{\text{max}}}\) with baclofen compared with placebo. Post-void residual volume, maximum cystometric capacity and MUCP were not significantly different between the groups. Adverse event rates were also similar, with the most common being somnolence, dizziness and nausea. An important limitation of this study was the lack of patient-reported outcomes to assess symptoms and QoL [586].

A small case series reported the outcomes of 20 women with functional BOO who were given oral baclofen 5 mg three times/day for twelve weeks. There was significant improvement in the mean voided volume and BVE. However, \(Q_{\text{max}}\), \(P_{\text{det}Q_{\text{max}}}\), PVR volume and urethral profile pressures did not significantly change. No significant adverse events were noted [587].

4.5.6.3 Oestrogens

The relative reduction in urethral wall compliance seen in atrophic urethritis due to oestrogen deprivation may be responsible for urethral obstruction in postmenopausal women. Oestrogen therapy is thus theoretically expected to improve the condition. There are no published studies on the use of oestrogens specifically for the management of female BOO.

4.5.6.4 Sildenafil

Sildenafil, by inhibiting phosphodiesterase 5, increases the levels of nitric oxide in the female urethral sphincter, thereby promoting urethral relaxation.

A placebo-controlled, randomised crossover trial that included twenty women with partial or complete retention or obstructive voiding, with high MUCP and elevated US-estimated sphincter volume (> 1.6 cm) showed that while there was significant improvement in symptom scores and urodynamic parameters from baseline with sildenafil treatment, this difference was not significant when compared with placebo [588].

4.5.6.5 Thyrotropin-releasing hormone

Intravenous thyrotropin-releasing hormone (TRH) has been postulated as a neurotransmitter that induces urethral relaxation [589]. The exact mechanism is unclear.

In a small RCT of sixteen women with voiding difficulty, eight (three with BOO) were randomised to receive 200 \(\mu\)g intravenous bolus of TRH, and eight (three with BOO) received saline. No difference in the decline in functional profile lengths and maximum urethral closure pressures were noted between treatment groups, despite a significant decline noted from baseline in the treatment group. No subgroup analysis of women with BOO was reported [589].

**4.5.7 Surgical management**

**4.5.7.1 Intra-sphincteric botulinum toxin injection**

Botulinum toxin inhibits the presynaptic release of acetylcholine, which reduces urethral sphincter tone. It is also believed to decrease the release of noradrenaline in the urethra to counteract external urethral sphincter overactivity [590].

Evidence on the use of botulinum toxin for female BOO is limited to small case series. Most studies included mixed populations without subgroup analyses, or the diagnosis of voiding dysfunction could not be ascertained as solely resulting from BOO. No comparative trial exclusively involving female BOO patients using botulinum toxin has been identified in the literature.

A SR including several reports of small case series using variable doses of botulinum toxin A injected periurethrally in women with dysfunctional voiding showed improvements in symptoms, and reductions in residual volume and voiding detrusor pressure. Larger series in adults (both sexes) showed success rates of 86–100% [590].

A double-blind, placebo-controlled RCT (n = 73) 100 U onabotulinumtoxinA vs. saline resulted in significantly lower IPSS score and larger voided volume compared with saline in 31 men and women with dysfunctional voiding. Dysfunctional voiding was defined by a spinning top appearance on real-time fluoroscopy, poorly relaxed urethral sphincter on EMG, and a normal-to-high voiding pressure with a low and/or intermittent urinary flow rate, a PVR volume > 300 mL, and a low voiding efficiency. Other urodynamic parameters were comparable between the groups [591]. A subgroup analysis on the female population of this study was not available.

Two small case series in women with BOO reported the effects of 100 U intra-sphincteric injection of BTA. Both showed improvement in symptom and bother scores and significant reduction in PVR volume [544, 592]. One study reported increased Q_{max} and improved static urethral pressure profile (UPP) [544]. The average symptom-free duration was 16.8 weeks in another study [592]. Adverse events included UTI and temporary need for CISC. No SUI was reported.

**4.5.7.2 Sacral nerve stimulation**

Sacral nerve stimulation is a type of neuromodulation that allows continuous ES from an electrode placed alongside the sacral nerve via a surgically implanted pulse generator. Electrical stimulation is postulated to decrease urethral tone. Sacral nerve stimulation is also postulated to work by blockade of the inhibitory urethral afferent impulses, which cause inhibition of normal bladder contraction.

No comparative trial as been identified in the literature on the use of neuromodulation for female BOO.

Most publications on neuromodulation for voiding dysfunction are retrospective reviews of cases, involving a mix of patient populations who underwent the procedure for different indications. In studies that indicated a subgroup of patients with urinary retention, there was either no urodynamic confirmation of the nature of the retention or separate outcomes were not reported for participants with retention.

A review of 60 women who underwent for urinary retention associated with outlet obstruction (defined as UPP > 100 cm H₂O, increased urethral sphincter volume > 1.8 mL, and abnormal EMG with repetitive discharges and decelerating bursts) showed an overall spontaneous voiding rate of 72% over a mean follow-up of four years. Of those who continued to require CISC up to twice daily postoperatively, the frequency was less than prior to surgery (degree not specified). There were 99 adverse events and 63 surgical revisions. In this series, half of the patients underwent a one-stage SNS procedure and the other half a two-stage procedure. The proportion of patients who required CISC-assisted voiding was higher in the two-stage group (27% vs. 17%). More serious adverse events (defined as events requiring admission or surgical revision to resolve issues such as loss of response, lead migration and surgical revisions) were associated with the one-stage procedure [588].

In a single-centre series in a subgroup of 32 patients diagnosed with idiopathic urinary retention (Fowler’s syndrome) who underwent SNS, 62.5% achieved a > 50% reduction in CISC rate [593].
4.5.7.3 Pelvic organ prolapse surgery
Pelvic organ prolapse surgery may relieve BOO by correcting the urethral kinking caused by the prolapse or by
relieving the urethral compression brought about by the prolapsing organ [75, 540, 561].

Bladder output obstruction due to POP may be addressed by corrective surgery. Based on reviews, the
majority of patients who had BOO caused by POP who had repair of their cystocele demonstrated
improvement of their voiding difficulties [495, 594].

A multicentre prospective study involving 277 women with at least grade two symptomatic POP who
underwent surgery demonstrated a significant reduction in voiding symptoms and PVR volume one year
postoperatively [595].

A retrospective study of 50 women who underwent laparoscopic sacrocolpopexy for POP showed a significant
increase in mean postoperative $Q_{\text{max}}$ and decrease in $P_{\text{det}}Q_{\text{max}}$ and PVR in those aged $\geq 65$ years. The OAB
symptom score improved but there was no significant difference in the ICIQ-SF score postoperatively [596].

In a case series of 35 women with stage III or IV POP presenting with a preoperative PVR volume > 100 mL
(mean 226 mL), 89% had PVR volume < 100 mL postoperatively [597]. In another case series of 39 patients
with cystoceles who complained of voiding symptoms preoperatively, 30 (79%) achieved normal voiding,
deefined as no obstructive symptoms and a PVR volume < 50 mL, after bladder neck suspension with anterior
colporrhaphy [598].

4.5.7.4 Urethral dilatation
Urethral dilation involves the passage of sequentially greater diameter dilators into the urethra, causing the
obstructing fibrotic tissue to break open, thereby widening the lumen. It is considered the primary procedure
of choice for women suspected of urethral stricture disease [559]. Dilation of up to 30–40 Fr has been done.
There is no standard dilatation technique; dilatation of up to 43 Fr has been described, although other authors
suggest dilating to 30 or 35 Fr.

A SR of female urethral stricture management included three trials involving urethral dilatation. Pooled analysis
of data from 93 women showed a mean success rate of 49% after urethral dilation to 41 Fr with a mean follow-
up of 46 months. Mean time to failure was twelve months. In treatment-naïve patients, success rate (as defined
by trialists) was 58%, compared with 27.2% in patients who had undergone previous dilatation [555].

An RCT of 50 women with OAB syndrome and associated urodynamically confirmed BOO (defined as a $Q_{\text{max}}$
< 15 mL/s with a voided volume of $\geq 100$ mL and/or PVR volume > 200 mL, not due to urethral stricture)
compared the effect of cystoscopy and bladder distension with urethral dilatation ($n=22$) and cystoscopy
only ($n=28$) after six weeks’ follow-up. Significantly more patients who had cystoscopy only had persistent
urgency at six weeks and six months postoperatively. Urodynamic parameters did not significantly change
pre- and postoperatively in both groups. The greater improvement in QoL scores based on the King’s Health
Questionnaire domain scores seen in the non-urethral dilatation group in this trial should be interpreted
cautiously because of the higher baseline scores. There were no significant changes in $Q_{\text{max}}$, PVR volume,
voided volume or $P_{\text{det}}Q_{\text{max}}$ in any of the two groups at six weeks’ questioning of the role of any of these two
options for therapeutic management of BOO. Also, six patients (12%) developed postoperative SUI [599].

A prospective trial of 86 women with primary urethral stricture compared on-demand vs. intermittent urethral
dilatation to 24 Fr (dilate every two months). It showed an overall increase in $Q_{\text{max}}$ and decrease in PVR volume
post-dilatation. Significantly greater improvements were seen in the intermittent urethral dilatation group [600].

Three small case series showed improvements in symptoms with relief of urgency and/or UI but inconsistent
results in terms of significant improvement in $Q_{\text{max}}$, PVR volume and $P_{\text{det}}Q_{\text{max}}$. Benefits were poorly sustained,
with most patients requiring additional or repeat intervention in the long-term [601-603].

Worsening or new-onset SUI is a concern with urethral dilatation but it is less of a concern than after
urethrotomy or surgical reconstruction. Patients have also reported frequency and urgency post-dilatation
[603].

4.5.7.5 Urethrotomy
Urethrotomy involves incision of the urethra endoscopically or using a urethrotome. It addresses the urethral
narrowing by cutting open the scar tissue which is causing the obstruction [75, 540, 561, 603].
A prospective study of ten women with urethral strictures investigated the effect of Otis urethrotomy to 40 Fr followed by six weekly dilatations. There was significant improvement in IPSS, QoL, voided volume, Q\textsubscript{max} and PVR volume at six months. Only the improvements in PVR volume and QoL were maintained on long-term follow-up (mean 82 months) [601].

4.5.7.6  **Bladder neck incision/resection**

Transurethral bladder neck incision decreases resistance at the bladder neck by cutting open the hypertrophic bladder neck smooth muscle in patients with primary bladder neck obstruction. Transurethral incision of the bladder neck may be performed with a unilateral incision at the twelve o’clock position or with bilateral incisions at the five and seven o’clock, two and ten o’clock or three and nine o’clock positions, or four incisions at the three, six, nine and twelve o’clock positions. This may be done using a resectoscope with a Collin’s knife, cold knife, or using laser energy. Some authors report additional resection of the bladder neck between the five and seven o’clock positions during the procedure.

Evidence on bladder neck incision or resection for female BOO is limited to non-comparative trials. A review of studies on bladder neck incision for the treatment of bladder neck obstruction in women reports success rates of 76–100% [543].

Bladder neck incision was compared with V-Y-reconstruction using Nesbit’s technique in a retrospective study of seventeen women with BOO, diagnosed by various uroradiological, endoscopic and urodynamic investigations. The results showed similar symptomatic improvement rates and postoperative PVR volume between the two groups. V-Y plasty had a longer operating and catheter time, lower uroradiological improvement rate, higher transfusion rate, and higher adverse event rate [604].

Several prospective case series consistently reported significant improvements in IPSS, QoL, Q\textsubscript{max}, P\textsubscript{det}Q\textsubscript{max} and PVR volume after treatment compared to baseline, regardless of the site of the incision, type of energy used or the length of follow-up [605-608].

The largest case series with 84 patients diagnosed with primary bladder neck obstruction (based on lack of funnel shape of the bladder neck during voiding on voiding cysto-urethrography, P\textsubscript{det} > 20 cm H\textsubscript{2}O and Q\textsubscript{max} < 12 mL/s) showed success in 84.5% of patients with improvement in IPSS, QoL, Q\textsubscript{max} and P\textsubscript{det}Q\textsubscript{max} after mean follow-up of 27.4 months (6–78 months). Complications included vesico-vaginal fistula (VVF) (3.6%), SUI (4.7%) and urethral stricture (3.6%) [605].

No comparisons have been made between the different incision techniques (location, length and depth of incision, implement used – cold knife vs. hot knife vs. laser, with or without resection). However, in a case series of 84 patients, complications of VVF and SUI were noted in the cohort of patients who had their incisions at two and ten o’clock positions, and not in those who had their incisions at two and ten o’clock [605].

Adverse events include SUI, requirement for reoperation, and recurrence. Postoperative SUI was reported in 3–33% [543].

4.5.7.7  **Urethroplasty/urethral reconstruction**

Surgical reconstruction of the female urethra has been used in the management of extensive urethral stricture. Several urethroplasty techniques have been reported including the use of vaginal or labial flaps, as well as vaginal and buccal grafts after cutting open the fibrotic tissue causing the urethral obstruction [609]. The use of bladder flaps has also been reported [610], and laboratory-engineered tissue grafts have also been used [610].

The surgical approaches have been described based on the position relative to the urethra; dorsal, ventral or circumferential. The dorsal approach is believed to provide better mechanical support and a more vascularised bed for a graft or flap. However, there is greater risk of damage to the sphincter and clitoral bodies with this approach. The ventral approach is more familiar to most surgeons and requires less urethral mobilisation. However, it is reported as being more prone to urethrovaginal fistulae, although it is not clear to what extent [559].

Reviews of studies reporting outcomes of urethroplasty state success rates of 57–100% [611]. Pooled analysis from six studies using vaginal or labial flaps showed a mean success rate of 91% with a mean follow-up of 32 months. Vaginal or labial graft urethroplasty was reported to have an 80% success rate with a mean follow-up of 22 months.
Oral mucosal grafts, reported in seven studies, had a mean success of 94% after a mean follow-up of fifteen months [559]. A later review of studies on dorsal buccal mucosal graft reported success rates of 62–100%, with a pooled success rate of 86% [612]. A long-term study with a mean follow-up of 32 months showed a stricture recurrence rate of 23.1% [611].

A retrospective comparative study of ten women who underwent urethral dilatation and twelve who underwent dorsal onlay pedicled labial flap urethroplasty, reported significant improvements in both groups in QoL, AUA Symptom Index, PVR volume and Qmax. The urethroplasty group had significantly better QoL scores and Qmax (17.0 vs. 12) at follow-up compared with the dilatation group [613]. Adverse events associated with urethroplasty include new-onset SUI and urgency and worsening of UUI.

4.5.7.8 Urethrolysis
Bladder outlet obstruction in women occurring as a complication of surgery for SUI may be managed surgically by urethrolysis, to regain urethral mobility. Urethrolysis may involve removal of periurethral anti-incontinence sutures, scar tissue and fibrosis.

Case series showed success rates measured as improved voiding and lower residual volumes, improvement or resolution of symptoms and QoL, and improvement of urodynamic parameters after treatment [614-616]. De novo SUI was reported in 39% in one study [616].

A study on 21 patients who underwent urethrolysis suggested an association of persistent postoperative bladder symptoms with greater delay in performing urethrolysis. Patients who presented with postoperative storage and voiding symptoms after a mean seventeen months’ follow-up had a longer time to urethrolysis compared to those who had no complaints (31 vs. nine months) [617].

4.5.7.9 Removal/excision/section/loosening of mid-urethral sling
In women who develop BOO after placement of a mid-urethral sling, surgical management may include tape loosening, incision or division, and excision and/or removal of the tape [495].

Several small retrospective reviews of cases using different techniques of sling revision (incision, partial excision, or excision) showed good success rates in terms of symptom reduction, resumption of voiding with significant reduction in PVR volume and improvement of urodynamic parameters. Stress urinary incontinence recurs in a small proportion of patients and often to a lesser degree than prior to the sling procedure. Studies have shown long-term efficacy, including preservation of continence.

In a series of 63 women who presented with voiding dysfunction and persistent PVR volume > 100 mL after tape surgery for UI, different techniques were compared. Comparisons involved sling revision: sling division (n = 46) vs. partial sling excision (n = 13) vs. sling revision (division or excision) with an additional anti-SUI procedure (n = 4). The authors reported an overall success rate of 87% (PVR volume < 150 mL). No significant difference in success rates was demonstrated among the different revision techniques. There was a greater need for surgery for recurrent SUI in the partial sling excision group without an anti-SUI procedure (23% vs. 2.2 and 0) [618].

4.5.7.9.1 Timing of sling revision
One study showed that patients who underwent surgical release > 180 days after initial anti-UI surgery had significantly less recurrent SUI compared with patients who underwent the release sooner (15% vs. 46%) [619].

4.5.7.10 Summary of evidence and recommendations for surgical management of bladder outlet obstruction

Programmed intermittent urethral dilatation results in better outcomes compared with on-demand dilatation. 3
Effects of urethral dilation are poorly sustained, requiring repeat intervention in the long term. 3
Internal urethrotomy followed by regular dilatations resulted in significant improvement in symptoms and urodynamic parameters in women with BOO. 3
Bladder neck incision in females with BOO results in improvements in symptoms and urodynamic parameters. 3
Complications of bladder neck incision are not common, but include VVF, SUI, and urethral stricture. 3
Urethroplasty using grafts or flaps in women with BOO due to urethral stricture have good success rates with significant improvements of symptoms, QoL scores and urodynamic parameters compared to baseline. 3
Urethroplasty results in better QoL and $Q_{\text{max}}$ compared to urethral dilatation. 2
Long-term results showed significant stricture recurrence rate after urethroplasty. 3
Urethroslysis performed on women with voiding problems after anti-UI surgery resulted in improvements in symptoms, QoL and urodynamic parameters post-operatively. 3
Delayed urethrolysis was associated with persistent post-operative bladder symptoms. 3
Sling revision in women who presented with urinary retention or voiding problems and significant PVRs after sling surgery for UI resulted in improvements in symptoms and urodynamic parameters, resumption of voiding and reductions in PVRs. 3
Sling revision is associated with the risk of recurrent SUI. 3

4.5.8 **Follow up**

Women with BOO should be followed up and monitored regularly due to the risk of further deterioration of voiding or renal function in case of persistence and progression of the obstruction. For those who received treatment, monitoring must be done for recurrence of BOO. In particular, women who undergo urethral dilation, urethrotomy or urethroplasty for urethral stricture need to be monitored for stricture recurrence.
4.6 Nocturia

Nocturia was defined by the ICS in 2002 as “the complaint that the individual has to wake at night one or more times to void” and quantified in an updated document in 2019 as “the number of times an individual passes urine during their main sleep period, from the time they have fallen asleep up to the intention to rise from that period” [620]. The EAU Guidelines Panel on Urinary Incontinence conducted a SR on nocturia in women (596). The search covered evidence up to 2017 and this review was updated with a scoping search in 2020.

4.6.1 Epidemiology, aetiology, pathophysiology

The prevalence of nocturia varies according to age with 4–18% of women aged 20–40 years experiencing ≥ 2 episodes per night, compared to 28–62% of women aged ≥ 70 years [621]. In a study of 1000 community-dwelling older adults, female nocturia was associated with older age, African–American race, history of UI, lower limb oedema and hypertension [622]. A report on > 5000 adults aged 30–79 years identified around 28% with nocturia and found additional correlates with increased BMI, cardiac disease, type 2 diabetes and diuretic use [623]. A SR and meta-analysis with moderate certainty evidence based on the GRADE approach, demonstrated that the higher incidence of nocturia among hypertensive patients was more strongly associated (1.2 to 1.3 fold) among Black and Asian women, unrelated to their age or BMI status [624]. Another SR with moderate certainty of evidence based on the GRADE approach showed that nocturia was associated with a 1.2-fold increase risk of falls and possibly an approximately 1.3-fold increased risk of fractures [625]. Another SR and meta-analysis concluded that nocturia is probably associated with an ~1.3-fold increased risk of death [600].

The aetiology of nocturia is multifactorial and can include both urological and non-urological causes. Urological conditions which may exhibit nocturia as a significant symptom include OAB syndrome, BOO, DU and dysfunctional voiding. Non-urological causes include 24-hour polyuria (which includes nocturnal polyuria), congestive heart failure, sleep apnoea, restless leg syndrome, peripheral vascular disease, sleep disorders, night-time food ingestion, dependent oedema, and excessive fluid intake [626]. Given the varied aetiology of this symptom, there are a range of possible pathophysiological mechanisms, including: (1) 24-hour polyuria (e.g., diabetes mellitus, primary polydipsia, and diabetes insipidus); (2) nocturnal polyuria (e.g., behavioural, peripheral oedema, obstructive sleep apnoea, glycosuria, hormonal abnormalities and cardiac dysfunction); (3) diminished bladder capacity (e.g., OAB syndrome/detrusor overactivity, PFM dysfunction, BOO, pharmaceuticals, LUT calculi or tumours, and neurological bladder dysfunction); and (4) primary or secondary sleep disorders [627].

In postmenopausal women the relative deficiency in endogenous estrogen production is thought to exacerbate all major pathophysiological mechanisms that may underlie nocturia [628].

4.6.2 Classification

Classification of nocturia is dependent on bladder diary analysis and several parameters have been defined as important [629]:

- nocturnal urine volume – total volume of urine passed during the night (this includes the first morning void but does not include the last void prior to sleep);
- maximum voided volume – largest single voided volume in 24 hours;
- nocturia index – nocturnal urine volume divided by maximum voided volume;
- nocturnal polyuria index – nocturnal urine volume divided by 24-hour urine volume;
- nocturnal urine production – nocturnal urine volume divided by duration of sleep in hours.

Analysis of these parameters allows clinical classification of nocturia based on physiological abnormalities that can cause nocturia:

- 24-hour polyuria;
- nocturnal polyuria;
- diminished bladder capacity;
- sleep disorders.

4.6.3 Diagnostic evaluation

Evaluation of nocturia should include a thorough medical history and physical examination with particular reference to history of sleep disorders, fluid balance, associated LUTS, cardiovascular and endocrine comorbidity, renal disease, current medications and history of urological disease [629]. There are several nocturia-specific symptom scores, such as the ICI Questionnaire-Nocturia, Nocturia Quality of Life Questionnaire (N-QoL) and Nocturia Impact Diary; some of which were developed in men. A further screening
A bladder diary is a vital initial investigation tool in patients complaining of nocturia and further supplementary investigations are guided by any abnormalities identified. Bladder diary analysis can allow for calculation of the parameters detailed in Section 4.6.2. A low nocturnal bladder capacity or global bladder capacity will be highlighted by reduced voided volumes during nocturnal hours or both night and day. This suggests an underlying urological condition such as OAB syndrome, BOO or DU. The term 24-hour polyuria is defined as 24-hour urine production > 40 mL/kg [633] and may be present in conditions such as diabetes mellitus or diabetes insipidus. The definition of nocturnal polyuria is age dependent and the thresholds for this diagnosis range from 20% (in younger persons) to 33% (age > 65 years) of the 24-hour urine volume produced during sleep. This may also be observed in patients with loss of circadian rhythm, cardiovascular disease, sleep apnoea, or sleep disorders [629]. A large study conducted across European and American centres involving ~2000 patients identified nocturnal polyuria as a contributory cause of nocturia in 89% of patients who were being treated for LUT abnormalities such as OAB syndrome or benign prostatic enlargement [634].

As an alternative to the > 3-day bladder diary a nocturnal-only diary has been investigated in men [635]. The results showed acceptable sensitivity and specificity for the nocturnal bladder diary compared with the standard bladder diary for most parameters. The nocturnal-only diary was not able to diagnose 24-hour polyuria and has not yet been validated for use in women.

### 4.6.4 Disease management

When evaluating the results of trials involving treatment strategies for nocturia, it is vital to examine for clinical significance as statistical significance can be achieved with small reductions in nocturia episodes.

#### 4.6.4.1 Conservative management

The individual components of self-management have not been critically evaluated and most recommendations are traditionally derived from consensus methodology. Interventions such as those listed below may help with nocturia but, for the majority, no quantification of their effect is possible:

- reduction of fluid intake at specific times;
- avoidance/moderation of intake of caffeine or alcohol;
- distraction techniques;
- bladder retraining;
- pelvic floor muscle training;
- reviewing medication;
- treatment of constipation.

The available data for conservative treatment of nocturia show significant heterogeneity. In the EAU SR [636], three studies [637-639] were favourable for conservative treatment with PFMT, with another failing to confirm a benefit [640].

The highest level of evidence comes from a study of 131 patients (a secondary analysis from a prospective RCT that had urgency-predominant UI as the primary inclusion criterion). The study found that training in PFM
contraction, which included four sessions of biofeedback-assisted PFMT reduced nocturia by a median 0.50 episodes per night and was significantly more effective than anticholinergic drug treatment or placebo [637]. The certainty of evidence associated with this treatment is moderate.

A smaller RCT of 50 women with urinary complaints, randomised 1:1 to bladder training and PFMT compared with a control group receiving no treatment, showed a significant decrease in patients’ complaints of nocturia [638]. Another RCT in only 24 women compared PFMT only to transcutaneous electrical nerve stimulation therapy plus PFMT [639]. Although the authors did not find significant differences between the groups, the change in nocturia episodes before and after treatment was statistically significant in both groups. This study [641] was underpowered by the authors’ own admission. The level of certainty of the evidence from these two trials is low. A large randomised, two-arm, parallel design, superiority trial (n = 647; women), compared the effects of unsupervised behavioural PFMT programs delivered in a two-hour class format and 20 minutes video format on UI prevention. No significant between-group differences of nocturia were observed at three months and twelve months, but at 24 months, women in the two hour class group were less likely to have fewer nocturia episodes (OR: 0.5; 95% CI: 0.3-0.7; p = 0.005) compared with those in the 20 minutes video group, but the authors concluded that the evidence is not sufficient to support one management strategy [642].

A multicentre, open-labeled, RCT evaluated whether cognitive behavioural therapy (CBT) using a self-assessment via a checklist is effective in improving nocturia in a mixed population (30/78 women). The mean rate of achievement of the CBT group was 64.4%. There was no significant difference between the two groups in night-time frequency based on the IPSS Q7 at four weeks but episodes of nocturia on the frequency volume chart (FVC) were significantly smaller in the CBT group (1.9 ± 0.9) than in the control group (2.4 ± 1.3; p = 0.039) [643].

In a secondary analysis from a prospective RCT, 210 women with UUI were evaluated for change from baseline in the number of episodes of nocturia and nocturnal incontinence between groups allocated to medical treatment (tolterodine ER 4 mg) alone vs. medical treatment plus PFMT [640]. No significant difference between the groups was found and the actual difference in nocturia episodes in either treatment arm was small. The level of certainty of the evidence from this trial is low.

A recent RCT has explored both individual and group PFMT with a specific secondary outcome of number of patients with two or more nocturia episodes per night [344]. The authors reported similar reductions, with > 30% of patients who had > 2 episodes of nocturia at baseline no longer experiencing this level of symptoms at one year after PFMT.

In patients with obstructive sleep apnoea who complain of nocturia, continuous positive airway pressure has been shown to be effective in a SR and meta-analysis of five RCTs involving both sexes [645]. This treatment was associated with an average numerical reduction in nocturia of > 2 episodes per night.

4.6.4.2 Pharmacological management

4.6.4.2.1 Desmopressin

Desmopressin is a synthetic analogue of the hormone vasopressin and is most often used for management of nocturia due to nocturnal polyuria. In a recent SR [636], three trials specifically conducted in women were found but more additional data could be extracted from studies in mixed populations. The earliest evidence comes from a 1982 single-site crossover trial involving 25 women treated with 20 μg desmopressin or placebo and revealed a significant decrease in nocturnal urine output at six weeks [646]. A more recent multicentre, multinational double-blind RCT involving 141 women used desmopressin 0.1, 0.2 or 0.4 mg orally at bedtime after a dose-titration period [647]. This increased the likelihood of a positive outcome because non-responders were excluded at that stage. At three weeks, significant reductions in nocturnal urinary frequency and nocturnal diuresis were reported. In another multicentre double-blind RCT, 58 women were randomised into five groups (twelve receiving placebo, twelve desmopressin 10 μg, eleven desmopressin 25 μg, eleven desmopressin 50 μg and twelve desmopressin 100 μg) for four weeks [648]. A dose–response relationship was observed and women appeared more sensitive than men to desmopressin. Significant changes in nocturnal urine volumes were reported in favour of the higher desmopressin doses. Differences in the nocturnal polyuria index also tended to favour desmopressin over placebo and the higher desmopressin doses. The level of certainty of the evidence from these trials is low.

Desmopressin can be safely combined with anticholinergics with significant benefit in women with OAB and nocturnal polyuria, as shown by a multicentre RCT of 97 patients [649]. A post hoc analysis of data comparing three-month once-daily combination (desmopressin 25 μg/tolterodine 4 mg, n = 49) or monotherapy (tolterodine 4 mg/placebo, n = 57) revealed a significant reduction in nocturnal void volume and time to first nocturnal void in favour of combination therapy. The level of certainty of the evidence from this trial is moderate.

Pooled data from three RCTs were used to examine the adverse event profile of desmopressin, specifically hyponatraemia [650]. The authors reported that the majority tolerate desmopressin treatment without clinically significant hyponatraemia, but risk increased with age and lower baseline serum sodium concentration. They advised that desmopressin treatment in elderly patients should include careful monitoring of the serum sodium concentration and should be avoided in patients with a baseline serum sodium concentration below normal range [650].

4.6.4.2.2 Anticholinergics

A SR [636] identified three RCTs involving anticholinergics such as oxybutynin 2.5 mg/day [637] and tolterodine 4 mg/day [640, 649]. A secondary analysis from a prospective RCT involving 131 women with nocturia followed up for eight weeks found that women receiving 2.5 mg immediate-release oxybutynin once daily (with the possibility of self-titration and dose escalation to 5 mg three times daily) had fewer nocturia episodes than women receiving placebo [637]. Women receiving oxybutynin plus behavioural therapy also exhibited a significant decrease in nocturia episodes compared with placebo and oxybutynin alone. A multicentre RCT with 305 women followed up for eight weeks examined the efficacy of tolterodine tartrate 4 mg alone or in combination with behavioural training [640]. Significant differences compared with baseline were observed in mean nocturia episodes and nocturnal incontinence episodes in both groups, but no difference was reported between the two treatment groups. The level of certainty of the evidence from this trial is moderate.

In an RCT including 97 women with nocturnal polyuria and OAB syndrome, comparing three months of once daily combination (desmopressin 25 μg/tolterodine 4 mg, n = 49) or monotherapy (tolterodine 4 mg/placebo, n = 57), a significant reduction in mean number of nocturnal voids compared with baseline was reported in both groups [649]. The level of certainty of the evidence from this trial is moderate.

A large comparative study followed 407 women with OAB and nocturia for four weeks [651]. The patients were given tolterodine as monotherapy in one group, and tolterodine combined with estazolam (a benzodiazepine) in the other group. Significant changes from baseline in both groups for the main outcome of number of nocturia episodes were reported. Combination therapy showed a significant benefit for women with OAB and nocturia compared with monotherapy in terms of differences in number of nocturia episodes, urgency episodes in 24 hours, UII episodes in 24 hours, and voided volume per micturition. The level of certainty of the evidence from this trial is very low.

A small multicentre RCT compared oxybutynin patch vs. mirabegron on nocturia-related QoL in women with OAB. Both treatments showed improvements in N-QoL score at four weeks, but mirabegron showed statistical differences at eight weeks. Additionally, only mirabegron decreased nocturnal frequency and water intake, and prolonged hours of uninterrupted sleep eight weeks after administration with statistical significance, whereas oxybutynin patch did not [652].
4.6.4.3 Oestrogens
In a recent SR [636] only a single RCT investigating the efficacy of oestrogen for nocturia was identified [653]. This trial compared an oestradiol-releasing vaginal ring with an oestriol vaginal pessary in 251 women followed up for six months. There was no difference between the treatment groups in the number of women reporting nocturia, although they reported significant change from baseline in both treatment arms with > 50% of subjects responding in each arm. The certainty of evidence for this outcome was low.

4.6.4.4 Diuretic treatment
In a randomised placebo-controlled study an afternoon dose of 40 mg furosemide (taken six hours before bedtime) in an attempt to establish complete diuresis before bedtime was given to elderly men [654]. In the 43 men who completed the study, night-time frequency in the furosemide group fell by 0.5 episodes compared with placebo, and percentage night-time voided volume fell by 18%. No such study has been carried out in female patients.

4.6.4.4 Surgical management
Surgical treatment is generally reserved for those with underlying correctable LUT disorders. The effect of surgical treatments on symptoms of nocturia can be found in the relevant condition-specific sections of this guideline.

4.6.5 Follow-up
Follow-up of patients with nocturia is dependent on the underlying aetiology of this symptom and the treatment given.
4.7 Pelvic organ prolapse and lower urinary tract symptoms

4.7.1 Epidemiology, aetiology, pathophysiology

Pelvic organ prolapse is a common condition in adult women. The prevalence of POP is 3–6% when bothersome symptoms are used to characterise the condition and increases to 50% when a purely anatomical definition is used [655].

The estimated lifetime risk for POP surgery is 12.6% [656]. Parity, vaginal delivery, ageing and obesity are the most commonly recognised risk factors [657].

Although the aetiology of POP is not fully understood, birth trauma to the levator ani complex is recognised as central to its development. In normal physiology, an intact levator ani complex functionally closes the genital hiatus surrounding the vagina, limiting the pressure gradient between the intra-abdominal and intravaginal areas. During physical activities, this reduces stress on the endopelvic fascia and its condensations (e.g., ligaments), which are crucial in securing the bladder, uterus and rectum to their surroundings. Current aetiological concepts include widening of the levator hiatus due to birth trauma, which creates a low-pressure area in the vagina and consequently increased stress on the ligaments, fascial elements and PFMs during physical activity. When the supporting function of the muscles and connective tissues fails, POP may develop [658]. This concept also explains the time lapse between birth trauma and occurrence of POP.

Pelvic organ prolapse and LUTS often occur simultaneously in women. In isolation, both POP and LUTS are prevalent conditions in women, although the prevalence of LUTS in women with POP exceeds that of LUTS in women without POP [655]. The observation that LUTS may improve or worsen after POP treatment suggests a link between these two entities [655]. Clinical examples include the occurrence of BOO symptoms in severe POP, and disappearance of SUI symptoms with progression of POP (and conversely the occurrence of SUI after treatment of POP) [659].

4.7.2 Classification

Since 1996, POP has been classified according to the Pelvic Organ Prolapse-Quantification (POP-Q) system [660]. For specifics on how to perform the POP-Q measurement and the nine standard points to be measured (Figures 2 and 3), we refer to the original publications [660, 661].

The vagina is divided into anterior (bladder), posterior (rectum) and apical (cervix or vaginal vault) compartments. After scoring the position of the nine POP-Q points, a prolapse of each compartment is graded numerically from stage 0 to 4, with stage 0 being no prolapse and stage 4 being complete eversion of the compartment. A crucial marker in staging POP is the hymenal remnant. Any POP with a maximum descent that is still 1 cm above the hymen (e.g., in the vagina) is considered a stage 1 POP. A maximum descent between 1 cm above and 1 cm below (outside the vagina) the hymen is a stage 2 POP. Any descent beyond 1 cm below the hymen is a stage 3 POP.

The figures below show the POP-Q staging in comparison to the Baden–Walker system (and others) used before the international consensus on the POP-Q staging was introduced as the new standard.

Figure 2: Prolapse classification system

Figure reproduced with permission from the publisher, from Theofratus JP et al. [630].
4.7.3 Diagnostic evaluation

Pelvic organ prolapse is a clinical diagnosis and is staged according to the POP-Q system. Pelvic organ prolapse that is above the hymen should only produce mild symptoms at most [662]. In cases where there is a discrepancy between the clinical symptoms and POP-Q staging, it is advised to consider performing the POP-Q measurement in a standing rather than supine position, or re-evaluating at a later time in the day. Magnetic resonance imaging assessment demonstrated a marked difference in POP staging between supine and standing position [663]. Additional diagnostic tests for POP are mainly indicated if there are accompanying symptoms like LUTS or bowel dysfunction. Imaging techniques are not advised for the routine diagnostic work-up of patients presenting with POP [67]. The role of urodynamics in the diagnostic work-up of SUI has been discussed in the SUI, Section 4.2, of this guideline.

The use of techniques to reduce POP during urodynamic evaluation to diagnose occult SUI is common practice. This information may be used to decide if additional anti-UI surgery should be offered at the time of POP surgery or to counsel patients on the possible after-effects of POP treatment.

There are several POP reduction methods that may be used during physical examination or urodynamic evaluation. In a multicentre observational study, five different cough/stress tests were compared for their ability to detect SUI in women with POP [664]. Stress urinary incontinence during at least one of the five tests occurred in 60/205 (29.2%) women without SUI symptoms. Looking at single test performance, the detection rate of occult SUI in women without symptoms increased from 4.4% in case of no reduction to 22% in case of reduction with a pessary.

A large randomised trial included women with POP without symptoms of SUI, who were randomised to sacrocolpopexy with or without Burch colposuspension [665]. Three hundred and twenty-two stress-continent women with stages 2–4 prolapse underwent standardised urodynamic testing, and the protocol included five prolapse reduction methods. Preoperatively, twelve of 313 (3.7%) women demonstrated urodynamic SUI without prolapse reduction. Preoperative detection of urodynamic SUI with prolapse reduction at 300 mL was by pessary, 6% (5/88); manual, 16% (19/122); forceps, 21% (21/98); swab, 20% (32/158); and speculum, 30% (35/118). Another large trial included women with POP without SUI symptoms randomised to vaginal POP surgery with or without (sham incision) MUS [666]. Before surgery, 33.5% (111/331) of women demonstrated SUI at a prolapse-reduction cough stress test. In an observational study of 172 women with POP without SUI, 19% of women were diagnosed with occult SUI by basic office evaluation (with prolapse reduction with swab on forceps) and 29% on urodynamic evaluation [667].

In summary, SUI can be demonstrated in women with POP without symptoms of SUI after POP reduction in up to 30% of cases. There is no consensus on the best reduction technique.

Although the detection rate of occult SUI increases after reduction of POP in women without SUI symptoms, its clinical value is under debate.
In one trial, preoperative stress-continent women were evaluated during urodynamic testing with prolapse reduction to determine if they were more likely to report postoperative SUI, regardless of concomitant colposuspension (controls 58% vs. 38% and Burch colposuspension 32% vs. 21%) [665]. In another trial, women with SUI during the cough stress test after POP reduction reported UI at three months in 29.6% in the synthetic MUS group, compared with 71.9% in the sham group [666]. Women with a positive prolapse reduction stress test before surgery appeared to receive more benefit from a synthetic MUS at three months, but not at twelve months, than did those with a negative test.

In a large observational study, women did not receive additional anti-UI surgery even if they had SUI after POP reduction preoperatively. In this scenario, 9% (16/172) of women developed postoperative de novo SUI and six underwent surgery for de novo SUI [667]. Women with demonstrable preoperative SUI were more at risk of postoperative SUI: 28% vs. 5%. Based on urodynamic evaluation only, one more woman was predicted to have postoperative SUI, but all six women who underwent treatment for de novo SUI showed SUI during basic office evaluation.

In a model developed to predict the risk of de novo SUI in women undergoing POP surgery based on findings from two trials, twelve preoperative predictors were tested [668]. Positive SUI during a preoperative prolapse reduction test was included in this model, but it failed to be a significant predictor as a single item. Preoperative POP stage was not associated with risk of de novo SUI.

4.7.3.2 Urodynamics in women with pelvic organ prolapse and LUTS (without stress urinary incontinence)
The role of urodynamics is less clear in women presenting with POP and concurrent LUTS, other than SUI. Pelvic organ prolapse is a complex condition incorporating different compartments of the vagina, and presenting at different stages of severity. Information about detrusor activity, as assessed with urodynamics, may provide information about the risk of developing DO after surgery, but also on the risk of urinary retention due to DU. An observational study assessed predictors for DO following POP surgery for POP-Q stage three or higher in 1503 women and the authors concluded that preoperative maximum urethral closure pressure ≥ 60 cm H2O, Qmax < 15 mL/s, maximum detrusor voiding pressure (Dmax) > 20 cm H2O and PVR volume > 200 mL were independent risk factors for postoperative DO [669]. A small observational study (n = 49) evaluated patients with preoperative DU (detrusor pressure at maximum flow was ≤ 10 cm H2O and Qmax ≤ 12 mL/s) after POP surgery. Surgery objectively cured DU in 47% of women and urodynamic findings normalised after surgery [670]. The 2019 NICE guidelines do not include a recommendation to perform urodynamics as part of the diagnostic work-up of POP, except for combination with symptomatic SUI [67].

4.7.4 Disease management
Pelvic organ prolapse symptoms can be treated with PFMT, vaginal pessary, surgery or a combination of these treatments. The scope of these guidelines is to focus on LUTS in women; therefore, only data on the effect of treatment of urinary symptoms are presented.

4.7.4.1 Conservative management of pelvic organ prolapse
The 2013 NICE guideline on Urinary Incontinence and POP in Women had an updated management section in 2019, including a full evidence review [67]. The overall conclusion with respect to conservative treatment for POP was that the evidence is of low quality. Thirteen RCTs were identified. Seven studies presented data on changes in urinary symptoms [671-677]. An additional search identified four RCTs that addressed the addition
of PFMT to POP surgery [678-681], and one that compared combined PFMT/Pilates therapy with lifestyle advice by leaflet [682].

Five studies [672, 674-676, 682] compared PFMT to lifestyle advice/leaflet; one study [673] compared PFMT alone to PFMT with pessary; one study [677] compared PFMT to pessary therapy; and five studies compared surgery for POP with or without addition of PFMT [671, 678-681].

4.7.4.1.1 Pelvic floor muscle training versus lifestyle advice

An RCT (n = 109) reported that, at six months’ follow-up, the ICIQ-UI-SF scores improved in favour of the PFMT group compared with a control group receiving lifestyle advice only (difference from baseline PFMT 2.40 points and control 0.2 points) [672]. However, the difference of 2.4 points from baseline, in favour of PFMT, has to be viewed with caution as the mean baseline score in the PFMT group was higher than in the control group (7.4 vs. 5.9). Likewise, it has to be noted that the absolute ICIQ-UI-SF values at six months’ follow-up were not significantly different between PFMT (4.8) and controls (5.2).

Two publications from one RCT reported on the three-, six- and twelve-month results of lifestyle advice only vs. lifestyle advice combined with group PFMT [674, 675]. The Urogenital Distress Inventory-6 (UDI-6) and Urinary Impact Questionnaire-7 (UIQ-7) questionnaires were used to assess urinary symptoms. At three months’ follow-up, both groups (53 women in the lifestyle group and 56 in the lifestyle + PFMT cohort) reported significantly improved UDI-6 scores, while the lifestyle-only group also reported significantly greater improvement in the UIQ-7 score. Between-group comparison showed no differences in UDI-6 and UIQ-7 scores at six months. At twelve months’ follow-up, the majority of women had sought additional treatment (70% in the lifestyle-only group and 48% in the lifestyle/PFMT group). The number of patients remaining on the original therapy was too small to reach strong conclusions.

One RCT reported on six and twelve months’ follow-up of 225 women with POP-Q stage 1–3 randomised to individualised PFMT and 222 women randomised to lifestyle leaflet information only (control) [676]. Urinary symptoms were assessed with a single question on the existence of UI; a single question regarding the need to strain to void; and a single question regarding incomplete bladder emptying; these were supplemented with the ICIQ-SF questionnaire score. At six months, significantly more women in the control group reported UI, the need to strain to empty their bladder, and the feeling of incomplete emptying compared to the PFMT group. The score on the ICIQ-SF was also significantly worse in the control group as compared to the PFMT group. However, at twelve months, there was no significant difference in these items between groups. It has to be noted that 50% in the control group received additional treatment within the twelve-month study period. Twenty-seven percent had additional PFMT, which may have had an effect on the twelve-month data.

Another RCT reported on the 24-month follow-up of 414 women with stage 1–3 POP (207 assigned to PFMT/ Pilates and 207 to lifestyle advice) [682]. Urinary symptoms were assessed with the ICIQ-UI-SF and a question about UI and difficulty emptying the bladder. At 24 months, the ICIQ-UI-SF score was significantly better in the intervention group (mean difference −0.83). However, the proportion of women reporting any UI did not differ between the groups, nor did the number of pads used weekly.

4.7.4.1.2 Pelvic floor muscle training versus pelvic floor muscle training with pessary

One RCT compared PFMT alone to PFMT and pessary for symptomatic POP [673]. Urinary tract symptom changes were assessed using UDI-6 and UIQ at six and twelve month's follow-up. At twelve months, there was no difference in the between-group comparison. With respect to the UIQ, women in the pessary/PFMT group showed a significant improvement from baseline, but the PFMT-only group did not. Women in the pessary/ PFMT group reported significantly more frequent de novo SUI (48% vs. 22%), and more improvement of pre-existing voiding difficulty (62.5% vs. 35.5%).

4.7.4.1.3 Pelvic floor muscle training versus pessary only

One RCT reported on the 24-month follow-up of 82 women with symptomatic POP randomised to pessary therapy and 80 women randomised to PFMT [683]. The UDI-6 was used as the outcome measure for urinary symptoms. Both in the ITT and per protocol analyses, the UDI score did not differ significantly between groups at 24 months of follow-up.

4.7.4.1.4 Surgery alone versus surgery with pelvic floor muscle training

An assessor-blinded RCT compared surgery for POP with or without additional pre-and postoperative PFMT. At twelve months after surgery, there were no significant differences between the groups on the change in scores of the UDI nor the IIQ scores [671].
Another RCT reported on the six-month follow-up of 57 women (28 surgery/29 surgery with PFMT). The UDI-6 was used to assess urinary symptoms. There was a significant improvement in the UDI-6 score for both groups, but not between groups [679].

Another RCT reported on the results of a 2x2 factorial design in which women were first randomised between two surgical techniques for POP and between additional PFMT (n = 188) or not (n = 186) [680]. The UDI was used to assess urinary symptoms up to 24 months. No significant differences were found between the addition of PFMT to surgery or not. Another study of the same population reported on SUI in particular [681]. No significant differences were found between women who had additional PFMT and those who had not.

In 2020 an RCT reported on 40 and 90 days’ follow-up of 48 women randomised to supervised PFMT before and after surgery and 40 women having surgery only [678]. UDI-6 was used to assess urinary symptoms. No significant differences in UDI-6 scores were identified at 40 and 90 days.

The NICE guidelines on the management of POP advocate considering supervised PFMT for > 16 weeks as initial treatment for symptomatic prolapse [67]. The use of pessary is also to be considered, alone or combined with PFMT. It is important to recognise that a benefit is expected on typical POP symptoms, like feeling or seeing a bulge out of the vagina, and not on LUTS, as the reported RCTs showed. From a urological perspective, initiating conservative treatment for asymptomatic POP in order to treat UI or bladder emptying problems is not supported by the data.

4.7.4.1.5 Pessary versus surgery alone
A prospective cohort study showed that surgery in comparison with pessary treatment resulted in statistically significant more women reporting subjective improvement [684].

4.7.4.2 Pelvic organ prolapse surgery and overactive bladder
Only a few studies have specifically addressed the effect of POP surgery on OAB symptoms. A SR of twelve studies, excluding women with SUI, evaluated OAB symptoms before and after surgery [685]. All but one study reported improvement of OAB symptoms. The same authors performed a prospective analysis of 505 women who had POP surgery with or without mesh [686]. Symptoms were assessed with UDI questions and each symptom was dichotomised into not bothersome or bothersome. Mean follow-up was 12.7 months. The incidence of bothersome urinary frequency reduced from 36.6% to 14.6%, with de novo symptoms occurring in 6.1% of women. Bothersome urgency symptoms reduced in 36.8% to 12.9% of women, with 5.0% developing de novo symptoms. Urgency urinary incontinence symptoms reduced from 21.2% to 6.1% of women, with 5.3% developing de novo symptoms.

One observational study evaluated frequency and urgency symptoms without consideration of bother in 87 women undergoing POP surgery and showed an improvement in frequency by 75%, and in urgency in 83% [687]. The effect of the POP-Q stage did not seem to influence the effect of surgery on OAB symptoms [686, 687].

Another observational study (n = 43) evaluated the effect of posterior repair on OAB/DO and showed a 70–75% improvement rate in both parameters after surgery [688].
4.7.4.3 Pelvic organ prolapse surgery and bladder outlet obstruction
The criteria for BOO are based on urodynamic assessment. Pelvic organ prolapse can be categorised as anatomical BOO, which is addressed in Sections 4.5.2.2 and 4.5.3.1.

4.7.4.4 Pelvic organ prolapse surgery and stress urinary incontinence
The aim of this section is to address the options available to women who require surgery for POP and who have associated SUI (either before or after reduction of prolapse), and to assess the value of prophylactic anti-UI surgery in women with no evidence of SUI.

A SR and meta-analysis of ten trials on prolapse surgery with or without an anti-incontinence procedure was reported in 2018 [689]. In addition, a Cochrane review including nineteen trials (n = 2,717) evaluating bladder function after surgery for POP presented analyses of women with POP and SUI, women with POP and occult SUI, and women with POP who were continent [690].

4.7.4.4.1 Vaginal pelvic organ prolapse surgery in women with stress urinary incontinence
Two trials addressed postoperative SUI in patients who had been diagnosed with SUI preoperatively and had vaginal POP surgery [691, 692]. Two trials (n = 185 and 134) compared the use of MUS at initial POP surgery to POP surgery alone. The RR for postoperative SUI was 0.30 in favour of the combined POP surgery and MUS group. One of these two trials also compared the use of MUS at initial POP surgery and at three months if SUI persisted [691]. At twelve months’ follow-up, there was no difference between the groups regarding postoperative UI (RR 0.41); however, 44% of the women without initial MUS never required surgery and 29% were dry.

4.7.4.4.2 Abdominal pelvic organ prolapse surgery in women with stress urinary incontinence
One RCT randomised 47 women with POP and SUI to an abdominal POP surgical procedure; e.g., sacro-colpopexy with or without Burch colposuspension. Additional SUI surgery did not improve postoperative SUI as compared to sacro-colpopexy alone (RR: 1.38) [693]. This finding remained consistent over five years’ follow-up [694]. Another RCT compared the addition of a MUS or Burch colposuspension to an abdominal sacro-colpopexy in 113 women with POP and SUI [695]. At two years’ follow-up, the RR for postoperative SUI was 0.54 in favour of the MUS group.

4.7.4.5 Vaginal pelvic organ prolapse surgery in continent women
One RCT compared vaginal POP surgery alone with concomitant POP surgery and MUS in 220 women. Postoperative SUI occurred in 46/113 (40.7%) women who had POP surgery alone, compared to 30/107 (28.0%) who had additional MUS (RR: 0.69) [690].

4.7.4.5.1 Abdominal pelvic organ prolapse surgery in continent women
Two RCTs compared abdominal sacro-colpopexy with (n = 189) or without (n = 190) Burch colposuspension with an outcome favouring the addition of Burch colposuspension (RR for de novo SUI: 0.69) [696, 697].

4.7.4.5.2 Vaginal pelvic organ prolapse surgery in women with prolapse and occult stress urinary incontinence
Five RCTs including a total of 194 women who had vaginal POP repair alone and 174 women who had an additional MUS at the time of primary surgery were identified [666, 698-701]. The RR of postoperative SUI was 0.38 in favour of the MUS group.

4.7.4.6 Adverse events associated with combined pelvic organ prolapse and stress urinary incontinence surgery
Data from six RCTs on vaginal POP surgery with MUS were pooled to assess adverse events [666, 691, 692, 699-701]. Urgency urinary incontinence was less frequent after combination surgery as compared to POP surgery alone (28% vs. 42%; RR: 0.7), but there was a tendency towards more voiding problems. Adverse events directly related to surgery occurred more often in the combination group (28% vs. 15%; RR: 1.8), as did serious adverse events such as bladder perforation, urethral injuries, and tape exposure (14% vs. 8%; RR 1.7) [689].

In summary, it is difficult to generalise the results of trials using different procedures to treat both POP and UI. It seems that with a combined procedure, the rate of postoperative SUI is lower but voiding symptoms and complication rates are higher. Studies using MUS have shown more significant differences in UI outcomes with combined procedures than when other types of anti-UI procedure have been used. It must be taken into account that although more women are dry after combined surgery for POP with MUS, there are potential adverse events that should be balanced against potential benefits.
Summary of evidence and recommendations for surgery in women with both pelvic organ prolapse and stress urinary incontinence

**Summary of evidence**

**Women with POP and UI**
- Surgery for POP and SUI shows a higher rate of cure of UI in the short-term than POP surgery alone.
- There is conflicting evidence on the relative long-term benefit of surgery for POP and SUI vs. POP surgery alone.
- Combined surgery for POP + SUI carries a higher risk of adverse events than POP surgery alone.

**Continent women with POP**
- Continent women with POP are at risk of developing SUI postoperatively.
- The addition of a prophylactic anti-UI procedure reduces the risk of postoperative UI but increases the risk of adverse events.

**Women with POP and OAB**
- There is some low-level inconsistent evidence to suggest that surgical repair of POP can improve symptoms of OAB.

**4.8 Urinary fistula**

The evidence relating to diagnosis and treatment of urinary fistulae is generally low level and largely composed of case series and other consensus statements. In particular, the epidemiology, aetiology, diagnosis, treatment and prevention of obstetric and non-obstetric fistulae have been described in detail during the 2016 ICI conference [702]. Most non-obstetric fistulae are iatrogenic in origin, with most caused by pelvic surgery (e.g., hysterectomy for benign or malignant conditions, bowel resection, and urological surgery). The risks during pelvic surgery increase relative to the complexity of the resection, the extent of primary disease, and prior radiotherapy (especially for recurrent disease). When a fistula occurs following radiotherapy for primary treatment, this may be an indication of tumour recurrence.

**4.8.1 Epidemiology, aetiology and pathophysiology**

**4.8.1.1 Obstetric fistula**

According to the WHO, fistulae affect > 2 million women, mostly from sub-Saharan African and Asian countries. The pooled prevalence of fistula from population studies is 0.29/1000 pregnancies [703]. Poor quality obstetric care, staff unaccountability, late referral, and poor nursing standards have been identified as health system causes [703]. However, obstructed labour is poorly documented. The main individual risk factors include age at first marriage, short stature, pregnancy with a male child, failure to attend antenatal care, low socio-economic status, low social class, lack of employment, and illiteracy [704-706]. Obstetric fistulae have detrimental consequences on global and individual health and are associated with malnutrition, sexual dysfunction, anxiety, depression, insomnia, social isolation, worsening poverty, and suicide [707, 708].

**4.8.1.2 Iatrogenic fistula**

Poor obstetric care is usually responsible for VVF in the developing world. By contrast, in the developed world, gynaecological or pelvic surgery is the main cause of VVF.

**4.8.1.2.1 Post-gynaecological surgery**

An injury to the urinary tract during hysterectomy for benign conditions (60–75%), hysterectomy for malignant conditions (30%) and caesarean section (6%) are the main causes of postoperative VVF in the developed world [709, 710]. The risk of pelvic organ fistula following hysterectomy ranges from 0.1 to 4% [711].
Fistulae may also occur as a result of primary or recurrent malignancy, or as a consequence of cancer treatment by surgery, radiotherapy, and/or chemotherapy.

In a study including 536 women undergoing radical hysterectomy for invasive cervical cancer, bladder injury occurred in 1.5% with VVFs forming in 2.6% and uretero-vaginal fistulae (UVFs) in 2.4% of cases [712]. Overall, the rate of urogenital fistula appears to be ~9 times higher following radical hysterectomy for malignant disease as compared to that following simple hysterectomy (abdominal or vaginal for benign conditions) [713]. Bladder-sparing techniques during pelvic exenteration can increase the risk of fistula formation [714].

4.8.1.2.2 Radiation fistula
The risk of fistula seems to be higher for postoperative external radiation (1.9%) compared to intravaginal brachytherapy (0.8%) [715], without any predictive factor being identified [716]. This is most likely due to the heterogeneity of data regarding the tumour type and stage, the form of radiation, and the site and dose delivered.

4.8.1.2.3 Rare causes of vesico-vaginal fistula
Foreign bodies such as pessaries, sex toys, cups etc. can be a cause of delayed presentation of VVF [717-719]. Ketamine abuse has also been shown to be responsible for fistula formation [720].

4.8.2 Classification
Due to the plethora of VVF classification systems, a consensual classification system needs to be adopted. The Waaldijk and Goh classifications are widely used for diagnosis and follow-up [721-723]. They were originally designed for obstetric fistulae and their use in iatrogenic fistulae is less relevant [724]. Waaldijk’s classification is based on the size and site of the fistulae and divides them into three main categories: type 1 are VVFs with no urethral involvement; type 2 are those that involve the urethra (and are sub-classified into those with circumferential and non-circumferential urethral involvement); and type 3 are fistulae involving other parts of the urinary tract. Goh’s classification also uses the presence or absence of urethral involvement to sub-categorise VVFs and takes into account the degrees of fibrosis present. The WHO classification (Table 6) was originally developed for obstetric fistulae and separates fistulae into simple and complex.

4.8.3 Diagnostic evaluation
Leakage of urine is the hallmark sign of a urogenital fistula. The leakage is usually painless, may be intermittent if it is position dependent, but more usually is constant. Unfortunately, intraoperative diagnosis of a genito-urinary or gastrointestinal injury is made in only about half of cases [725]. Diagnosis of VVF usually requires clinical assessment often in combination with appropriate imaging or laboratory studies. Direct visual inspection, cystoscopy, retrograde bladder filling with a coloured fluid, or placement of a tampon into the vagina to identify staining may facilitate diagnosis of VVF. A double-dye test to differentiate between UVF and VVF may be useful in some cases [710]. Testing the creatinine level in either the extravasated or collected fluid will confirm fluid leakage as urine. Contrast-enhanced CT with late excretory phase reliably diagnoses urinary fistulae and provides information about ureteric integrity and the possible presence of associated urinoma. Magnetic resonance imaging, in particular with T2 weighting, also provides diagnostic information regarding fistulae [726].

4.8.4 Disease management of fistula
4.8.4.1 Management of vesico-vaginal fistula
4.8.4.1.1 Conservative management
4.8.4.1.1.1 Spontaneous closure
The reported spontaneous closure rate is 13 ± 23% [727], although this applies largely to small fistulae (< 1 cm) [702, 728]. Hence, immediate management is usually by urinary catheterisation or diversion; however, within the first two weeks following fistula occurrence, surgical exploration and repair can be considered.
4.8.4.1.1.2 Pharmacotherapy
Several case reports describe a successful fistula closure rate following the induction of amenorrhoea by oestrogen, oestrogen/progesterone combinations or luteinising hormone releasing hormone analogues specifically for small (< 7 mm), uretero- or vesico-uterine fistulae following caesarean section [729-735]. One RCT comparing the efficacy of using fibrin glue compared to Martius flap inter-positioning (n = 14; < 4 cm and n = 5; > 5 cm) did not report significantly different outcomes between the two types of treatment [736].
4.8.4.1.1.3 Palliation and skin care
During the intervening period between diagnosis and repair, UI pads with the aim of prevention of skin complications related to chronic urinary leakage can be provided and the use of a barrier cream or local oestrogen can also be considered [737, 738].
4.8.4.1.1.4 Nutrition
Nutritional support is essential in patients with fistulae induced by malignant disease or radiotherapy [739], or following diversion surgery [739-741].
4.8.4.1.1.5 Physiotherapy
Early involvement of the physiotherapist in preoperative management and rehabilitation of fistula patients suffering from limb weakness, foot drop and limb contracture is essential [742, 743].
4.8.4.1.1.6 Antimicrobial therapy
Active infection in the genital or urinary tracts should be treated prior to surgical repair [744].
4.8.4.1.1.7 Counselling
Confident and realistic counselling by the surgeon is essential and the involvement of nursing staff or counsellors with experience of fistula patients is also desirable.
4.8.4.1.2 Surgical management
4.8.4.1.2.1 Timing of surgery
Findings from uncontrolled case series suggest no difference in success rates for early (within three weeks) or delayed (after three months) closure of VVF.
4.8.4.1.2.2 Surgical approaches

**Vaginal procedures**
There are two main types of closure techniques applied to the repair of urinary fistulae, the classical saucerisation/partial colpocleisis [727] and the more commonly used dissection and repair in layers or flap-splitting technique [745]. There are no data comparing their outcomes.

**Abdominal procedures**
Repair by the abdominal route is indicated when high fistulae are fixed at the vaginal vault and are inaccessible via a vaginal approach. A transvesical repair has the advantage of being entirely extraperitoneal. A simple transperitoneal repair is used less often although it is favoured by some using the laparoscopic approach. A combined transperitoneal and transvesical procedure may be utilised for fistula repair following caesarean section. There are no RCTs comparing abdominal and vaginal approaches. Results of secondary and subsequent repairs are not as successful as the initial repair [746].

A single RCT compared trimming of the fistula edge with no trimming. There was no difference in success rates but failed repairs in trimmed cases had larger recurrences than untrimmed cases, which were smaller [747].

**Laparoscopic and robotic procedures**
Small series (single figures) have reported using these techniques, but while laparoscopic repair is feasible with and without robotic assistance, it is not possible to compare outcomes with alternative surgical approaches.

**Tissue interposition**
Tissue flaps are often added as an additional layer of repair during VVF surgery. Most commonly, such flaps are utilised in the setting of recurrence after a prior attempt at repair, for VVF related to previous radiotherapy (described later), ischaemic or obstetric fistulae, large fistulae, and finally those associated with a difficult or tenuous closure due to poor tissue quality. However, there is no high-level evidence that the use of such flaps improves outcomes for either complicated or uncomplicated VVF.

**Postoperative management**
There is no high-level evidence to support any particular practice in postoperative management but most reported series used catheter drainage for > 10 days and longer periods in complex or radiation-associated fistulae (up to three weeks). The performance of postoperative cystography prior to catheter removal can miss a persistent fistula if not done with a micturition phase or if the fistula is located at the bladder neck.

4.8.4.1.3 Management of complications of vesico-vaginal fistulae
The complications of VVF repair are varied and can include:
- Persistence or recurrence of fistula;
- Persistence or recurrence of UI;
- Persistence of LUTS or occurrence of new LUTS, including de novo overactive bladder symptoms and/or SUI;
- Infections: wound and UTIs/urosepsis;
- Ureteric obstruction (ligation, fibrosis or injury);
- Bladder outlet obstruction (meatal stenosis, urethral stenosis or bladder neck obstruction);
- Bladder contracture;
- Vaginal stenosis;
- Sexual dysfunction (vaginismus/dyspareunia);
- Rare complications (granulomas/diverticulum formation);
- Neurological complications (foot drop/neurogenic bladder);
- Psychological trauma (social isolation/divorce/mental illness);
- Infertility.

The literature on the treatment and management of complications of fistula repairs is scarce and is mostly experience-based. It is impossible to provide any specific evidence-based guidance.

4.8.4.2 Management of radiation fistulae
Modified surgical techniques are often required, and indeed, where the same techniques have been applied to both surgical and post-radiation fistulae, the results from the latter have been consistently poorer [748]. Due to the wide field abnormality surrounding many radiotherapy-associated fistulae, approaches include, permanent urinary and/or faecal diversion [748, 749] or preliminary urinary and faecal diversion, with later undiversion in selected cases following reconstruction. In cases where life expectancy is deemed to be short, ureteric occlusion might be more appropriate.
4.8.4.3 Management of ureteric fistulae

4.8.4.3.1 General principles
Patients at higher risk of ureteric injury require experienced surgeons who can identify and protect the ureter and its blood supply to prevent injury and recognise injury promptly. Immediate repair of any intraoperative injury should be performed by observing the principles of debridement, adequate blood supply and tension-free anastomosis with internal drainage using stents [750]. Delayed presentation of UUT injury should be suspected in patients whose recovery after relevant abdominal or pelvic surgery is slower than expected, if there is any fluid leak, and if there is any unexpected dilatation of the pelvicalyceal system.

While there is no evidence to support the use of one surgical approach over another, there is consensus that repair should adhere to the standard principles of tissue repair and safe anastomosis, and be undertaken by an experienced team. Conservative management is possible with internal or external drainage, endoluminal management using nephrostomy and stenting where available, and early (< 2 weeks) or delayed (> 3 months) surgical repair when required [751]. Functional and anatomical imaging should be used to follow-up patients after repair to guard against development of ureteric stricture and deterioration in renal function.

4.8.4.3.2 Uretero-vaginal fistulae
Uretero-vaginal fistula occurring in the early postoperative phase predominantly after hysterectomy is the most frequent presentation of UUT fistulae in urological practice. An RCT in 3141 women undergoing open or laparoscopic gynaecological surgery found that prophylactic insertion of ureteric stents made no difference to the low risk (1%) of ureteric injury [752].

Endoscopic management is sometimes possible by retrograde stenting, percutaneous nephrostomy and antegrade stenting if there is pelvicalyceal dilatation, or ureteroscopic realignment [753]. However, the long-term success rate is unknown. If endoluminal techniques fail or result in secondary stricture, the abdominal approach to repair is standard and may require end-to-end anastomosis, reimplantation into the bladder using psoas hitch or Boari flap, or replacement with bowel segments with or without reconfiguration. As a last resort, nephrectomy may be considered, particularly in the context of a poorly functioning kidney and an otherwise normal contralateral kidney [754-758].

4.8.4.3.3 Management of urethra-vaginal fistulae

4.8.4.3.3.1 Aetiology
Although urethro-vaginal fistulae are rare, most of them in adults have an iatrogenic aetiology. Causes include surgical treatment of SUI with bulking agents or synthetic slings, surgery for urethral diverticulum and genital reconstruction. Irradiation and even conservative treatment of prolapse with pessaries can lead to formation of fistulae.

4.8.4.3.3.2 Diagnostic evaluation
Clinical vaginal examination, including the three-swab test, is often sufficient to diagnose UVF. Urethroscopy and cystoscopy can be performed to assess the extent and location of the fistulae. In cases of difficult diagnosis, VCUG or US can be useful. An 3D-MRI or CT scan is becoming utilised more widely to clarify anatomy [759, 760].

4.8.4.3.3.3 Surgical management
Choice of surgery will depend on the size, localisation, and aetiology of the fistula and the amount of tissue loss. Principles of reconstruction include identifying the fistula, creation of a plane between the vaginal wall and urethra, watertight closure of the urethral wall, eventual interposition of tissue, and closure of the vaginal wall.

One case series reported that a vaginal approach yielded a success rate of 70% at first attempt and 92% at second attempt, and that an abdominal approach only led to successful closure in 58% of cases [761]. A vaginal approach required less operating time, had less blood loss and shorter hospitalisation.

Most authors have described surgical principles that are identical to those of VVF repair, and primary closure rates of 53–95.4% have been described. A series of 71 women, treated for UVF reported that 90.1% of fistulae were closed at the first vaginal intervention. Additionally, 7.4% were closed during a second vaginal intervention. Despite successful closure, SUI developed in 52% of cases. Stress urinary incontinence patients were treated with synthetic or autologous slings and nearly 60% became dry and an additional 32% improved. Urethral obstruction occurred in 5.6% and was managed by urethral dilation or urethrotomy [762].
4.8.4.3.3.4 Flaps and neo-urethra

The simplest flap is a vaginal advancement flap to cover the urethral suture line. Labial tissue can be harvested as a pedicled skin flap. This labial skin can be used as a patch to cover the urethral defect, but can also be used to create a tubular neo-urethra [763, 764]. The construction of a neo-urethra has mostly been described in traumatic aetiologies. In some cases, a transpubic approach has been used [765]. The numbers of patients reported are small and there are no data on the long-term outcome of fistula closure and continence rates. The underlying bulbo-cavernous tissue can be incorporated in the pedicled flap and probably offers better vascularisation and more bulking to the repair. This could allow a safer placement of a sling afterwards, in those cases where bothersome SUI would occur postoperatively [766, 767].

4.8.4.3.3.5 Martius flap

In obstetrical fistula repair, the Martius labial bulbocavernous muscle/fat flap was not found to have any benefit. However, the Martius flap is still considered by some to be an important adjunctive measure in the treatment of genitourinary fistulae for which additional bulking with well-vascularised tissue is needed [768]. The series of non-obstetrical aetiology are small and all of them are retrospective. There are no prospective data, nor randomised studies [769]. The indications for Martius flap in the repair of UVF remain unclear.

4.8.4.3.3.6 Rectus muscle flap

Rectus abdominis muscle flaps have been described by some authors [770, 771].

4.8.4.3.3.7 Alternative approaches

An alternative retropubic retro-urethral technique has been described by Koriatim [772]. This approach allows a urethro-vesical flap tube to be fashioned to form a continent neo-urethra.

4.8.4.4 Summary of evidence and recommendations for the management of urinary fistula

</tr>
<tr>
<td>A variety of interpositional grafts can be used in either abdominal or vaginal procedures, although there is little evidence to support their use in any specific setting.</td>
<td>3</td>
</tr>
</tbody>
</table>

**Post-radiation fistula**

Successful repair of irradiated fistulae may require prior urinary diversion and the use of non-irradiated tissues to effect repair. 3

**Ureteric fistula**

Prophylactic ureteric stent insertion does not reduce risk of ureteric injury during gynaecological surgery. 2

Antegrade endoluminal distal ureteric occlusion combined with nephrostomy tube diversion often palliates urinary leakage due to malignant fistula in the terminal phase. 4

**Urethro-vaginal fistula**

Urethro-vaginal fistula repair may be complicated by SUI, urethral stricture and urethral shortening, which may necessitate long-term follow-up. 3

*Limited LNS C3 classification of urethral diverticula [777, 781, 782].

4.9 **Urethral diverticulum**
A female urethral diverticulum is a sac-like protrusion composed of the entire urethral wall or only the urethral mucosa, situated between the periurethral tissues and the anterior vaginal wall.

4.9.1 **Epidemiology, aetiology, pathophysiology**
Urethral diverticulum is an uncommon condition with an estimated prevalence of 1–6%. A prevalence of up to 10% was reported among women with LUTS attending a tertiary referral centre [773]. However, as many patients are asymptomatic or misdiagnosed, the true incidence is unknown [774-776]. Given the rarity of the condition, most published series are small and single institutional. Urethral diverticulum is thought to arise from repeated obstruction, infection, and subsequent rupture of periurethral glands into the urethral lumen, resulting in an epithelialised cavity that communicates with the urethra [774].

Iatrogenic damage to the urethra may also play a role, as up to 20% of women with urethral diverticula are noted to have a history of urethral surgery, dilation, or traumatic delivery [774, 777]. Iatrogenic urethral diverticula formation associated with synthetic suburethral sling has also been reported [778-780].

4.9.2 **Classification**

**Table 7: Classification system for female urethral diverticula based on characteristics***

*Limited LNS C3 classification of urethral diverticula [777, 781, 782].
4.9.3 Diagnostic evaluation

The commonly encountered symptoms for urethral diverticulum such as pain, urgency, frequency, recurrent UTIs, vaginal discharge, dyspareunia, voiding difficulties or UI [783], are common to many other LUT dysfunctions. Consequently, there is no pathognomonic cluster of symptoms to identify urethral diverticulum. Many patients with urethral diverticulum are asymptomatic. However, urethral diverticulum often presents with a palpable urethral mass. It may be possible to express a purulent exudate from the urethra. Occasionally a stone may develop within the diverticulum.

Urethral diverticulum can be diagnosed by physical examination, VCUG and MRI. Other investigations include urethrocystoscopy, endocavitary (often transvaginal or sometimes transurethral) pelvic floor US and double balloon urethrography.

No robust diagnostic accuracy studies have addressed the question of the best test to confirm the diagnosis in women with clinical suspicion of urethral diverticulum. However, a case series of 27 patients concluded that endoluminal (vaginal or rectal) MRI has better diagnostic accuracy than VCUG [784] and determines the size and extent of urethral diverticulum more accurately. A case series of 60 patients reported that the sensitivity, specificity, positive predictive value and negative predictive value of MRI was 100%, 83%, 92% and 100%, respectively [785]. Another case series reported 100% specificity and sensitivity of MRI in 60 patients [786]. However, a case series of 41 patients reported a 25% discrepancy between MRI and surgical findings [787]. Endoluminal MRI with either a vaginal or rectal coil may provide even better image quality than simple MRI [788].

Magnetic resonance imaging is the gold standard for the diagnosis and planning of surgical repair. Magnetic resonance imaging is also useful in diagnosing diverticular inflammation or tumour [789, 790].

Urethrocystoscopy can be used to visualise the ostia of the diverticula. Knowledge of the ostias’ location and number can assist with surgical planning since they need to be closed after diverticulectomy. However, given the challenges of urethroscopy in women, the ostia are only seen in 42% of cases [783].

If VCUG is performed, antero-posterior and lateral images are required to optimally characterise the configuration of the diverticulum. There is a high risk of false negatives since the ostia of the diverticula must be patent and the patients must be able to void during the study. In more complex diverticula where there is septation, the entire diverticulum may not be visualised underestimating its complexity or size [791]. The sensitivity of VCUG is 73.5% which is significantly worse than MRI [783].

Ultrasound can be performed transabdominally, transvaginally or transperineally to identify the diverticulum. In particular, the transvaginal approach allows imaging of the urethra from the meatus to the bladder neck in several planes and can identify the number, size, location and contents of the diverticulum. This technique is challenging and requires a skilled ultrasonographer. Additionally, the probe can compress the urethra, causing distortion [791]. A meta-analysis reported that US of any kind had a sensitivity of 82.0%, which was inferior to that of MRI [791]. However, a recent publication on translabial US reported a sensitivity of 95% [792]; therefore, this approach may be explored further by researchers in the future.

For patients who cannot undergo MRI and those in whom the ostia cannot be seen on cystoscopy, double balloon urethrography is an option. Sensitivity of 94.7% has been reported, which is comparable to that of MRI. The technique uses positive pressure to force contrast medium into the diverticular sac between two balloons; one placed in the bladder and one outside the ostium of the diverticulum. It is technically difficult to achieve a seal sufficient to create a closed urethral space and avoid contrast medium leaking around the catheter. The procedure can be painful for the patient and carries a risk of UTI. An experienced radiologist is required as well as specialised equipment. Given the current popularity of other imaging modalities, many units may not have access to this technique [791].

4.9.3.1 Associated voiding dysfunction

Although the presentation of urethral diverticulum is often non-specific and variable, urethral diverticulum can be associated with voiding dysfunction and SUI or urgency UUI.

One recent series reported SUI in 60% of patients with urethral diverticulum [793]. Urethral diverticulum is most often located at the level of the mid-urethra. This location often overlaps with the external sphincter. However, urethral diverticulum may also extend proximally toward the bladder neck in the vicinity of the proximal sphincter mechanism. This morphology may, in part, explain the association between urethral diverticulum and SUI, with potentially more proximal lesions at risk for postoperative SUI [794].
Urethral diverticulum may also be associated with BOO due to the mass effect of the urethral diverticulum, urinary retention, or urgency and UUI [795]. Pain and dysuria associated with urethral diverticulum may also result in acquired voiding dysfunction.

Pressure-flow studies may have a role in the preoperative assessment of patients with urethral diverticula and coexisting voiding dysfunction or SUI [776, 796-798]. Indeed, urodynamics may evaluate coexisting detrusor dysfunction or document the presence of SUI or obstruction prior to repair [799, 800].

Urethral pressure profilometry has also been used in the assessment or diagnosis of urethral diverticulum, noting a biphasic pattern, or pressure drop at the level of the lesion [796, 798, 801]. Video-urodynamics may be helpful in differentiating SUI from paradoxical UI due to fluid accumulation in the urethral diverticulum. Additionally, resting and straining images obtained during fluoroscopic imaging may document an open bladder neck at rest. This may be a consideration in some patients with an extensive urethral diverticulum at the level of the mid-urethra, and potential implications for postoperative UI due to compromise of both sphincter mechanisms.

4.9.4 **Disease management**

For women with minimal symptoms who would prefer to avoid invasive treatment, conservative management can be considered. Patients should be warned of the small risk of cancer (1–6%) within the diverticulum [802, 803].

4.9.4.1 **Surgical treatment**

No RCTs have investigated the effectiveness of surgery in women who have a bothersome urethral diverticulum. Thorough evaluation of the anatomy of the diverticulum is essential in planning reconstructive surgery.

There are three surgical approaches to treatment of diverticulum: marsupialisation, endoscopic incision, and curative treatment with diverticulectomy.

Surgical removal is the most commonly reported treatment in contemporary case series. The principles of successful transvaginal diverticulectomy are to: dissect a well-vascularised vaginal flap; preserve the periurethral fascia for closure; remove all the diverticular wall; excise the ostium and close the urethra in a watertight fashion; close the incision in a multilayered fashion with no overlapping suture lines; and preservation or creation of continence.

The decision to use a labial fat pad flap, commonly known as a Martius flap, varies, and the flap is used more frequently in the following situations: recurrent cases, large urethral defects or for deficient vaginal flaps for closure [777, 781], transection of the urethra required for access to a circumferential diverticulum [790], or in the case of complex configuration [795], and if there is a planned future sling procedure required for UI to facilitate the dissection at that time [777].

Marsupialisation involves incision into the mass on the vaginal side to drain the infected contents. The wall is sutured open with absorbable suture to allow drainage and prevent reaccumulation of infectious materials. This approach leaves the cystic structure in place and can theoretically cause a urethro-vaginal fistula because there is communication with the diverticular ostium, but it is a rapid procedure with little dissection required. This approach has been advocated in pregnant patients to decompress the diverticulum and allow safe vaginal delivery. A small case series suggested that 75% of pregnant women with urethral diverticula managed expectantly eventually required postpartum surgery [804].

Endoscopic incision is a rarely reported treatment option [805, 806]. This procedure involves finding the narrow neck of the ostium and incising it with a resectoscope. This unroofing of the diverticulum transforms the narrow communication with the urethra that causes symptoms when it becomes obstructed into a wide-mouthed sac that drains freely.

4.9.4.2 **Management of concomitant stress urinary incontinence**

Many women present with concomitant SUI and urethral diverticulum, and may request both conditions to be simultaneously treated. A meta-analysis reported that diverticulectomy cured SUI even without a concomitant anti-incontinence procedure. However, no data regarding symptom severity were given and it could be assumed that many of these cured patients had less-severe UI before surgery [783]. Therefore, additional surgical correction may be required [794, 806]. However, there is no consensus on appropriate timing of surgical management of these two conditions. Thus, patients with symptomatic bothersome SUI in
association with urethral diverticulum may be offered simultaneous anti-UI surgery. Although historical series have shown good results with concomitant bladder neck suspension [800], more contemporary series have utilised pubovaginal fascial slings, with satisfactory outcomes [807-810]. Synthetic MUS are not recommended as a concomitant anti-UI procedure at the time of urethral diverticulectomy [811]. Synthetic material adjacent to a fresh suture line following diverticulectomy in the setting of potentially infected urine may place the patient at higher risk for subsequent urethral erosion and vaginal extrusion of the sling material, as well as urethro-vaginal fistula formation and foreign body granuloma formation.

Transvaginal urethral diverticulectomy has a high success rate (defined by being dry) of 84–98%, with a reoperation rate of 2–13% after primary repair during a mean follow-up of twelve to 50 months [774, 777, 794, 812]. The resolution of symptoms after surgery has been reported to reach 68.8% but less than half of studies comment on symptom improvement [813]. One case series reported that storage symptoms decreased significantly postoperatively from 60% to 16% following surgery for urethral diverticulum [794]. Other series with long-term follow-up, however, have demonstrated rates of postoperative urgency of 54% [814], and de novo UUI in 36% of patients [806]. Such postoperative symptoms indicate persistence of urethral diverticulum, recurrence of urethral diverticulum, or de novo overactive bladder syndrome or urethral obstruction.

Early common postoperative complications include: UTI (0–39%), de novo SUI (3.8–33%), and de novo urinary retention (0–9%), especially in the setting of concomitant placement of an autologous pubovaginal sling [774, 777, 794, 812]. Delayed complications such as urethral stricture are reported in 0–5.2% of cases [774, 777, 806, 812]. Urethro-vaginal fistula is a devastating complication presenting in 0.9–8.3% of cases [815]. A distal fistula located beyond the sphincteric mechanism can present with split urinary stream or vaginal voiding and may not require repair. However, a fistula located anywhere from the mid-urethra to the bladder neck may result in UI. These patients should undergo repair with consideration of an adjuvant tissue flap, such as a Martius flap, to aid in closure. The timing of the fistula repair is not well defined, with a delay of three to six months after the initial repair being a good balance between patient discomfort and optimal tissue quality. Rare complications include: distal urethral necrosis, bladder injury, urethral injury, ureteric injury, and vaginal scarring or narrowing with consequent dyspareunia [815].

One case series reported a recurrence rate of 33% in U-shaped and of 60% in circumferential diverticula within one year [781]. Ingber et al., found a 10.7% recurrence rate in 122 women undergoing diverticulectomy, with a higher risk of recurrence in those with proximal or multiple diverticula or after previous pelvic surgery [814] or radiation. Recurrent urethral diverticulectomy following initial successful urethral diverticulectomy may occur as a result of a new infection or traumatic insult such as childbirth, a new urethral diverticulum, or recurrence of the original lesion. Recurrence of urethral diverticulum may be due to incomplete removal of the urethral diverticulum, inadequate closure of the urethra, residual dead space (circumferential diverticula), or other technical factors. Repeat urethral diverticulectomy represents a unique challenge due to altered anatomy, scarring, and difficulty identifying proper anatomical planes.

Stress urinary incontinence can be worsened or occur de novo after diverticulectomy. This is most likely due to sphincteric damage from the dissection or scarification preventing urethral closure. De novo SUI (10.6% of women) seems to be more common in proximal and large (> 30 mm) diverticula [794]. However, Lee et al., noted at least some de novo SUI in 49% of patients following urethral diverticulectomy; most of which was minor and did not require additional therapy [816]. Only 10% of these individuals underwent subsequent SUI surgery. Treatment for SUI after diverticulectomy is not well described in the literature. The most commonly reported operation is an autologous pubovaginal sling [805] followed by retropubic suspension [806]. However, there are two reported cases of synthetic mesh sling to treat SUI, without mesh complications [781, 794], but this is controversial.

4.9.4.3 Pathological findings

Most urethral diverticula are lined with squamous cells, urothelium or columnar epithelium [777, 817, 818]. In a meta-analysis, there was a high prevalence of chronic or acute inflammation (68.6%) and the most commonly reported lesions were nephrogenic metaplasia, which occurred in 8% of cases. Diverticula may undergo neoplastic alterations (6%), including invasive adenocarcinoma [819], followed by squamous cell carcinoma in 0.7%. It is unknown if the diverticulum forms first and then transforms into a malignancy or if the malignancy develops first. These malignancies are treated in a similar fashion to urethral cancer in women.

6. CONFLICT OF INTEREST

All members of the Non-neurogenic Female LUTS Panel have provided disclosure statements of all relationships that they have that might be perceived as a potential source of a conflict of interest. This information is publicly accessible through the European Association of Urology website: https://uroweb.org/guideline/non-neurogenic-female-luts/. This guidelines document was developed with the financial support of the European Association of Urology. No external sources of funding and support have been involved. The EAU is a non-profit organisation and funding is limited to administrative assistance and travel and meeting expenses. No honoraria or other reimbursements have been provided.

7. CITATION INFORMATION

The format in which to cite the EAU Guidelines will vary depending on the style guide of the journal in which the citation appears. Accordingly, the number of authors or whether, for instance, to include the publisher, location, or an ISBN number may vary.

The compilation of the complete Guidelines should be referenced as:

If a publisher and/or location is required, include:

References to individual guidelines should be structured in the following way:
Contributors’ names. Title of resource. Publication type. ISBN. Publisher and publisher location, year.

6. CITATION INFORMATION  56
1. INTRODUCTION

1.1 Aim and objectives
The European Association of Urology (EAU) Neuro-Urology Guidelines aim to provide information for clinical practitioners on the incidence, definitions, diagnosis, therapy, and follow-up of neuro-urological disorders. These Guidelines reflect the current opinion of experts in this specific pathology and represent a state-of-the-art reference for all clinicians, as of the publication date.

The terminology used and the diagnostic procedures advised throughout these Guidelines follow the recommendations for investigations of the lower urinary tract (LUT) as published by the International Continence Society (ICS) [1-3]. Readers are advised to consult other EAU Guidelines that may address different aspects of the topics discussed in this document.

It must be emphasised that clinical guidelines present the best evidence available to the experts but following guideline recommendations will not necessarily result in the best outcome. Guidelines can never replace clinical expertise when making treatment decisions for individual patients, but rather help to focus decisions - also taking personal values and preferences/individual circumstances of patients into account. Guidelines are not mandates and do not purport to be a legal standard of care.

1.2 Panel composition
The EAU Neuro-Urology Guidelines Panel consists of an international multidisciplinary group of neuro-urological experts. All experts involved in the production of this document have submitted potential conflict of interest statements which can be viewed on the EAU website: http://www.uroweb.org/guideline/neuro-urology/.

1.3 Available publications
A quick reference document, the Pocket Guidelines, is available in print and as an app for iOS and Android devices. These are abridged versions which may require consultation with the full text version. A guideline summary has also been published in European Urology [4]. All are available through the EAU website: http://www.uroweb.org/guideline/neurourology/.

1.4 Publication history

1.5 Background
The function of the LUT is mainly storage and voiding of urine, which is regulated by the nervous system that coordinates the activity of the urinary bladder and bladder outlet. The part of the nervous system that regulates LUT function is disseminated from the peripheral nerves in the pelvis to highly specialised cortical areas. Any disturbance of the nervous system involved, can result in neuro-urological symptoms. The extent and location of the disturbance will determine the type of LUT dysfunction, which can be symptomatic or asymptomatic. Neuro-urological symptoms can cause a variety of long-term complications; the most significant being deterioration of renal function. Since symptoms and long-term complications do not correlate [5], it is important to identify patients with neuro-urological symptoms, and establish if they have a low or high risk of subsequent complications. The risk of developing upper urinary tract (UUT) damage and renal failure is much lower in patients with slowly progressive non-traumatic neurological disorders than in those with spinal cord injury or spina bifida [6]. In summary, treatment and intensity of follow-up examinations are based on the type of neuro-urological disorder and the underlying cause.

2. METHODS

2.1 Introduction
For the 2022 Neuro-Urology Guidelines, new and relevant evidence has been identified, collated, and appraised through a structured assessment of the literature. A broad and comprehensive literature search, covering all sections of the Neuro-Urology Guidelines was performed. Databases searched included Medline, EMBASE, and the Cochrane Libraries, covering a time frame between the 1st of May 2019 and 1st May 2021. A total of 1,743 unique records were identified, retrieved, and screened for relevance. A detailed search strategy is available online: http://uroweb.org/guideline/neuro-urology/?type=appendices-publications.
For each recommendation within the guidelines there is an accompanying online strength rating form, the bases of which is a modified GRADE methodology [7, 8]. Each strength rating form addresses a number of key elements namely:

1. the overall quality of the evidence which exists for the recommendation, references used in this text are graded according to a classification system modified from the Oxford Centre for Evidence-Based Medicine Levels of Evidence [9];
2. the magnitude of the effect (individual or combined effects);
3. the certainty of the results (precision, consistency, heterogeneity and other statistical or study related factors);
4. the balance between desirable and undesirable outcomes;
5. the impact of patient values and preferences on the intervention;
6. the certainty of those patient values and preferences.

These key elements are the basis which panels use to define the strength rating of each recommendation. The strength of each recommendation is determined by the balance between desirable and undesirable consequences of alternative management strategies, the quality of the evidence (including certainty of estimates), and nature and variability of patient values and preferences.

Additional information can be found in the general Methodology section of this print, and online at the EAU website; http://www.uroweb.org/guideline/. A list of associations endorsing the EAU Guidelines can also be viewed online at the above address.

2.2 Review
Publications ensuing from panel-lead systematic reviews (SR) have all been peer-reviewed. The 2015 Neuro-Urology Guidelines were subject to peer review prior to publication.

3. THE GUIDELINE

3.1 Epidemiology, aetiology and pathophysiology

3.1.1 Introduction
Neuro-urological symptoms may be caused by a variety of diseases and events affecting the nervous system controlling the LUT. The resulting neuro-urological symptoms depend predominantly on the location and the extent of the neurological lesion. There are no exact figures on the overall prevalence of neuro-urological disorders in the general population, but data are available on the prevalence of the underlying conditions and the relative risk of these for the development of neuro-urological symptoms. It is important to note that the majority of the data shows a very wide range of prevalence/incidence. This reflects the variability in the cohort (e.g., early or late-stage disease) and the frequently small sample sizes, resulting in a low level of evidence in most published data (summarised in Table 1).

### Spina bifida (SB)
- Prevalence: 3-4/10,000
- Lumbar and lumbosacral form are the most common (60%) [33].
- Bladder function is impaired in up to 96% of SB patients [34]. Over 50% of patients are incontinent [35]. Patients with open and closed defects can have equally severe neurogenic LUT dysfunction [36].

### Hereditary spastic paraplegia (HSP)
- Prevalence 1.3-9/100,000 [37].
- LUTS in about 75%, mainly urgency and voiding dysfunction. Neurogenic DO in 81% (of whom 76% with DSD) [37].

### Lesions and diseases of the peripheral nervous system

</tbody>
</table>

### 3.2 Classification systems
#### 3.2.1 Introduction
Relevant definitions can be found in the general ICS standardisation reports [2, 3, 46]. Supplementary online Tables S1 and S2 list the definitions from these references, partly adapted, and other definitions considered useful for clinical practice: https://uroweb.org/guideline/neuro-urology/?type=appendices-publications.

### 3.3 Diagnostic evaluation
#### 3.3.1 Introduction
The normal physiological function of the LUT depends on an intricate interplay between the sensory and motor nervous systems. When diagnosing neuro-urological symptoms, the aim is to describe the type of dysfunction involved. A thorough medical history, physical examination and bladder diary are mandatory before any additional diagnostic investigations can be planned. Results of the initial evaluation are used to decide the patient’s long-term treatment and follow-up.

#### 3.3.2 Classification systems
The pattern of LUT dysfunction following neurological disease is determined by the site and nature of the lesion. A very simple classification system for use in daily clinical practice to decide on the appropriate therapeutic approach is provided in Figure 1 [6].
The pattern of LUT dysfunction following neurological disease is determined by the site and nature of the lesion. Panel (A) denotes the region above the pons, panel (B) the region between the pons and the sacral cord and panel (C) the sacral cord and infrasacral region. Figures on the right show the expected dysfunctional states of the detrusor-sphincter system. Figure adapted from Panicker et al., [6] with permission from Elsevier. PVR = post-void residual.

3.3.3 **Timing of diagnosis and treatment**

Early diagnosis and treatment are essential in both congenital and acquired neuro-urological disorders. This helps to prevent irreversible changes within the LUT, even in the presence of normal reflexes [47]. Furthermore, urological symptoms can be the presenting feature of neurological pathology [48, 49]. Early intervention can prevent irreversible deterioration of the LUT and UUT [49]. Long term follow-up (life-long) is mandatory to assess risk of UUT damage and renal failure [50].

3.3.4 **Patient history**

History taking should include past and present symptoms and disorders (Table 4). It is the cornerstone of evaluation, as the answers will aid selection of diagnostic investigations and treatment options.

- In non-traumatic neuro-urological patients with an insidious onset, a detailed history may find that the condition started in childhood or adolescence [51].
- Urinary history consists of symptoms associated with both urine storage and voiding.
- Bowel history is important because patients with neuro-urological symptoms may also have related neurogenic bowel dysfunction [52].
- Sexual function may be impaired because of the neuro-urological condition [53].
- Special attention should be paid to possible warning signs and symptoms (e.g., pain, infection, haematuria, and fever) requiring further investigation.
- Patients with SCI usually find it difficult to report urinary tract infection (UTI)-related symptoms accurately [54, 55].
• The presence of urinary, bowel and sexual symptoms without neurological symptoms could be suggestive of an underlying neurological disease or condition.
• The severity of lesion after acute SCI does not predict the presence or absence of unfavourable urodynamic parameters [47].

3.3.4.1  **Bladder diaries**

Bladder diaries are considered a valuable diagnostic tool for the initial assessment of neurogenic LUT dysfunction. They provide data on the number of voids (spontaneous or intermittent catheter), voided volume, UUI episodes and contribute to the interpretation of urodynamic testing. Preferably, bladder diaries should be completed for three consecutive days [56].

3.3.5  **Patient quality of life questionnaires**

An assessment of the patient’s present and expected future quality of life (QoL) is important to evaluate the effect of any therapy. Quality of life is an essential aspect of the overall management of neuro-urological patients, for example when evaluating treatment related changes on a patient’s QoL [57]. The type of bladder management has been shown to affect health-related QoL (HRQoL) mainly in patients with SCI [58, 59] and MS.
[60], as does the presence or absence of urinary, sexual and faecal incontinence [61]. Other research has also highlighted the importance of urological treatment and its impact on the urodynamic functionality of the neuro-urological patient in determining patient QoL [62].

In recent years a proliferation in the number of questionnaires to evaluate symptoms and QoL has been seen. Condition-specific questionnaires can be used to assess symptom severity and the impact of symptoms on QoL. A patient’s overall QoL can be assessed using generic questionnaires. It is important that the questionnaire of choice has been validated in the neuro-urological population, and that it is available in the language that it is to be used in.

3.3.5.1 Available Questionnaires

Three condition-specific questionnaires for urinary or bowel dysfunction and QoL have been developed specifically for adult neuro-urological patients [63]. In MS and SCI patients the Qualiveen, also available in a short version, is validated and translated into various languages [64, 65]. Although several objective and subjective tools have been used to assess the influence of neurogenic lower urinary tract dysfunctions (N-LUTD) on QoL in SCI, the Quality life index-SCI and Qualiveen are the only validated condition-specific outcomes that have shown consistent sensitivity [66]. The Neurogenic Bladder Symptom Score (NBSS) and its short version has been validated in neurological patients to measure urinary symptoms and their consequences [67-69]. The QoL scoring tool related to Bowel Management (QoL-BM) [70] can be used to assess bowel dysfunction in MS and SCI patients. A new tool has recently been developed to understand the reasons for poor compliance in long-term management of neurogenic patients. [71, 72]. A variety of patient-reported outcome measures (PROMs) are available to evaluate sexual function in neuro-urological patients. However, only the Multiple Sclerosis Intimacy and Sexuality Questionnaire-15 (MSISQ-15) and -19 is supported by evidence [73-75].

In addition, several validated questionnaires that evaluate QoL and assess urinary symptoms as a subscale or question in neuro-urological patients have been identified [76] (Table 5). The condition-specific Incontinence-Quality of Life (I-QoL) questionnaire which was initially developed for the non-neurological population has now also been validated for neuro-urological patients [77].

A patient’s overall QoL can be assessed by generic HRQoL questionnaires, the most commonly used being the I-QOL, King’s Health Questionnaire (KHQ), or the Short Form 36-item and 12-item Health Survey Questionnaires (SF-36, SF-12) [63]. In addition, the quality-adjusted life year (QALY), quantifies outcomes, by weighing years of life spent in a specified health state, adjusted by a factor representing the value placed by society or patients on their specific health state [78].

No evidence was found for which validated questionnaires are the most appropriate for use, since no quality criteria for validated questionnaires have been assessed [63].

3.3.6 Physical examination and additional tests

In addition to a detailed patient history, attention should be paid to possible physical and intellectual disabilities with respect to the planned investigations [89, 90]. Neuro-urological status should be described as completely as possible (Figure 2) [6]. Patients with a high spinal cord lesion or supraspinal neurological lesions may suffer from a significant drop in blood pressure when moved into a sitting or standing position. All sensations and reflexes in the urogenital area must be tested [6]. Furthermore, detailed testing of the anal sphincter and pelvic floor functions must be performed (Figure 2) [6, 91]. It is essential to have this clinical information to reliably interpret later diagnostic investigations (Table 6).

Additionally, urinalysis, blood chemistry, ultrasonography, post void residual, incontinence quantification and were indicated free uroflowmetry, should be performed as part of the routine assessment of neuro-urological patients [6, 92].

3.3.6.1 Autonomic dysreflexia

Autonomic dysreflexia is a sudden and exaggerated autonomic response to various stimuli generally manifests in patients with SCI or spinal dysfunction at or above level Th 6. It is defined by an increase in systolic blood pressure > 20 mmHg from baseline [93] and can have life-threatening consequences if not managed adequately. The stimulus can be distended bladder or bowel. For example, iatrogenic stimuli during cystoscopy or urodynamics can trigger AD [94]. It can also be secondary to sexual stimulation or any noxious stimulus, e.g., infected toenail or pressure sore.

Figure 2: Lumbosacral dermatomes, cutaneous nerves, and reflexes

The physical examination includes testing sensations and reflexes mediated through the lower spinal cord. Abnormal findings would suggest a lesion affecting the lumbosacral segments; mapping out distinct areas of sensory impairment helps to further localise the site of the lesion. Distribution of dermatomes (areas of skin mainly supplied by a single spinal nerve) and cutaneous nerves over the perianal region and back of the upper thigh (A), the perineum [95] (B), male external genitalia [96] (C) and root values of lower spinal cord reflexes (D). Figure adapted from Panicker et al., [8] with parts A-C adapted from Standing [97], both with permission from Elsevier.

3.3.7 **Urodynamics**

3.3.7.1 **Introduction**

Urodynamic investigation is the only method that can objectively assess the function and dysfunction of the LUT. In neuro-urological patients, invasive urodynamic investigation is even more challenging than in general patients. Any technical source of artefacts must be critically considered. It is essential to maintain the quality of the urodynamic recording and its interpretation [1]. Same session repeat urodynamic investigations are crucial in clinical decision making, since repeat measurements may yield completely different results [98].

In patients at risk of AD, it is advisable to measure blood pressure during the urodynamic study [99, 100]. The rectal ampulla should be empty of stool before the start of the investigation. All urodynamic findings must be reported in detail and performed, according to the ICS technical recommendations and standards [1, 101].

3.3.7.2 **Urodynamic tests**

*Free uroflowmetry and assessment of residual urine:* It is recommended prior to planning any invasive urodynamics that patients are able to void in the usual position. For reliable information, it should be repeated at least two to three times [1]. Possible pathological findings include a low flow rate, low voided volume, intermittent flow, hesitancy and PVR.

*Filling cystometry:* This test is the only method for quantifying the patient’s filling function. The status of LUT function must be documented during the filling phase. However, this technique has limited use as a solitary procedure. It is much more effective combined with bladder pressure measurement during micturition and is even more effective in video-urodynamics.

The bladder should be empty at the start of filling. A physiological filling rate should be used with body-warm saline. Possible pathological findings include neurogenic detrusor overactivity (NDO), low bladder compliance, abnormal bladder sensations, low cystometric capacity and urinary incontinence.

*Detrusor leak point pressure* [112]: Appears to have no use as a diagnostic tool. Some positive findings have been reported [50, 103, 104], but sensitivity is too low to estimate the risk to the UUT or for secondary bladder damage [105, 106].

*Pressure flow study (or voiding cystometry):* Reflects the coordination between detrusor and urethra or pelvic floor during the voiding phase. It is even more effective if combined with filling cystometry and video-urodynamics. Possible pathological findings include detrusor underactivity, acontractility, bladder outlet obstruction (BOO), DSD, a high urethral resistance, and residual urine.

Most types of obstruction caused by neuro-urological disorders are due to DSD [107, 108], non-relaxing urethra, and/or non-relaxing bladder neck [109, 110]. Pressure-flow analysis mainly assesses the amount of mechanical obstruction caused by the urethra’s inherent mechanical and anatomical properties and has limited value in patients with neuro-urological disorders.

*Electromyography (EMG):* Reflects the activity of the external urethral sphincter, the peri-urethral striated musculature, the anal sphincter, and the striated pelvic floor muscles. Correct interpretation may be difficult due to artefacts introduced by other equipment. In the urodynamic setting, an EMG is useful as a gross indication of the patient’s ability to control the pelvic floor. Possible pathological findings include inadequate recruitment upon specific stimuli (e.g. bladder filling, involuntary detrusor contractions, onset of voiding, coughing, Valsalva manoeuvre) suggesting a diagnosis of DSD [111].

*Urethral pressure measurement:* Has a very limited role in neuro-urological disorders. There is no consensus on parameters indicating pathological findings [112].

*Video-urodynamics:* Is the combination of filling cystometry and pressure flow studies with imaging. It is the optimum procedure for urodynamic investigation in neuro-urological disorders [5]. Possible pathological findings include all those described in the filling cystometry and the pressure flow study sections, and any morphological pathology of the LUT and reflux to the UUT [113].

*Ambulatory urodynamics:* This is the functional investigation of the urinary tract, which predominantly uses the natural filling of the urinary tract to reproduce the patient’s normal activity. Although this type of study might be considered when conventional urodynamics does not reproduce the patient’s symptoms, its role in the neuro-urological patient still needs to be determined [114, 115].
Triggered tests during urodynamics: Lower urinary tract function can be provoked by coughing, triggered voiding, or anal stretch. Fast-filling cystometry with cooled saline (the 'ice water test') was initially described to discriminate between upper and lower motor neuron lesions [116, 117]. Patients with upper motor neuron lesions develop a detrusor contraction if the detrusor is intact, while patients with lower motor neuron lesions do not. However, the test does not seem to be fully discriminative since also non neurological and lower motor SCI have shown positive test [118, 119].

Previously, a positive bethanechol test [120] (detrusor contraction > 25 cm H₂O) was thought to indicate detrusor denervation hypersensitivity and the muscular integrity of an acontractile detrusor. However, in practice, the test has given equivocal results. A variation of this method was reported using intravesical electromotive administration of the bethanechol [121], but there was no published follow-up. Currently, there is no indication for this test.

3.3.7.3 Specialist uro-neurophysiological tests
The following tests are advised as part of the neurological work-up [122):
- electromyography (in a neurophysiological setting) of pelvic floor muscles, urethral sphincter and/or anal sphincter;
- nerve conduction studies of pudendal nerve;
- reflex latency measurements of bulbocavernosus and anal reflex arcs;
- evoked responses from clitoris or glans penis;
- sensory testing on bladder and urethra.

Other elective tests, for specific conditions, may become obvious during the work-up and urodynamic investigations.

3.3.8 Renal function
In many patients with neuro-urological disorders, the UUT is at risk, particularly in patients who develop high detrusor pressure during the filling phase. Although effective treatment can reduce this risk, there is still a relatively high incidence of renal morbidity [123, 124]. Patients with SCI or SB have a higher risk of developing renal failure compared with patients with slowly progressive non-traumatic neurological disorders, such as MS and Parkinson's disease (PD) [125].

Caregivers must be informed of this risk and instructed to watch carefully for any signs or symptoms of a possible deterioration in the patient's renal function. In patients with poor muscle mass cystatin C based glomerular filtration rate (GFR) is more accurate in detecting chronic kidney disease than serum creatinine estimated GFR [126, 127]. There are no high-level evidence publications available which show the optimal management to preserve renal function in these patients [128].
3.4 Disease management

3.4.1 Introduction

The primary aims for treatment of neuro-urological symptoms, and their priorities, are [129, 130]:

- protection of the UUT;
- achievement (or maintenance) of urinary continence;
- restoration of LUT function;
- improvement of the patient’s QoL.

Further considerations are the patient’s disability, cost-effectiveness, technical complexity and possible complications [130].

Renal failure is the main mortality factor in SCI patients who survive the trauma [131, 132]. Keeping the detrusor pressure during both the filling and voiding phases within safe limits significantly reduces the mortality from urological causes in these patients [133-135] and has consequently become the top priority in the treatment of patients with neuro-urological symptoms [129, 130].

In patients with high detrusor pressure during the filling phase (DO, low bladder compliance), treatment is aimed primarily at conversion of an overactive, high-pressure bladder into a low-pressure reservoir despite the resulting residual urine [129]. Reduction of the detrusor pressure contributes to urinary continence, and consequently to social rehabilitation and QoL. It is also critical for preventing UTIs [136, 137]. However, complete continence cannot always be obtained.

3.4.2 Non-invasive conservative treatment

3.4.2.1 Assisted bladder emptying - Credé manoeuvre, Valsalva manoeuvre, triggered reflex voiding

Incomplete bladder emptying is a serious risk factor for UTI, high intravesical pressure and incontinence. Methods to improve the voiding process should therefore be practiced.

**Bladder expression:** The downwards movement of the lower abdomen by suprapubic compression (Credé) or by abdominal straining (Valsalva) leads to an increase in intravesical pressure, and generally also causes a reflex sphincter contraction [138, 139]. The latter may increase bladder outlet resistance and lead to inefficient emptying. The high pressures created during these procedures are hazardous for the urinary tract [140, 141]. Therefore, their use should be discouraged unless urodynamics show that the intravesical pressure remains within safe limits [130].

Long-term complications are unavoidable for both methods of bladder emptying [139]. The already weak pelvic floor function may be further impaired, thus introducing or exacerbating already existing SUI [141].

**Triggered reflex voiding:** Stimulation of the sacral or lumbar dermatomes in patients with a upper motor neuron lesion can elicit a reflex detrusor contraction [141]. The risk of high pressure voiding is present and interventions to decrease outlet resistance may be necessary [142]. Triggering can induce AD, especially in patients with high level SCI (at or above Th 6) [143]. All assisted bladder emptying techniques require low outlet resistance. Even then, high detrusor pressures may still be present. Hence, patients need dedicated education and close urodynamic and urological surveillance [141, 144, 145].

**Note:** In the literature, including some of the references cited here, the concept “reflex voiding” is sometimes used to cover all three assisted voiding techniques described in this section.

**External appliances:** Social continence may be achieved by collecting urine during incontinence, for instance using pads. Condom catheters with urine collection devices are a practical method for men [130]. The penile clamp is absolutely contraindicated in case of NDO or low bladder compliance due to the risk of developing high intravesical pressure and pressure sores/necrosis in cases of altered/absent sensations.

3.4.2.2 Neuro-urological rehabilitation

3.4.2.2.1 Bladder rehabilitation including electrical stimulation

The term bladder rehabilitation summarises treatment options that aim to re-establish bladder function in patients with neuro-urological symptoms. Strong contraction of the urethral sphincter and/or pelvic floor, as well as anal dilatation, manipulation of the genital region, and physical activity inhibit micturition in a reflex manner [130, 146]. The first mechanism is affected by activation of efferent nerve fibres, and the latter ones are produced by activation of afferent fibres [105]. Electrical stimulation of the pudendal nerve afferents strongly and inhibits the micturition reflex and detrusor contraction [147]. This stimulation might then support the restoration of the balance between excitatory and inhibitory inputs at the spinal or supraspinal level [130, 148]. Evidence for bladder rehabilitation using electrical stimulation in neurological patients is mainly based on small non-comparative studies with a high risk of bias.
Behavioural therapy and bladder training: In patients with PD, behavioural therapy and bladder training may be considered based on randomised controlled trials (RCTs) with very limited number of patients [149, 150].

Peripheral temporary electrostimulation: Tibial nerve stimulation and transcutaneous electrical nerve stimulation (TENS) might be effective and safe for treating neurogenic LUT dysfunction, but more reliable evidence from well-designed RCTs is required to reach definitive conclusions [148, 151-153]. In post-stroke patients TENS has been shown to effectively improve urodynamic and bladder diary findings as well as QoL [154-156]. In an RCT, transcutaneous tibial nerve home stimulation has proven to significantly reduce bladder diary parameters in women with PD [157]. In acute SCI, TENS is able to achieve bladder neuromodulation via modulation of the autonomous nervous system functions [158]. Greater volumes until full sensation, less detrusor-sphincter dyssynergia and an increased bladder capacity can be found when compared to sham-treated patients [159].

A SR on dorsal genital nerve stimulation showed a higher relative and absolute bladder capacities and inhibition of detrusor hyperactivity in SCI people, although these therapeutic effects may be dependent on the current, amplitude and longer periods of stimulation [160].

Interferential medium frequency current electrical stimulation for SCI patients with American spinal cord injury association impairment scale (AIS) levels B, C and D demonstrated a significant decrease in PVR and volume of urine leakage between catheterisation [161]. Neuromuscular electrical stimulation applied in the sacral area has also improved the performance in symptoms scores in highly selected patients with UI after stroke [155]; however, new RCTs with more patients and longer follow-up are required.

Peripheral temporary electrostimulation combined with pelvic floor muscle training and biofeedback: In MS patients, combining active neuromuscular electrical stimulation with Pelvic Floor Muscle Training (PFMT) and EMG biofeedback can achieve a substantial reduction of neuro-urological symptoms [162, 163]. This treatment combination seems to be more effective than either therapy alone [164, 165]. However, the combination of intravaginal electrostimulation and PFMT was not superior to PFMT alone in reducing UI in women with incomplete SCI [166].

Intravesical electrostimulation: Intravesical electrostimulation can increase bladder capacity and improve bladder filling sensation in patients with incomplete SCI or myelomeningocele (MMC) [167]. In patients with neurogenic detrusor underactivity, intravesical electrostimulation may also improve voiding and reduce residual volume [168, 169].

Repetitive transcranial magnetic stimulation: Although improvement of neuro-urological symptoms has been described in PD, SCI and MS patients, this technique is still under investigation [170]. The role of cortical as well as sacral magnetic stimulation in MS patients with underactive bladder needs to be better defined [171].

Summary: To date, bladder rehabilitation techniques are mainly based on electrical or magnetic stimulation; however, there is a lack of well-designed studies.

3.4.2.3 Drug treatment

A single, optimal, medical therapy for neuro-urological symptoms is not always available. Commonly, a combination of different therapies (e.g. intermittent catheterisation and antimuscarinic drugs) is advised to prevent urinary tract damage and improve long-term outcomes, particularly in patients with a suprasacral SCI or MS [141, 172-174].

3.4.2.3.1 Drugs for storage symptoms

Antimuscarinic drugs: are the first-line choice for treating NDO, increasing bladder capacity and reducing episodes of UI secondary to NDO by the inhibition of parasympathetic pathways [130, 175-181]. Antimuscarinic drugs have been used for many years to treat patients with NDO [179, 180, 182], and the responses of individual patients to antimuscarinic treatment are variable. Despite a meta-analysis confirming the clinical and urodynamic efficacy of antimuscarinic therapy compared to placebo in adult NDO, a more recent integrative review has indicated that the information provided is still too limited for clinicians to be able to match trial data to the needs of individual patients with SCI, mainly due to the lack of use of standardised clinical evaluation tools such as the American Spinal Injury Association bladder diary and validated symptoms score [180, 183].

Higher doses or a combination of antimuscarinic agents may be an option to maximise outcomes in neurological patients [176, 177, 184-187]. However, these drugs have a high incidence of adverse events, which may lead to early discontinuation of therapy. Despite this, NDO patients have generally shown better treatment adherence compared to idiopathic DO patients [188].
Choice of antimuscarinic agent: Oxybutynin [130, 176, 177, 179, 180, 189], trospium [180, 186, 190], tolterodine [191] and propiverine [180, 192] are established, effective and well tolerated treatments even in long-term use [179, 180, 193, 194]. Darifenacin [195, 196] and solifenacin [197] have been evaluated in NDO secondary to SCI and MS [180, 195-197] with results similar to other antimuscarinic drugs. A pilot study using solifenacin in NDO due to PD showed an improvement in UI [198]. Fesoterodine, an active metabolite of tolterodine, has also been introduced; and preliminary results are promising [199, 200]. Favourable results with the new drug imidafenacin have been reported in suprapontine as well as SCI patients [201, 202].

Side effects: Controlled-release antimuscarinics have some minor side effects, e.g. dry mouth [203]. It has been suggested that different ways of administration may help to reduce side effects [204]. Imidafenacine has been safely used in neurological patients with no worsening of cognitive function [201]. Nevertheless, the potential risk of developing dementia should be considered [205].

Beta-3-adrenergic receptor agonists
The role of mirabegron in neuro-urological patients is still unclear [206, 207]. In MS and SCI patients, with very short follow-up, mirabegron has not demonstrated any significant effect on detrusor pressure or cystometric capacity despite the reported improvement in LUT symptoms [208, 209]. A significant subjective improvement in OAB symptoms has also been reported using lower dosages of mirabegron in patients affected by CNS lesions without any negative effects on voiding function [210]. A standard dosage of 50 mg has been found effective with no worsening of cognitive function in patients with PD [211, 212]. Combination therapy with mirabegron and desmopressin in MS patients has shown promising results; however, clinical experience is still very limited in neuro-urological populations [213].

Other drugs
In preliminary studies, improvements in daily incontinence rates, nocturia, daytime and 24-hour voids, as well as the low risk of adverse events, suggest that cannabinoids may be effective and safe in MS patients [214]. A concomitant improvement in OAB symptoms has been reported in male MS patients using daily tadalafil to treat neurogenic erectile dysfunction (ED) [215]. A SR found that desmopressin may be effective for treating nocturia in MS patients; however, adverse events were common, with the included studies being heterogeneous and of low quality [216].

3.4.2.3.2 Drugs for voiding symptoms

Detrusor underactivity: Cholinergic drugs, such as bethanechol and distigmine, have been considered to enhance detrusor contractility and promote bladder emptying, but are not frequently used in clinical practice [217]. Only preclinical studies have documented the potential benefits of cannabinoid agonists for improving detrusor contractility when administered intravesically [218, 219].

Decreasing bladder outlet resistance: α-blockers (e.g. tamsulosin, naftopidil and silodosin) seem to be effective for decreasing bladder outlet resistance, PVR and AD [220-224].

Increasing bladder outlet resistance: Several drugs have shown efficacy in selected cases of mild SUI, but there are no high-level evidence studies in neurological patients [130].

3.4.2.5 Minimally invasive treatment

3.4.2.5.1 Catheterisation

Intermittent self- or third-party catheterisation [225, 226] is the preferred management for neuro-urological patients who cannot effectively empty their bladders [130]. An adequate hand function is an independent risk factor for cessation of intermittent catheterisation (IC) [227].

Sterile IC, as originally proposed by Guttmann and Frankel [225], significantly reduces the risk of UTI and bacteriuria [130, 228, 229], compared with clean IC introduced by Lapides, et al., [226]. However, it has not yet been established whether or not the incidence of UTI, other complications and user satisfaction are affected by either sterile or clean IC, coated or uncoated catheters or by any other catheter type [230].

Sterile IC cannot be considered a routine procedure [130, 229] and careful counselling should be employed before commencing IC. In those with MS, commencing IC increases UTI rate over one year by seven fold, without improvement in QoL or symptom score [231]. In addition, in those with SCI, dissatisfaction (and discontinuation) is associated with increased UTI frequency, as well as being of the female sex [232]. It is worth considering patient satisfaction and subsequent compliance when instigating and continuing IC. Shared decision making is imperative, as although IC has better medical outcomes than indwelling catheterisation, in the SCI population it is associated with worse reported QoL compared to indwelling catheters, especially if recurrent (> 4 per year) UTIs complicate management [58, 233]. The use of hydrophilic catheters is associated with a lower rate of UTI [234]. An observational study found that of the 56.9% of patients who used IC 42.1% of patients discontinued IC within 12 months with inconvenience (36%), leakage (20%) and increased infections (19%) listed as the main reasons for the discontinuation [233].

To minimize the risk of UTI in neuro-urological patients, it is important that patient should be adequately taught to self-catheterise [130, 235-239]. The average frequency of catheterisations per day is four to six times [240] and the catheter size most often used is between 12-16 Fr. In aseptic IC, an optimum frequency of five times showed a reduction of UTI [240]. Ideally, bladder volume at catheterisation should, as a rule, not exceed 400-500 mL.

Indwelling transurethral catheterisation and, to a lesser extent, suprapubic cystostomy are associated with a range of complications as well as an enhanced risk for UTI [130, 241-248]; therefore, both procedures should be avoided, when possible. Silicone catheters are preferred as they are less susceptible to encrustation and because of the high incidence of latex allergy in the neuro-urological patient population [249].

3.4.2.5.3 Intravesical drug treatment

To reduce DO, antimuscarinics can also be administered intravesically [204, 250-253]. The efficacy, safety, and tolerability of intravesical administration of 0.1% oxybutynin hydrochloride compared to its oral administration for treatment of NDO has been demonstrated in a recent randomised controlled study [204]. This approach may reduce adverse effects due to the fact that the antimuscarinic drug is metabolised differently [250] and a greater amount is sequestered in the bladder, even more than with electromotive administration [251].

The vanilloids, capsaicin and resiniferatoxin, desensitise the C-fibres for a period of a few months [254, 255]. Clinical studies have shown that resiniferatoxin has limited clinical efficacy compared to botulinum toxin A injections in the detrusor [254].

Although preliminary data suggest that intravesical vanilloids might be effective for treating neurological LUT dysfunction, their safety profile appears to be unfavourable [256]. Currently, there is no indication for the use of these substances, which are not licensed for intravesical treatment.

3.4.2.5.5 Botulinum toxin injections in the bladder

Botulinum toxin A causes a long-lasting but reversible chemical denervation that lasts for about nine months [257, 258]. The toxin injections are mapped over the detrusor in a dosage that depends on the preparation used. Botulinum toxin A has been proven effective in patients with neuro-urological disorders due to MS, SCI and PD in multiple RCTs and meta-analyses [259-262]. Urodynamic studies might be necessary after treatment in patients with maximal filling pressure of > 40 cm H₂O cm in order to monitor the effect of the injections on bladder pressure [263]. Repeated injections seem to be possible without loss of efficacy, even after initial low response rates, based on years of follow-up [257, 264-267]. The clinical efficacy of botulinum toxin A injection in patients with low morbidity after failure of augmentation enterocystoplasty has been demonstrated [268, 269]. A switch between different toxin variations may improve responsiveness [270]. The most frequent side effects are UTIs, urinary retention and haematuria [271]. Intermittent catheterisation may become necessary, this is especially relevant in MS patients as they do not often perform IC prior to intravesical botulinum toxin injections. However, a lower dose of botulinum toxin A (100 U) may reduce the rate of clean IC in MS patients [272]. Rare complications include generalised muscle weakness and AD [271]. Current research focuses on different delivery approaches to injection such as liposome encapsulated botulinum toxin to decrease side effects [273]. Neuro-urological patients with an indwelling catheter and concomitant bladder pain and/or catheter bypass leakage could benefit from intravesical botulinum injections [274].

3.4.2.5.6 Bladder neck and urethral procedures

Reduction of the bladder outlet resistance may be necessary to protect the UUT. This can be achieved by chemical denervation of the sphincter or by surgical interventions (bladder neck or sphincter incision or urethral stent – Section 3.4.3.1). Incontinence may result and can be managed by external devices (Section 3.4.2.1).

**Botulinum toxin A:** This can be used to treat DSD effectively by injecting the sphincter at a dose that depends on the preparation used. The dyssynergia is abolished only for a few months, necessitating repeat injections. The efficacy of this treatment has been reported to be high with few adverse effects [275-277]. However, a recent SR concluded that, because of limited evidence, future RCTs assessing the effectiveness of botulinum toxin A injections also need to address the uncertainty about the optimal dose and mode of injection [278]. In addition, this therapy is not licensed.

**Balloon dilatation:** Favourable immediate results were reported [279], but there have been no further reports since 1994; therefore, this method is no longer recommended.

**Increasing bladder outlet resistance:** This can improve the continence condition. However, despite early positive results with urethral bulking agents, a relative early loss of continence is reported in patients with neuro-urological disorders [130, 280, 281].

**Urethral inserts:** Urethral plugs or valves for the management of (female) stress incontinence have not been applied in neuro-urological patients. The experience with active pumping urethral prosthesis for treatment of the underactive or acontractile detrusor were disappointing [282].

3.4.3 Surgical treatment

There is considerable heterogeneity in outcome parameters and definitions of cure used to report on outcomes of surgical interventions for SUI in neuro-urological patients [283]. The heterogeneity of outcome reporting makes it difficult to interpret and compare different studies and therapies. A consistent comparison of the outcomes of therapy can only be made after standardisation of outcome parameters and definitions of cure or success; therefore, it would seem prudent to develop a core outcome set (COS) for use in UI research in neuro-urological patients [283]. Until such a COS is developed it would seem feasible to use both a subjective and objective outcome parameter and the combination of both to define cure [283]. Due to the importance of QoL for neuro-urological patients a disease-specific QoL questionnaire or a bother questionnaire validated for neuro-urological patients should be used as the subjective outcome parameter [283].

3.4.3.1 Bladder neck and urethral procedures

Increasing the bladder outlet resistance has the inherent risk of causing high intravesical pressure. Procedures to treat sphincteric incontinence are therefore suitable only when the detrusor activity can be controlled and when no significant reflux is present. A simultaneous bladder augmentation and IC may be necessary [130].

Urethral sling: Various materials have been used for this procedure with enduring positive results. The procedure is established in women with the ability to self-catheterise [130, 284-287]. There is growing evidence that synthetic slings can be used effectively with acceptable medium to long-term results and minimal morbidity in neurological patients [288, 289]. Besides the pubovaginal sling, which has been considered the procedure of choice in this subgroup of patients, recent reports suggest that both the transobturator and the retropubic approaches may also be considered, with similar failure rates and a reduction in the need for IC. However, for both approaches a higher incidence of de novo urgency was reported [289, 290]. A SR reporting on 100 women treated with an autologous fascial sling (in five studies), with a follow-up of 24 to 52 months, had a success rate ranging from 75% to 100%. In the same review, 80 women in four studies received a synthetic sling (TVT, TOT or mini-sling), with a follow-up ranged from 46 to 119 months and reported a success rate ranging from 75% to 85%. Complications were the need to perform IC, mesh erosion or extrusion requiring partial or total removal and retropubic haematoma [291].

In men, both autologous and synthetic slings may also be an alternative [292-296]. A SR reported 84 men treated with autologous puboprostatic slings or various types of synthetic tapes [291]. The cure rate ranged from 29% to 71% at a follow-up of 12 to 36 months. Complications included haematoma, tape infection or erosion into urethra and difficulty to perform IC [291].

Artificial urinary sphincter (AUS): This device was introduced by Light and Scott for patients with neuro-urological disorders [297]. It has stood the test of time and acceptable long-term outcomes can be obtained [298]. Implantation of AUS is the most often performed procedure for neurogenic SUI in both men and women and accounts for 49% of all the reported neurogenic SUI procedures (67% in men and 33% in women) with a high success/improvement rate [291]. However, the complication rates and re-operation rates are higher than in non-neurogenic patient groups (up to 60%), so it is advisable that patients are conscientiously informed about the success rates as well as the possible need for re-intervention [299, 300]. In a case series with 25 years follow-up only 7.1% of patients were revision free at twenty years [301]. Re-interventions are commonly due to mechanical failure, urethral atrophy or erosion and infection.

There is growing interest in the use of this device in women with development of laparoscopic and robot-assisted approaches via an anterior or a posterior access to the bladder neck [302-305], which may reduce the infection and erosion rate. Although from a single institution series, long-term surgical results are now available and support the potentially prominent role of AUS placement in female patients with neurogenic SUI [291, 306-308].

Long-term surgical and patient-reported outcomes are needed to determine the role of AUS placement in female patients with neurogenic SUI [308].

Adjustable continence device - ProACT/ACT®: The efficacy of this device has been reported mainly in post-prostatectomy incontinence. A marginally lower cure rate has been reported in neurological patients when compared to non-neurological patients [309]. A retrospective study in neuro-urological patients reported a low rate of efficacy and high complication rate for this device [310].

</tbody>
</table>
**Functional sphincter augmentation:** Transposing the gracilis muscle to the bladder neck [311] or proximal urethra [312], can enable the possible creation of a functional autologous sphincter by electrical stimulation [311-313]; therefore, raising the prospect of restoring control over the urethral closure.

**Bladder neck and urethra reconstruction:** The classical Young-Dees-Leadbetter procedure [314] for bladder neck reconstruction in children with bladder exstrophy, and Kropp urethra lengthening [315] improved by Salle [316], are established methods to restore continence provided that IC is practiced and/or bladder augmentation is performed [130, 317].

**Endoscopic techniques for treating anatomic bladder outlet obstruction [318]:**

- **Transurethral resection of the prostate** is indicated in male patients with refractory LUT symptoms due to benign prostatic obstruction. Special consideration should be given to pre-operative abnormal sphincter function which can lead to de novo or persistent UI [319, 320].

- **Bladder neck resection** is indicated in patients with high PVR and when a prominent obstruction of the sclerotic ring in the bladder neck is identified during cystoscopy. The resection can be performed between the three or nine o’clock position or full circle [321].

- **Urethrotomy** is indicated in patients with urethral strictures. Cold knife or neodymium:YAG contact laser urethrotomy at the twelve o’clock position can be performed [322, 323]. In recurrent strictures, open surgery should be considered.

- **Sphincterotomy** has been shown to be an efficient technique for the resolution of AD, hydronephrosis and recurrent UTI, and for decreasing detrusor pressure, PVR and vesicoureteral reflux. It is irreversible and should be limited to men who are able to wear a condom catheter. By staged incision, bladder outlet resistance can be reduced without completely losing the closure function of the urethra [129, 130, 324]. The incision with less complications, is the twelve o’clock sphincterotomy with cold knife [325] or neodymium:YAG laser [326]. Sphincterotomy needs to be repeated at regular intervals in many patients [327], but it is efficient and does not cause severe adverse effects [129, 279]. Secondary narrowing of the bladder neck may occur, for which combined bladder neck incision might be considered [328].

**Bladder neck incision:** This is indicated only for secondary changes at the bladder neck (fibrosis) [129, 329]. This procedure is not recommended in patients with detrusor hypertrophy, which causes thickening of the bladder neck [129].

**Stents:** Implantation of urethral stents results in continence being dependent on adequate closure of the bladder neck [130]. The results are comparable with sphincterotomy and the stenting procedure has a shorter duration of surgery and hospital stay [330, 331]. However, the costs [129], possible complications and re-interventions [332, 333] are limiting factors in their use [334-337].

### 3.4.3.2 Denervation, deafferentation, sacral neuromodulation

Sacral anterior root stimulation (SARS) is aimed at producing detrusor contraction. The technique was developed by Brindley [338] and is only applicable to complete lesions above the implant location, as its stimulation amplitude is over the pain threshold. The urethral sphincter efferents are also stimulated, but because the striated muscle relaxes faster than the smooth muscle of the detrusor, so-called “post-stimulus voiding” occurs. This approach has been successful in highly selected patients [339-341]. Although it has been shown that detrusor pressure during SARS decreases over time, the changes do not seem to be clinically relevant during the first decade after surgery [342]. By changing the stimulation parameters, this method can also induce defecation or erection. A recent study reported that Charcot spinal arthropathy should be considered as a potential long-term complication of SARS, leading to spinal instability and to SARS dysfunction [343].

Sacral rhizotomy, also known as sacral deafferentation, has achieved some success in reducing DO [344-346], but nowadays, it is used mostly as an adjuvant to SARS [339, 347-350]. Alternatives to rhizotomy are sought in this treatment combination [351-353].

There is growing evidence, based mostly on case series, on the use of sacral neuromodulation for treating neuro-urological symptoms, but due to the lack of RCTs it remains unclear which neurological patients are most suitable [354-356]. With the development of MRI-compatible pulse generators and leads, the avoidance of this procedure in patients needing this imaging technique for their follow-up is no longer required.

Other neuromodulation techniques like deep brain stimulation in PD patients may have beneficial effects in the LUT but these depend on the site of stimulation and although prospective, specifically designed studies are needed in neuro-urological patients [357].
3.4.3.3 Bladder covering by striated muscle
When the bladder is covered by striated muscle, that can be stimulated electrically, or ideally that can be contracted voluntarily, voiding function can be restored to an acontractile bladder. The rectus abdominis [358] and latissimus dorsi [359] have been used successfully in patients with neuro-urological symptoms [360, 361].

3.4.3.4 Bladder augmentation
The aim of auto-augmentation (detrusor myectomy) is to reduce DO or improve low bladder compliance. The advantages are low surgical burden, low rate of long-term adverse effects, positive effect on patient QoL, and it does not preclude further interventions [129, 130, 362-365].

Replacing or expanding the bladder by intestine will improve bladder compliance and at least reduce the pressure effect of DO [366, 367]. Improved QoL and stable renal function has been reported during long-term follow-up [368]. Patients performing IC with augmentation cystoplasty had better urinary function and satisfaction with their urinary symptoms compared to patients performing IC with or without botulinum toxin treatment [369]. Long-term complications included bladder perforation (1.9%), mucus production (12.5%), metabolic abnormalities (3.35%), bowel dysfunction (15%), and stone formation (10%) [368].

The procedure should be used with caution in patients with neuro-urological symptoms, but may become necessary if all less-invasive treatment methods have failed. Special attention should be paid to patients with pre-operative renal scars since metabolic acidosis can develop [370]. Bladder substitution with bowel after performing a supratrigonal cystectomy [367], to create a low-pressure reservoir, is indicated in patients with a severely thick and fibrotic bladder wall [130]. Intermittent catheterisation may become necessary after this procedure. The long-term scientific evidence shows that bladder augmentation is a highly successful procedure that stabilises renal function and prevents anatomical deterioration; however, lifelong follow-up is essential in this patient group given the significant morbidity associated with this procedure [368, 371, 372].

3.4.3.5 Urinary diversion
When no other therapy is successful, urinary diversion must be considered for the protection of the UUT and for the patient's QoL [130].

Continent diversion: This should be the first choice for urinary diversion. Patients with limited dexterity may prefer a stoma instead of using the urethra for catheterisation. For cosmetic reasons, the umbilicus is often used for the stoma site [373-379]. A SR of the literature concluded that continent catheterisable tubes/stomas are an effective treatment option in neuro-urological patients unable to perform intermittent self-catheterisation through the urethra [380]. However, the complication rates were significant with 85/213 post-operative events requiring re-operation [380]. Tube stenosis occurred in 4-32% of the cases. Complications related to concomitant procedures (augmentation cystoplasty, pouch) included neovesicocutaneous fistulae (3.4%), bladder stones (20-25%), and bladder perforations (up to 40% in one case series). In addition, data comparing HRQoL before and after surgery were not reported [380].

Incontinent diversion: If catheterisation is impossible, incontinent diversion with a urine-collecting device is indicated. Ultimately, it could be considered in patients who are wheelchair bound or bed-ridden with intractable and untreatable incontinence, in patients with LUT destruction, when the UUT is severely compromised, and in patients who refuse other therapy [130]. An ileal segment is used for the deviation in most cases [130, 381-384]. Patients gain better functional status and QoL after surgery [385]. Concomitant cystectomy to avoid pyocystitis may be advisable [386]. All procedures can be done robotically [387].

Undiversion: Long-standing diversions may be successfully undiverted or an incontinent diversion changed to a continent one with the emergence of new and better techniques for control of detrusor pressure and incontinence [130]. The patient must be carefully counselled and must comply meticulously with the instructions [130]. Successful undiversion can then be performed [388].

In a prospective observational study (n=1,479), QoL was investigated in neuro-urological patients using four different bladder management options. It is the first study to focus on PROMS and noted that surgery was associated with fewer bladder management difficulties and a better QoL [58].

3.5 Urinary tract infection in neuro-urological patients

3.5.1 Epidemiology, aetiology and pathophysiology

Urinary tract infection is the onset of signs and/or symptoms accompanied by laboratory findings of a UTI (bacteriuria, leukocyturia and positive urine culture) [374]. There are no evidence-based cut-off values for the quantification of these findings. The published consensus is that a significant bacteriuria in persons performing IC is present with > 10^2 cfu/mL, > 10^4 cfu/mL in clean-void specimens and any detectable concentration in suprapubic aspirates. Regarding leukocyturia, ten or more leukocytes in centrifuged urine samples per microscopic field (400x) are regarded as significant [374].

The pathogenesis of UTI in neuro-urological patients is multifactorial. Male gender seems to be a risk factor for febrile UTI [389]. Several etiological factors have been described: altered intrinsic defence mechanisms, impaired washout and catheterisation [390]. Poor glycemic control has also been established as a risk factor for UTI in women with type 1 diabetes [391]. However, the exact working mechanisms remain unknown. The presence of asymptomatic bacteriuria in SCI patients is higher than in the general population and varies depending on bladder management. Prevalence of bacteriuria in those performing clean IC varies from 23%-89% [392]. Sphincterotomy and condom catheter drainage has a 57% prevalence [393]. Asymptomatic bacteria should not be routinely screened for in this population [394] but a nomogram can be a helpful tool for early prediction of UTIs [395].

Individuals with neuro-urological symptoms, especially those with SCI, may have other signs and symptoms in addition to or instead of traditional signs and symptoms of a UTI in able-bodied individuals. Other problems, such as AD, may develop or worsen due to a UTI [234]. The most common signs and symptoms suspicious of a UTI in those with neuro-urological disorders are fever, new onset or increase in incontinence, including leaking around an indwelling catheter, increased spasticity, malaise, lethargy or sense of unease, cloudy urine with increased urine odour, discomfort or pain over the kidney or bladder, dysuria, or AD [234, 396]. New incontinence is the most specific symptom, whereas cloudy and foul-smelling urine has the highest positive predictive value for UTI diagnosis [397].

3.5.2 Diagnostic evaluation

Urine culture and urinalysis are the optimum tests for the diagnosis of UTI in neuro-urological patients. A dipstick test may be more useful to exclude rather than to prove UTI [398, 399]. As bacterial strains and resistance patterns in persons with neuro-urological disorders may differ from those of able-bodied patients, microbiologic testing is mandatory [400].
3.5.3 **Disease management**

Bacteriuria in patients with neuro-urological disorders should not be treated. Treatment of asymptomatic bacteriuria results in significantly more resistant bacterial strains without improving the outcome [401]. Urinary tract infections in persons with neuro-urological disorders are by definition a complicated UTI; therefore, single-dose treatment is not advised. There is no consensus in the literature about the duration of treatment as it depends on the severity of the UTI and the involvement of the kidneys and the prostate. Generally, a five to seven day course of antibiotic treatment is advised, which can be extended up to fourteen days according to the extent of the infection [401]. The choice of antibiotic therapy should be based on the results of the microbiologic testing. If immediate treatment is mandatory (e.g., fever, sepsisemia, intolerable clinical symptoms, extensive AD), the choice of treatment should be based on local and individual resistance profiles [402]. In patients with afebrile UTI, an initial non-antibiotic treatment may be justified [403, 404].

3.5.3.1 **Recurrent UTI**

Recurrent UTI in patients with neuro-urological disorders may indicate suboptimal management of the underlying functional problem, e.g., high bladder pressure during storage and voiding, incomplete voiding or bladder stones. The improvement of bladder function, by treating DO by botulinum toxin A injection in the detrusor [405], and the removal of bladder stones or other direct supporting factors, especially indwelling catheters, as early as possible, are mandatory [400].

3.5.3.2 **Prevention**

If the improvement of bladder function and removal of foreign bodies/stones is not successful, additional UTI prevention strategies should be utilised. In a meta-analysis the use of hydrophilic catheters was associated with a lower rate of UTI [234]. Bladder irrigation has not been proven effective [406].

Various medical approaches have been tested for UTI prophylaxis in patients with neuro-urological disorders. The benefit of cranberry juice or probiotics for the prevention of UTI could not be demonstrated in RCTs [407, 408]. Methenamine hippurate is not effective in individuals with neuro-urological symptoms [409]. There is no sufficient evidence to support the use of L-methionine for urine acidification to prevent recurrent UTIs [410]. There is only weak evidence that oral immunotherapy reduces bacteriuria in patients with SCI [411] and that recurrent UTIs are reduced [412]. Low-dose, long-term, antibiotic prophylaxis can reduce UTI frequency, but increases bacterial resistance and is therefore not recommended [401].

Weekly cycling of antibiotic prophylaxis provided long-term positive results, but the results of this trial need to be confirmed in further studies [413]. Another possible future option, the inoculation of apathogenic *Escherichia coli* strains into the bladder, has provided positive results in initial studies, but because of the paucity of data [414], cannot be recommended as a treatment option. There is initial evidence that homeopathic treatment can decrease UTI frequency [415]. In addition, intravesical gentamycin instillations can reduce UTI frequency without increasing the number of multi-resistant bacteria [416].

In summary, based on the criteria of evidence-based medicine, there is currently no preventive measure for recurrent UTI in patients with neuro-urological disorders that can be recommended without limitations. Therefore, individualised concepts should be taken into consideration, including immunostimulation, phytotherapy and complementary medicine [417]. Prophylaxis in patients with neuro-urological disorders is important to pursue, but since there are no data favouring one approach over another, prophylaxis is essentially a trial-and-error approach.

3.6 Sexual function and fertility

These Guidelines specifically focus on sexual dysfunction and infertility in patients with a neurological disease [418, 419]. Non-neurogenic, male sexual dysfunction and infertility are covered in separate EAU Guidelines [420, 421]. In neuro-urological patients sexual problems can be identified at three levels: primary (direct neurological damage), secondary (general physical disabilities) and tertiary (psychosocial and emotional issues) sexual dysfunction [422]. Adopting a systematic approach, such as the PLISSIT model (Permission, Limited Information, Specific Suggestions and Intensive Therapy) [423], provides a framework for counselling and treatment involving a stepwise approach to the management of neurogenic sexual dysfunction. Sexual dysfunction is associated with neurogenic LUT dysfunction in patients with MS [424] and SB [425]. Although various PROMs are available to evaluate sexual function, the evidence for good PROMs is limited and studies with high methodological quality are needed [75].

3.6.1 Erectile dysfunction

3.6.1.1 Phosphodiesterase type 5 inhibitors (PDE5Is)

Phosphodiesterase type 5 inhibitors (PDE5Is) are recommended as first-line treatment in neurogenic ED [418, 419]. In SCI patients, tadalafil, vardenafil and sildenafil have all improved retrograde ejaculation and improved erectile function and satisfaction on IIEF-15. Tadalafil 10 mg was shown to be more effective than sildenafil 50 mg. All currently available PDE5Is appear to be effective and safe, although there are no high-level evidence studies in neuro-urological patients investigating the efficacy and side effects across different PDE5Is, dosages and formulations [426].

For MS patients two studies reported significant improvement in ED when using sildenafil and tadalafil [427, 428] however, another study showed no improvement in ED with sildenafil [429]. One study found a significant improvement in ED in SB patients when using sildenafil [430].

In PD normal erectile function was described in over half of the patients using sildenafil 100 mg and a significant improvement in IIEF-15 score was found compared to placebo. While most neuro-urological patients require long-term therapy for ED some have a low compliance rate or stop therapy because of side effects [431, 432], most commonly headache and flushing [419]. In addition, PDE5Is may induce relevant hypotension in patients with tetraplegia/high-level paraplegia and multiple system atrophy [431, 432]. As a prerequisite for successful PDE5I-therapy, some residual nerve function is required to induce erection. Since many patients with SCI use on-demand nitrates for the treatment of AD, they must be counselled that PDE5Is are contraindicated when using nitrate medication.

3.6.1.2 Drug therapy other than PDE5Is

Fampridine to treat neurogenic spasticity has been shown to be beneficial in improving ED in two domains of the IIEF-15 in SCI and MS patients, however, with a significant discontinuation rate due to severe adverse events [433]. Sublingual apomorphine was shown to have poor results on ED in SCI patients and side-effects in half of the patients [434]. In PD, pergolide mesylate showed a significant improvement in IIEF-15 scores up to twelve months follow-up [435].

3.6.1.3 Mechanical devices

Mechanical devices (vacuum tumescence devices and penile rings) may be effective but are less popular [436-440].

3.6.1.4 Intracavernous injections and intraurethral application

Patients not responding to oral drugs may be offered intracavernous injections (alprostadil, papaverine and phentolamine) that have been shown to be effective in a number of neurological conditions, including SCI, MS, and diabetes mellitus [441-447], but their use requires careful dose titration and some precautions. Complications of intracavernous drugs include pain, priapism and corpora cavernosa fibrosis.

Intracavernous vasoactive drug injection is the first-line therapeutic option in patients taking nitrate medications, as well as those with concerns about drug interactions with PDE5Is, or in whom PDE5Is are ineffective. The impact of intracavernous injections on ejaculation and orgasmic function, their early
use for increasing the recovery rate of a spontaneous erection, and their effectiveness and tolerability in the long-term are unclear [431]. Intra-urethral alprostadil application is an alternative, but less effective, route of administration [443, 448].

3.6.1.5 Sacral neuromodulation

Sacral neuromodulation for LUT dysfunction may improve sexual function; however, high level evidence studies are lacking.

3.6.1.6 Penile prostheses

Penile prostheses may be considered for treatment of neurogenic ED when all conservative treatments have failed. At a mean follow-up of seven years, 83.7% of patients with SCI were able to have sexual intercourse [419]. Serious complications, including infection and prosthesis perforation, may occur in about 10% of patients, depending on implant type [449-451].

3.6.2 Male fertility

Male fertility can be compromised in the neurological patient by ED, ejaculation disorder, impaired sperm quality or various combinations of these three disorders. Among the major conditions contributing to neurogenic infertility are pelvic and retroperitoneal surgery, diabetes mellitus, SB, MS and SCI [452]. Erectile dysfunction is managed as described previously. Retrograde ejaculation may be reversed by sympathomimetic agents contracting the bladder neck, including imipramine, ephedrine, pseudoephedrine, and phenylpropanolamine [452]. The use of a balloon catheter to obstruct the bladder neck may be effective in obtaining antegrade ejaculation [453]. If antegrade ejaculation is not achieved, the harvest of semen from the urine may be considered [454].

Prostatic massage is safe and easy to use for obtaining semen in men with lesions above Th 10 [455]. In several patients, vibrostimulation or transrectal electroejaculation are needed for sperm retrieval [452, 456, 457]. Semen retrieval is more likely with vibrostimulation in men with lesions above Th 10 [458-460]. In men with SCI, especially at or above Th 6, AD might occur during sexual activity and ejaculation [461, 462]; patients at risk and fertility clinics must be informed and aware of this potentially life-threatening condition. In SCI patients the use of oral midodrine can improve sperm retrieval at vibrostimulation [463].

In men with MS, use of disease modifying drugs during the conception phase, has not been associated with altered pregnancy outcomes [464]. Surgical procedures, such as, microsurgical epididymal sperm aspiration or testicular sperm extraction, may be used if vibrostimulation and electroejaculation are not successful [465, 466]. Pregnancy rates in patients with SCI are lower than in the general population, but since the introduction of intracytoplasmic sperm injection, men with SCI now have a good chance of becoming biological fathers [467-469].
3.6.2.1 Sperm quality and motility

The following has been reported on sperm quality and motility:

- bladder management with clean IC may improve semen quality compared to indwelling catheterisation, reflex voiding or bladder expression [470];
- in SCI patients sperm quality decreases at the early post traumatic phase demonstrating lower spermatozoid vitality (necrospermia), reduced motility (asthenospermia) and leucospermia [465];
- long-term valproate treatment for epilepsy negatively influences sperm count and motility [471];
- vibrostimulation produces samples with better sperm motility than electrostimulation [472, 473];
- electroejaculation with interrupted current produces better sperm motility than continuous current [474];
- freezing of sperm is unlikely to improve fertility rates in men with SCI [475].

3.6.3 Female sexuality

The most relevant publications on neurogenic female sexual dysfunction are in women with SCI and MS. After SCI, about 65-80% of women continue to be sexually active, but to a much lesser extent than before the injury, and about 25% report a decreased satisfaction with their sexual life [476-478]. Although sexual dysfunction is very common in women with MS, it is still often overlooked by medical professionals [479, 480]. A vast majority of female SB patients considered information about sexuality from their physicians insufficient [481]. Women with SCI reported dissatisfaction with the quality and quantity of sexuality-related rehabilitation services and were less likely to receive sexual information than men [482-484].

The greatest physical barrier to sexual activity is UI. A correlation has been found between the urodynamic outcomes of low bladder capacity, compliance and high maximum detrusor pressure and sexual dysfunction in MS patients. Problems with positioning and spasticity affect mainly tetraplegic patients. Peer support may help to optimise the sexual adjustment of women with SCI in achieving a more positive self-image, self-esteem and feelings of being attractive to themselves and others [476, 485-487].

The use of specific drugs for sexual dysfunction is indicated to treat inadequate lubrication. Data on sildenafil for treating female sexual dysfunction are poor and controversial [419]. Although good evidence exists that psychological interventions are effective in the treatment of female hypoactive sexual desire disorder and female orgasmic disorder [488], there is a lack of high-level evidence studies in the neurological population.

Neurophysiological studies have shown that women with the ability to perceive Th 11-L2 pin-prick sensations may have psychogenic genital vasocongestion. Reflex lubrication and orgasm are more prevalent in women with SCI who have preserved the sacral reflex arc (S2-S5), even when it has not been shown in an individual woman that a specific level and degree of lesion is the cause of a particular sexual dysfunction. In SCI women with a complete lesion of the sacral reflex, arousal and orgasm may be evoked through stimulation of other erogenous zones above the level of lesions [482, 489, 490].

Sacral neuromodulation for LUT dysfunction may improve sexual function but high-evidence studies are lacking [419].
3.6.4  **Female fertility**

There are few studies on female fertility in neurological patients. More than a third (38%) of women with epilepsy had infertility and the relevant predictors were exposure to multiple (three or more) antiepileptic drugs, older age and lower education [491].

Although it seems that the reproductive capacity of women with SCI is only temporarily affected by SCI with cessation of menstruation for approximately six months after SCI [492], there are no high-level evidence studies. About 70% of sexually active women use some form of contraception after injury, but fewer women use the birth control pill compared to before their injury [493].

Women with SCI are more likely to suffer complications during pregnancy, labour and delivery compared to able-bodied women. Complications of labour and delivery include bladder problems, spasticity, pressure sores, anaemia, and AD [494-498]. Obstetric outcomes include higher rates of Caesarean sections and an increased incidence of low birth-weight babies [493, 496-498].

Epidural anaesthesia is chosen and effective for most patients with AD during labour and delivery [499, 500].

There is very little published data on women’s experience of the menopause following SCI [501]. Women with MS who plan a pregnancy should evaluate their current drug treatment with their treating physician [502-504]. Clinical management should be individualised to optimise both the mother’s reproductive outcomes and MS course [502, 503, 505].

3.7  **Follow-up**

3.7.1  **Introduction**

Neuro-urological disorders are often unstable, and the symptoms may vary considerably, even within a relatively short period. Regular follow-up is therefore necessary to assess the UUT [128].

Depending on the type of the underlying neurological pathology and the current stability of the neuro-urological symptoms, the interval between initial investigations and control diagnostics may vary and, in many cases, should not exceed one to two years. In high-risk neuro-urological patients this interval should be much shorter. Urinalysis should be performed only when patients present with symptoms [506]. The UUT should be checked by ultrasonography at regular intervals in high-risk patients; about once every six months [6, 507]. In these patients, physical examination and urine laboratory should take place every year [6, 507]. In MS patients higher scores on the Expanded Disability Status Scale (EDSS) are associated with risk factors for UUT deterioration [508]. A urodynamic investigation should be performed as a diagnostic baseline, and repeated during follow-up, more frequently in high-risk patients [6, 507]. In addition, bladder wall thickness can be measured on ultrasonography as an additional risk assessment for upper tract damage [509], although a ‘safe’ cut-off threshold for this has not been agreed [510]. The utility of DMSA (dimercaptosuccinic acid) for follow-up of neuro-urological patients has not been fully evaluated [511]. Any significant clinical change warrants further, specialised, investigation [6, 507]. However, there is a lack of high level evidence studies on this topic and every recommendation must be viewed critically in each individual neuro-urological patient [128].

The increased prevalence of muscle invasive bladder cancer in neuro-urological patients also warrants long-term follow-up [512]. The exact frequency of cystoscopy with or without cytology remains unknown, but presence of risk factors similar to the general population should trigger further investigation [506].

Adolescent patients with neurological pathology are at risk of being lost to follow-up during the transition to
adulthood. It is important that a standardised approach during this transition is adopted to improve follow-up and specific treatment during adult life [513].

3.8 Conclusions

Neuro-urological disorders have a multi-faceted pathology. They require an extensive and specific diagnosis before one can embark on an individualised therapy, which takes into account the medical and physical condition of the patient and the patient’s expectations about their future. The urologist can select from a wealth of therapeutic options, each with its own pros and cons. Notwithstanding the success of any therapy embarked upon, close surveillance is necessary for the patient’s entire life.

These Guidelines offer you expert advice on how to define the patient’s neuro-urological symptoms as precisely as possible and how to select, together with the patient, the appropriate therapy. This last choice, as always, is governed by the golden rule: as effective as needed, as non-invasive as possible.

5.1 Definition and classification 46
5.2 Risk factors 46
5.3 Pathophysiology 47
  5.3.1 Pelvic surgery and prostate cancer treatment 49
  5.3.2 Summary of evidence on the epidemiology/aetiology/pathophysiology of ED 50
5.4 Diagnostic evaluation (basic work-up) 50
  5.4.1 Medical and sexual history 50
  5.4.2 Physical examination 51
  5.4.3 Laboratory testing 51
  5.4.4 Cardiovascular system and sexual activity: the patient at risk 52
    5.4.4.1 Low-risk category 54
    5.4.4.2 Intermediate- or indeterminate-risk category 54
    5.4.4.3 High-risk category 54
5.5 Diagnostic Evaluation (advanced work-up) 54
  5.5.1 Nocturnal penile tumescence and rigidity test 54
  5.5.2 Intracavernous injection test 54
  5.5.3 Dynamic duplex ultrasound of the penis 54
  5.5.4 Arteriography and dynamic infusion cavernosometry or cavernosography 54
  5.5.5 Psychopathological and psychosocial assessment 55
  5.5.6 Recommendations for diagnostic evaluation of ED 56
5.6 Treatment of erectile dysfunction 56
  5.6.1 Patient education - consultation and referrals 56
  5.6.2 Treatment options 56
    5.6.2.1 Oral pharmacotherapy 58
    5.6.2.2 Topical/Intraurethral alprostadil 63
    5.6.2.3 Shockwave therapy 63
    5.6.2.4 Psychosocial intervention and therapy 64
    5.6.2.5 Hormonal treatment 64
    5.6.2.6 Vacuum erection devices 64
    5.6.2.7 Intracavernous injections therapy 64
      5.6.2.7.1 Alprostadil 65
      5.6.2.7.2 Combination therapy 65
    5.6.2.8 Other treatments 66
      5.6.2.8.1 Platelet-Rich Plasma 66
      5.6.2.8.2 Herbal medicine and natural supplements 67
  5.6.2.9 Erectile dysfunction after radical prostatectomy 67
  5.6.2.10 Surgical management 68
    5.6.2.10.1 Surgery for post-traumatic arteriogenic ED 68
5.6.2.10.2 Venous ligation surgery 68
5.6.2.10.3 Penile prostheses 68
5.6.2.10.4 Penile prostheses implantation: complications 69
5.6.2.10.5 Conclusions about penile prostheses implantation 70
5.6.3 Recommendations for treatment of ED 70
5.6.4 Follow-up 71

6. DISORDERS OF EJACULATION 71
6.1 Introduction 71
6.2 Premature ejaculation 71
6.2.1 Epidemiology 71
6.2.2 Pathophysiology and risk factors 71
6.2.3 Impact of PE on quality of life 72
6.2.4 Classification 72
6.2.5 Diagnostic evaluation 73
6.2.5.1 Intravaginal ejaculatory latency time (IELT) 73
6.2.5.2 Premature ejaculation assessment questionnaires 73
6.2.5.3 Physical examination and investigations 74
6.2.5.4 Recommendations for the diagnostic evaluation of PE 74
6.2.6 Disease management 74
6.2.6.1 Psychological aspects and intervention 75
6.2.6.1.1 Recommendation for the assessment and treatment (psychosexual approach) of PE 76
6.2.6.2 Pharmacotherapy 76
6.2.6.2.1 Dapoxetine 76
6.2.6.2.2 Off-label use of antidepressants: selective serotonin reuptake inhibitors and clomipramine 77
6.2.6.2.3 Topical anaesthetic agents 78
6.2.6.2.3.1 Lidocaine/prilocaine cream 78
6.2.6.2.3.2 Lidocaine/prilocaine spray 78
6.2.6.2.4 Tramadol 78
6.2.6.2.5 Phosphodiesterase type 5 inhibitors 79
6.2.6.2.6 Other drugs 79
6.2.7 Summary of evidence on the epidemiology/aetiology/pathophysiology of PE 80
6.2.8 Recommendations for the treatment of PE 80
6.3 Delayed Ejaculation 80
6.3.1 Definition and classification 80
6.3.2 Pathophysiology and risk factors 80
6.3.3 Investigation and treatment 81
6.3.3.1 Psychological aspects and intervention 82
6.3.3.2 Pharmacotherapy 82
6.4 Anejaculation 82
6.4.1 Definition and classification 82
6.4.2 Pathophysiology and risk factors 82
6.4.3 Investigation and treatment 82
6.5 Painful Ejaculation 82
6.5.1 Definition and classification 82
6.5.2 Pathophysiology and risk factors 83
6.5.3 Investigation and treatment 83
6.5.3.1 Surgical intervention 83
6.6 Retrograde ejaculation 83
6.6.1 Definition and classification 83
6.6.2 Pathophysiology and risk factors 83
6.6.3 Disease management 84
6.6.3.1 Pharmacological 84
6.6.3.2 Management of infertility 84
6.7 Anorgasmia 85
6.7.1 Definition and classification 85
6.7.2 Pathophysiology and risk factors 85
6.7.3 Disease management 85
6.7.3.1 Psychological/behavioural strategies  85  
6.7.3.2 Pharmacotherapy  85  
6.7.3.3 Management of infertility  85  
6.8  Haemospermia  85  
6.8.1 Definition and classification  85  
6.8.2 Pathophysiology and risk factors  85  
6.8.3 Investigations  86  
6.8.4 Disease management  87  
6.9 Recommendations for the management of recurrent haemospermia  88  

7.  LOW SEXUAL DESIRE AND MALE HYPOACTIVE SEXUAL DESIRE DISORDER  89  
7.1 Definition, classification and epidemiology  89  
7.2 Pathophysiology and risk factors  89  
7.2.1 Psychological aspects  89  
7.2.2 Biological aspects  89  
7.2.3 Risk factors  90  
7.3 Diagnostic work-up  90  
7.3.1 Assessment questionnaires  90  
7.4 Disease management  90  
7.4.1 Psychological intervention  90  
7.4.2 Pharmacotherapy  91  
7.5 Recommendations for the treatment of low sexual desire  91  

8.  PENILE CURVATURE  92  
8.1 Congenital penile curvature  92  
8.1.1 Epidemiology/aetiology/pathophysiology  92  
8.1.2 Disease management  92  
8.1.3 Summary of evidence for congenital penile curvature  92  
8.1.4 Recommendation for the treatment congenital penile curvature  92  
8.2 Peyronie's Disease  92  
8.2.1 Epidemiology/aetiology/pathophysiology  92  
8.2.1.1 Epidemiology  92  
8.2.1.2 Aetiology  92  
8.2.1.3 Risk factors  94  
8.2.1.4 Pathophysiology  94  
8.2.1.5 Summary of evidence on epidemiology/aetiology/pathophysiology of Peyronie's disease  95  
8.2.2 Diagnostic evaluation  95  
8.2.2.1 Summary of evidence for diagnosis of Peyronie's disease  96  
8.2.2.2 Recommendations for diagnosis of Peyronie's disease  96  
8.2.3 Disease management  96  
8.2.3.1 Conservative treatment  96  
8.2.3.1.1 Oral treatment  97  
8.2.3.1.2 Intral Lexusional treatment  97  
8.2.3.1.3 topical treatments  100  
8.2.3.1.4 Multimodal treatment  102  
8.2.3.1.5 Summary of evidence for conservative treatment of Peyronie's disease  103  
8.2.3.1.6 Recommendations for non-operative treatment of Peyronie's disease  103  
8.2.3.2 Surgical treatment  104  
8.2.3.2.1 Tunical shortening procedures  104  
8.2.3.2.2 Tunical lengthening procedures  105  
8.2.3.2.3 Penile prosthesis  107  
8.2.3.2.4 Summary of evidence for surgical treatment of Peyronie's disease  108  
8.2.3.2.5 Recommendations for surgical treatment of penile curvature  108  
8.2.3.3 Treatment algorithm  109
9. PRIAPISM

9.1 Ischaemic (Low-Flow or Veno-Occlusive) Priapism

9.1.1 Epidemiology, aetiology, pathophysiology and Diagnosis

9.1.1.1 Summary of evidence on the epidemiology, aetiology and pathophysiology of ischaemic priapism

9.1.2 Diagnostic evaluation

9.1.2.1 History

9.1.2.2 Physical examination

9.1.2.3 Laboratory testing

9.1.2.4 Penile imaging

9.1.2.5 Recommendations for the diagnosis of ischaemic priapism

9.1.3 Disease management

9.1.3.1 Medical Management

9.1.3.1.1 First-line treatments

9.1.3.1.2 Penile anaesthesia/analgesia

9.1.3.1.3 Aspiration ± irrigation with 0.9% w/v saline solution

9.1.3.1.4 Aspiration ± irrigation with 0.9% w/v saline solution in combination with intracavernous injection of pharmacological agents.

9.1.3.2 Surgical management

9.1.3.2.1 Second-line treatments

9.1.3.2.1.1 Penile shunt surgery

9.1.4 Summary of evidence for treatment of ischaemic priapism

9.1.5 Recommendations for the treatment of ischaemic priapism

9.2 Priapism in Special Situations

9.2.1 Stuttering (recurrent or intermittent) priapism

9.2.1.1 Epidemiology/aetiology/pathophysiology

9.2.1.1.1 Summary of evidence on the epidemiology, aetiology and pathophysiology of stuttering priapism

9.2.1.2 Classification

9.2.1.3 Diagnostic evaluation

9.2.1.3.1 History

9.2.1.3.2 Physical examination

9.2.1.3.3 Laboratory testing

9.2.1.3.4 Penile imaging

9.2.1.3.5 Recommendations for diagnosis of stuttering priapism

9.2.1.4 Disease management

9.2.1.4.1 \(\alpha\)-Adrenergic agonists

9.2.1.4.2 Hormonal manipulations of circulating testosterone

9.2.1.4.3 Digoxin

9.2.1.4.4 Terbutaline

9.2.1.4.5 Gabapentin

9.2.1.4.6 Baclofen

9.2.1.4.7 Hydroxyurea

9.2.1.4.8 Phosphodiesterase type 5 inhibitors

9.2.1.4.9 Intracavernosal injections

9.2.1.4.10 Penile prosthesis

9.2.1.5 Summary of evidence for treatment of stuttering priapism

9.2.1.6 Recommendations for treatment of stuttering priapism

9.2.1.7 Follow-up

9.2.2 Priapism in children

9.3 Non-ischaemic (high-flow or arterial) priapism

9.3.1 Epidemiology/aetiology/pathophysiology

9.3.1.1 Summary of evidence on the epidemiology, aetiology and pathophysiology of arterial priapism

9.3.2 Classification

9.3.3 Diagnostic evaluation

9.3.3.1 History

9.3.3.2 Physical examination

9.3.3.3 Laboratory testing
9.3.3.4 Penile imaging 130
9.3.3.5 Recommendations for the diagnosis of non-ischaemic priapism 130
9.3.4 Disease management 131
9.3.4.1 Conservative management 131
9.3.4.2 Selective arterial embolisation 131
9.3.4.3 Surgical management 131
9.3.4.4 Summary of evidence for the treatment of arterial priapism 131
9.3.4.5 Recommendations for the treatment of arterial priapism 132
9.3.4.6 High-flow priapism in children 132
9.3.4.7 Follow-up 132
9.4 Controversies and future areas of focus in the management of priapism 132

10. MALE INFERTILITY 133
10.1 Definition and classification 133
10.2 Epidemiology/aetiology/pathophysiology/risk factors 133
10.2.1 Introduction 133
10.2.2 Recommendations on epidemiology and aetiology 134
10.3 Diagnostic work-up 134
10.3.1 Medical/reproductive history and physical examination 134
10.3.1.1 Medical and reproductive history 134
10.3.1.2 Physical examination 135
10.3.2 Semen analysis 135
10.3.3 Measurement of sperm DNA Fragmentation Index (DFI) 137
10.3.4 Hormonal determinations 138
10.3.5 Genetic testing 138
10.3.5.1 Chromosomal abnormalities 138
10.3.5.1.1 Sex chromosome abnormalities (Klinefelter syndrome and variants [47,XXY; 46,XY/47, XX mosaicism]) 139
10.3.5.1.2 Autosomal abnormalities 139
10.3.5.2 Cystic fibrosis gene mutations 140
10.3.5.2.1 Unilateral or bilateral absence/abnormality of the vas and renal anomalies 140
10.3.5.3 Y microdeletions – partial and complete 140
10.3.5.3.1 Clinical implications of Y microdeletions 140
10.3.5.3.1.1 Testing for Y microdeletions 141
10.3.5.3.1.2 Genetic counselling for AZF deletions 141
10.3.5.3.1.3 Y-chromosome: ‘gr/gr’ deletion 141
10.3.5.3.1.4 Autosomal defects with severe phenotypic abnormalities and infertility 142
10.3.5.4 Sperm chromosomal abnormalities 142
10.3.5.5 Measurement of Oxidative Stress 142
10.3.5.6 Outcomes from assisted reproductive technology and long-term health implications to the male and offspring 142
10.3.6 Imaging in infertile men 142
10.3.6.1 Scrotal US 143
10.3.6.1.1 Testicular neoplasms 143
10.3.6.1.2 Varicocele 144
10.3.6.1.3 Other 144
10.3.6.2 Transrectal US 144
10.3.7 Recommendations for the diagnostic work-up of male infertility 144

10.4 Special Conditions and Relevant Clinical Entities 145
10.4.1 Cryptorchidism 145
10.4.1.1 Classification 145
10.4.1.1.1 Aetiology and pathophysiology 145
10.4.1.1.2 Pathophysiological effects in maldescended testes 146
10.4.1.1.2.1 Degeneration of germ cells 146
10.4.1.1.2.2 Relationship with fertility 146
10.4.1.1.2.3 Germ cell tumours 146
10.4.1.2 Disease management 146
10.4.1.2.1 Hormonal treatment 146
10.4.1.2.2 Surgical treatment 146
10.4.1.3 Summary of evidence recommendations for cryptorchidism 147
10.4.2 Germ cell malignancy and male infertility 147
10.4.2.1 Testicular germ cell cancer and reproductive function 147
10.4.2.2 Testicular microcalcification (TM) 148
10.4.2.3 Recommendations for germ cell malignancy and testicular microcalcification 149
10.4.3 Varicocele 150
10.4.3.1 Classification 150
10.4.3.2 Diagnostic evaluation 150
10.4.3.3 Basic considerations 150
10.4.3.3.1 Varicocele and fertility 150
10.4.3.3.2 Varicocelectomy 150
10.4.3.3.3 Prophylactic varicocelectomy 151
10.4.3.3.4 Varicocelectomy for assisted reproductive technology and raised DNA fragmentation 151
10.4.3.4 Disease management 152
10.4.3.5 Summary of evidence and recommendations for varicocele 153
10.4.4 Male accessory gland infections and infertility 153
10.4.4.1 Introduction 153
10.4.4.2 Diagnostic evaluation 154
10.4.4.2.1 Semen analysis 154
10.4.4.2.2 Microbiological findings 154
10.4.4.2.3 White blood cells 154
10.4.4.2.4 Sperm quality 154
10.4.4.2.5 Seminal plasma alterations 154
10.4.4.2.6 Glandular secretory dysfunction 155
10.4.4.2.7 Disease management 155
10.4.4.3 Epididymitis 155
10.4.4.3.1 Diagnostic evaluation 155
10.4.4.3.1.1 Ejaculate analysis 155
10.4.4.3.1.2 Disease management 155
10.4.4.4 Summary of evidence and recommendations for male accessory gland infections 156
10.5 Non-Invasive Male Infertility Management 156
10.5.1 Idiopathic male infertility and oligo-astheno-terato-zoospermia 156
10.5.2 Empirical treatments 156
10.5.2.1 Life-style 156
10.5.2.1.1 Weight loss 156
10.5.2.1.2 Physical activity 156
10.5.2.1.3 Smoking 156
10.5.2.1.4 Alcohol consumption 156
10.5.2.2 Antioxidant treatment 157
10.5.2.3 Selective oestrogen receptor modulators 157
10.5.2.4 Aromatase inhibitors 157
10.5.3 Hormonal therapy 158
10.5.3.1 Gonadotrophins 158
10.5.3.2 Secondary hypogonadism 158
10.5.3.2.1 Pre-Pubertal-Onset 158
10.5.3.2.2 Post-Pubertal Onset Secondary 158
10.5.3.3 Primary Hypogonadism 159
10.5.3.4 Idiopathic Male Factor Infertility 159
10.5.3.5 Anabolic Steroid Abuse 159
10.5.3.6 Recommendations for treatment of male infertility with hormonal therapy 159
10.6 Invasive Male Infertility Management 160
10.6.1 Obstructive azoospermia 160
10.6.1.1 Classification of obstructive azoospermia 160
10.6.1.1.1 Intratesticular obstruction 160

1. INTRODUCTION

1.1 Aims and Objectives
The European Association of Urology (EAU) Sexual and Reproductive Health Guidelines aim to provide a comprehensive overview of the medical aspects relating to sexual and reproductive health in adult men. These Guidelines cover the former EAU Guidelines on Male Sexual Dysfunction, Male Infertility and Male Hypogonadism.

It must be emphasised that guidelines present the best evidence available to the experts. However following guideline recommendations will not necessarily result in the best outcome. Guidelines can never replace clinical expertise when making treatment decisions for individual patients, but rather help to focus decisions - while taking personal values and preferences/individual circumstances of patients into account. Guidelines are not mandates and do not purport to be a legal standard of care.

1.2 Panel Composition
The EAU Sexual and Reproductive Health Guidelines Panel consists of an international multi-disciplinary group of urologists, endocrinologists and a psychologist. All experts involved in the production of this document have submitted potential conflict of interest statements which can be viewed on the EAU website: http://www.uroweb.org/guideline/sexualandreproductivehealth/.

1.3 Available Publications
Alongside the full text version, a quick reference document (Pocket Guidelines) is available in print and as an app for iOS and android devices. These are abridged versions that may require consultation together with the full text version. All documents can be viewed through the EAU website: http://www.uroweb.org/guideline/sexualandreproductivehealth/.

1.4 Publication History
This document is a further update of the 2021 Guidelines which already included a comprehensive update of the 2018 versions of Male Sexual Dysfunction, Male Infertility and Male Hypogonadism guidelines, along with several new topics. Additional sections will be added in the coming years to address male contraception, vasectomy, and penile cosmetic surgery, which have not previously been addressed.

1.5 Changes in the Guideline for 2022
The literature for the complete document has been assessed and updated, wherever relevant. Key changes in the 2022 publication:

- Section 3.4 - Classification and causes of male hypogonadism: update on effects of coronavirus 2 (SARS-CoV-2) infection (COVID-19);
- Section 5.6.2.8.1 – Treatment of Erectile Dysfunction - Platelet Rich Plasma: addition to the text and a new recommendation;
- Section 6.2.6.2.4 - Treatment of Premature Ejaculation – Tramadol: amendment to the text and amended recommendation;
- Section 8.2.3.1 - Conservative Treatment of Penile Curvature - Platelet Rich Plasma (PRP): addition to the text and new recommendation;
- Section 10.3 – Diagnostic Evaluation of Male Infertility: the text has been amended in light of the 6th edition of the WHO Manual for the Examination and Processing of Human Semen;
- Section 10.6.2 Male Infertility - Non-obstructive azoospermia: text and recommendation amended for indications and techniques of sperm retrieval relating to conventional and microdissection TESE.

2. METHODOLOGY

2.1 Methods
For the 2022 Sexual and Reproductive Health Guidelines, further new evidence has been identified, collated and appraised through a structured assessment of the literature.

For each recommendation within the Guidelines there is an accompanying online strength rating form; the basis of which is a modified Grading of Recommendations Assessment, Development and Evaluation (GRADE) methodology [1, 2]. Each strength rating form addresses several key elements namely:

1. the overall quality of the evidence which exists for the recommendation, references used in this text are graded according to a classification system modified from the Oxford Centre for Evidence-Based Medicine Levels of Evidence [3];
2. the magnitude of the effect (individual or combined effects);
3. the certainty of the results (precision, consistency, heterogeneity and other statistical or study-related factors);
4. the balance between desirable and undesirable outcomes;
5. the impact of patient values and preferences on the intervention;
6. the certainty of those patient values and preferences.

These key elements are the basis that panels use to define the strength rating of each recommendation. The strength of each recommendation is represented by the term ‘strong’ or ‘weak’ [4]. The strength of each recommendation is determined by the balance between desirable and undesirable consequences of alternative management strategies, the quality of the evidence (including certainty of estimates), and nature and variability of patient values and preferences. Additional information can be found in the general Methodology section of this print, and online at the European Association of Urology (EAU) website: http://www.uroweb.org/guideline/.

A list of associations endorsing the EAU Guidelines can also be viewed online at this address.

2.2 Review
The existing sections of the Sexual and Reproductive Health Guidelines were peer reviewed prior to publication in 2020. The new section for priapism was reviewed prior to publication in 2021.

2.3 Future goals
The results of ongoing and new systematic reviews will be included in the 2023 update of the Sexual and Reproductive Health Guidelines. Systematic reviews planned for 2022 are:
• Penile augmentation surgery;
• Vasectomy and male contraception;
• Penile prosthesis implantation peri-operative complications;
• Importance of psychology/psychosexology in the field of urology;
• Sexual function outcomes in men undergoing interventions for prostate cancer.

3. MALE HYPOGONADISM

3.1 Epidemiology and prevalence of male hypogonadism
Male hypogonadism is associated with decreased testicular function, with decreased production of androgens and/or impaired sperm production [5]. This is caused by poor testicular function or as a result of inadequate stimulation of the testes by the hypothalamic-pituitary axis. Several congenital or acquired disorders causing impaired action of androgens are also described [5]. Hypogonadism may adversely affect multiple organ functions and quality of life (QoL) [6]. Late-onset hypogonadism (LOH) is a clinical condition in ageing men, which, by definition, must comprise both persistent specific symptoms and biochemical evidence of testosterone deficiency [5, 7]. Late-onset hypogonadism is frequently diagnosed in the absence of an identifiable classical cause of hypogonadism, which becomes more prevalent with age, usually occurring, but not exclusively, in men aged > 40 years.

Male hypogonadism has also been called Testosterone Deficiency. The Panel has agreed to use the term Male Hypogonadism, which may better reflect and explain the underlying pathophysiology. Likewise, the Panel has further agreed to continue with the term testosterone therapy. The present Guidelines specifically address the management of adult male hypogonadism also called LOH. Some insights related to congenital or pre-pubertal hypogonadism are also provided and summarised.

The prevalence of hypogonadism increases with age and the major causes are central obesity, other co-morbidities (e.g., diabetes) and overall poor health [8]. In healthy ageing men, there is only a small gradual decline in testosterone; up to the age of 80 years, aging accounts for a low percentage of hypogonadism [8]. In men aged 40-79 years, the incidence of symptomatic hypogonadism varies between 2.1-5.7% [9-11]. The incidence of hypogonadism has been reported to be 12.3 and 11.7 cases per 1,000 people per year [9, 12].

There is a high prevalence of hypogonadism within specific populations, including patients with type 2 diabetes (T2DM), metabolic syndrome (MetS), obesity, cardiovascular disease (CVD), chronic obstructive pulmonary disease, renal disease and cancer [11]. Low testosterone levels are common in men with T2DM [13] and a high prevalence of hypogonadism (42%) has been reported in T2DM patients [14].

Klinefelter syndrome, a trisomy associated with a 47,XXY karyotype, is the most prevalent genetic cause of primary hypogonadism (hypergonadotropic hypogonadism), with a global prevalence of 1/500-1,000 live male births [15-17]. However, < 50% of individuals with Klinefelter syndrome are diagnosed in their lifetime [18].
3.1.1 Body Composition and Metabolic Profile

Low testosterone levels are common in men with obesity. Male hypogonadism is associated with a greater percentage of fat mass and a lesser lean mass compared to men with adequate testosterone levels [19]. There is much evidence that a low testosterone level is strongly associated with increased visceral adiposity, but it also leads to lipid deposition in the liver and muscle and is associated with atherosclerosis [19]. In vitro studies have suggested that hypogonadism impairs glucose and triglyceride uptake into subcutaneous fat depots [19]. This enhances the uptake of glucose and triglycerides into ectopic fat depots.

Testosterone therapy has been associated with a reduced percentage of body fat and increase of lean body mass [20]. Data from a registry study have suggested that over a period of 11 years, testosterone therapy with long-acting intramuscular testosterone undecanoate was associated with a substantial but gradual loss of weight, along with a reduction in waist circumference [21]. Testosterone also reduces liver fat content and muscle fat storage [19].

3.1.2 Metabolic Syndrome/Type 2 Diabetes

Metabolic Syndrome (MetS) is characterised by several specific components, including increased waist circumference, dyslipidaemia, hypertension, and impaired glucose tolerance. Hypogonadism is associated with central obesity, hyperglycaemia, insulin resistance and dyslipidaemia [low high-density lipoprotein (HDL) cholesterol, raised total and low-density lipoprotein (LDL) cholesterol and triglycerides], hypertension and predisposition to T2DM, which are all components of MetS [22].

Several randomised controlled trials (RCTs) have shown that testosterone therapy might improve insulin resistance and hyperglycaemia and lower cholesterol and LDL-cholesterol [23-27]. Testosterone therapy in hypogonadal T2DM improved glycaemic control in some RCTs and registry trials; however, there is no conclusive evidence from RCTs and meta-analyses [24, 28, 29]. A recent large placebo-controlled RCT, including 1,007 patients with impaired glucose tolerance or newly-diagnosed T2DM and total testosterone < 14 nmol/L, showed that testosterone therapy for 2 years reduced the proportion of patients with T2DM regardless of a lifestyle programme [30]. Similarly, a previously published registry study reported that testosterone therapy was associated in time with remission of T2DM [28]. HDL-cholesterol may decrease, remain unchanged or increase with testosterone therapy. Testosterone therapy in men with MetS and low testosterone has been shown to reduce mortality compared to that in untreated men [31, 32], although no conclusive evidence is available.

Erectile dysfunction (ED) is common in men with MetS and T2DM (up to 70% of patients). The causes of ED are multi-factorial and 30% of men with ED have co-existing testosterone-deficiency hypogonadism. Some evidence has suggested that for patients with T2DM this is only found in men with clearly reduced testosterone levels (< 8 nmol/L or 2.31 ng/mL) [33]. From a pathophysiological point of view, it has been reported that this is because ED is predominantly caused by vascular and neuropathic disease, and therefore not likely in men who do not have established vascular disease. Therefore, men presenting with ED should be screened for MetS. Likewise, patients with ED and diabetes may be offered testosterone measurement.

Placebo-controlled RCTs of testosterone therapy in T2DM have demonstrated improved sexual desire and satisfaction, but not erectile function [24, 33]. The presence of multiple comorbidity in this group of patients may confound the response to testosterone therapy alone. In a long-term registry study in men with T2DM, parenteral testosterone undecanoate therapy led to one third of patients entering remission from diabetes during 11 years’ follow-up [34]. A large 2-year RCT of testosterone undecanoate vs. placebo showed that testosterone therapy significantly decreased progression of 999 men with low testosterone (< 14 nmol/L) from pre-diabetes to overt T2DM [30].

3.2 Physiology of testosterone production

The pituitary gland regulates testicular activity through secretion of luteinising hormone (LH), which regulates testosterone production in Leydig cells and follicle-stimulating hormone (FSH), which mainly controls sperm production in seminiferous tubules [35, 36]. The production and secretion of gonadotropins is stimulated by hypothalamic gonadotropin releasing hormone (GnRH) and inhibited by negative feedback mediated by the central action of sex steroids and inhibin B (Figure 1) [35, 36]. Gonadotropin releasing hormone is secreted in a pulsatile manner and negatively controlled by the activity of hypothalamic neurons, including corticotropin-releasing hormone (CRH) and β endorphin neurons [35, 36]. Conversely, kisspeptin-1 (Kiss-1) neurons, neurokinin-B and tachykinin-3 are involved in GnRH stimulation. Leptin is involved in activation of Kiss-1 signalling [37]. About 25 mg of testosterone is present in the normal testes, and, on average, 5-10 mg of testosterone are secreted daily [35, 36]. The testes also produce lesser amounts of other androgens, such as androstenedione and dihydrotestosterone (DHT). A small amount of extra-gonadal testosterone is derived from
circulating weak adrenal androgen precursor dehydroepiandrosterone (DHEA), although its specific contribution to daily testosterone production is limited in men [38, 39]. In physiological terms, DHT formation accounts for 6-8% of testosterone metabolism, and the ratio of plasma testosterone/DHT is approximately 1:20 [35, 36]. Finally, testosterone and its precursor, Δ4 androstenedione, can be aromatised through P450 aromatase to other bioactive metabolites, such as oestrone (E1) and 17-β-oestradiol (E2), with a daily production of ~45 μg [35, 36]. Leydig cells, can also directly produce and release into the bloodstream small amounts of oestrogens, with a daily production rate of 5-10 μg (up to 20% of circulating oestrogens) [40].

Figure 1: Physiology of testosterone production

GnRH = gonadotropin releasing hormone; LH = luteinising hormone; FSH = follicle-stimulating hormone; T = testosterone; E2 = 17-β-estradiol; DHT = dehydroepiandrosterone; CRH = corticotrophin releasing hormone.

3.2.1 Circulation and transport of testosterone

In healthy men, 60-70% of circulating testosterone is bound to the high-affinity sex-hormone-binding globulin (SHBG), a protein produced by the liver, which prevents its bound testosterone sub-fraction from biological action. The remaining circulating testosterone binds to lower affinity, high-capacity binding proteins, (albumin, α-1 acid glycoprotein and corticosteroid-binding protein), and only 1-2% of testosterone remains non-protein bound [41]. There is a general agreement that testosterone bound to lower-affinity proteins can easily dissociate in the capillary bed of many organs, accounting for so-called ‘bioavailable’ testosterone [41]. It is important to recognise that several clinical conditions and ageing itself can modify SHBG levels, thus altering circulating total testosterone levels (Table 1). Therefore, if not recognised, these factors could lead to an incorrect estimation of male androgen status. Therefore, when indicated (Table 1), SHBG should be tested and free testosterone calculated.

3.2.2 Androgen receptor
Testosterone and DHT exert their biological action through activation of a specific nuclear receptor. The androgen receptor (AR) gene is localised on the X chromosome (Xq11–12), encoded in eight exons [43]. Exon 1 includes two polymorphic trinucleotide repeat segments encoding polyglutamine (CAG) and polyglycine (GGN) tracts in the N-terminal transactivation domain of its protein. Activity of the AR is inversely associated with the length of the CAG repeat chains [43]. However, the specific role of AR CAG repeat number in relation to hypogonadal symptoms or to clinical management of testosterone deficiency remains unclear [44, 45]. A RCT has shown that a higher CAG repeat number is positively associated with a change in fasting insulin, triglyceride and diastolic blood pressure, demonstrating the more sensitive the receptor, the greater the benefit [46].

3.3 Role of testosterone in male sexual and reproductive health
3.3.1 Sexual development and maturation
Testosterone production in the foetal testis starts between the eighth and ninth week of gestation after the expression of the SRY gene, which regulates organisation of the undifferentiated gonadal ridge into the testis [47]. During the first trimester, the testes drive the virilisation of internal and external genitalia through placental human chorionic gonadotropin (hCG)-stimulated androgen secretion by Leydig cells. During foetal life, testosterone mainly controls the differentiation of internal genitalia and testicular descent (regression of gubernaculum testis), whereas DHT is mainly involved in the development of the external male genitalia [48]. During puberty, reactivation of the hypothalamus–pituitary-gonadal (HPG) axis allows the development of secondary sexual characteristics, spermatogenesis maturation and, along with the contribution of other hormonal axes, completion of the adolescent growth spurt [5, 49]. Clinical models of aromatase deficiency and oestrogen receptor insensitivity have demonstrated that testosterone conversion to oestradiol is essential for epiphyseal closure and growth arrest [50].

3.3.2 Sexual function
Testosterone is involved in the regulation of all steps of the male sexual response. Sexual thoughts and motivations are universally accepted as the most testosterone-dependent aspects of male sexual behaviour [20]. The European Male Aging Study (EMAS), a population-based survey including 3,369 subjects aged 40-79 years from eight European countries, showed that sexual symptoms, particularly impairment of sexual desire, ED and decreased frequency of morning erections, were the most specific symptoms associated with age-dependent decline of testosterone [10]. Similar findings were reported in patients consulting for sexual dysfunctions [51]. Accordingly, several brain areas, including the amygdala, medial preoptic area, paraventricular nucleus of the hypothalamus, and peri-aqueductal grey matter express androgen receptors [51, 52]. Experimental and clinical studies have both documented that testosterone plays a crucial role in regulating penile function. In particular, testosterone controls the structural integrity necessary for penile erection, as well as several enzymatic activities within the corpus cavernosum, including a positive action on nitric oxide (NO) formation and a negative influence on the activity of the Ras homolog gene family member A/Rho-associated kinase (RhoA/ROCK) pathways [51, 53]. Testosterone is also involved in penile adrenergic response and cavernous smooth muscle cell turnover [51, 53]. Although some authors have suggested a positive role for testosterone in regulating penile phosphodiesterase 5 (PDE5) expression and activity, others have shown an inhibitory role of oestrogens on this pathway [51, 54].
3.4 Classification and causes of male hypogonadism
Male hypogonadism can be classified according to the origin of the underlying problem into primary, if due to a consequence of testicular dysfunction, or secondary, if due to a pituitary or hypothalamic dysfunction (Table 2).

Primary hypogonadism is also called hypergonadotropic hypogonadism, since the pituitary tries to compensate for testicular dysfunction by increasing central stimulation. Conversely, in secondary hypogonadism the testes are inadequately stimulated by gonadotropins, usually with inappropriately normal or reduced gonadotropin levels [5, 36]. A compensated or subclinical form of hypogonadism, characterised by normal testosterone serum levels and elevated LH production, has also been reported [56]; the clinical significance of the latter condition is unclear [56-58]. Finally, hypogonadism can also result from several conditions leading to reduced sensitivity/insensitivity to testosterone and its metabolites [5, 36] (Table 2). This classification, based on the aetiology of hypogonadism, allows clinicians to adequately select appropriate treatment. In patients with secondary hypogonadism, both fertility and testosterone normalisation can be theoretically achieved with adequate treatment whereas in primary hypogonadism only testosterone therapy can be considered, which impairs fertility due to suppression of the HGP axis [5, 36] (Table 2). However, it should also be recognised that symptoms and signs of hypogonadism can be similarly independent of the site of origin of the disease. Conversely, the age of onset of hypogonadism can influence the clinical phenotype [37]. Accordingly, when the problem starts early, such as during foetal life, clinical phenotype can span from an almost complete female phenotype (e.g., complete androgen insensitivity or enzymatic defects blocking androgen synthesis) to various defects in virilisation. In the case of a pre- or peri-pubertal appearance of hypogonadism due to a milder central (isolated hypergonadotropic hypogonadism [IHH]) or a peripheral defect (such as in Klinefelter’s syndrome), there might be delayed puberty with an overall eunochoid phenotype. Finally, when hypogonadism develops after puberty and especially with ageing (i.e., LOH; see below), symptoms can be mild, and often confused with the ageing process per se [5, 37].

In 2017, Grossmann and Matsumoto suggested a new classification of adult male hypogonadism, distinguishing functional versus organic hypogonadism [59]. Accordingly, organic hypogonadism is characterised by any proven pathology affecting the HPG axis and should be treated with conventional medication (i.e., gonadotropins or testosterone therapy). Conversely, functional hypogonadism is based on the absence of any recognised organic alterations in the HPG axis and should be treated first by resolving or improving the associated comorbidity. These Guidelines refer to the validated international classification of adult male hypogonadism.

A growing body of evidence has documented that although men and women show similar prevalence of severe acute respiratory syndrome coronavirus 2 (SARS-CoV-2) infection (COVID-19), men usually present with worse outcomes when compared to females [60]. The possible mechanisms underlying this sex disparity are not completely understood. The demonstration that testosterone can modulate the tissue expression of angiotensin-converting enzyme 2 (ACE2) and the transcription of a transmembrane protease, serine 2 (TMPRSS2), both involved over the process of virus-cellular internalisation, suggests the possibility that androgens play a role in explaining the aforementioned sex differences [61, 62]. Interestingly, emerging data seem to suggest that low rather than elevated circulating testosterone levels are more frequently associated with worse clinical outcomes in men with COVID-19 [63-70]. This is not surprising since ACE2 is expressed in several tissues including the testis and the ACE2 receptor has been demonstrated to be present on seminiferous duct cells, as well as on spermatogonia and on Leydig and Sertoli cells, with SARS-CoV-2 potentially contributing to impaired testosterone and sperm production [71, 72]. Furthermore, it has also been suggested that the virus can result in a local intense inflammatory reaction in the testis supporting the development of a viral orchitis, eventually evolving into a vasculitis or to an autoimmune response which can contribute to testis damage and impaired testosterone production [71, 72].

Whether or not low testosterone can directly contribute to worse COVID-19 outcomes is still the objective of an intense debate. Accordingly, the possibility that low testosterone in the acute phase of the virus infection can represent as an adaptive and resilient mechanism to mitigate an external insult by turning off testosterone-dependent functions, including reproduction and/or physical and sexual activity, which are not required when the physical condition is worsening, cannot be excluded [73, 74]. Similar considerations have been proposed for late onset hypogonadism [75]. Accordingly, studies evaluating subjects in the recovery phase of COVID-19 have documented either restored [76] or persistently low testosterone levels in the majority of cases [77]. In addition, no information on the role of testosterone therapy in the acute phase of the disease is available yet. Nevertheless, male subjects recovered from SARS-CoV2 infection should be accurately followed-up to exclude any long-term andrological consequences including impairment in sperm and testosterone production.

* Conditions acting and central and peripheral levels resulting in either primary and secondary hypogonadism.

1. Different autosomal translocations can cause rare cases of hypogonadism and infertility.

### 3.5 Late-onset hypogonadism

Testosterone production declines with ageing. The EMAS study reported a 0.4% per annum (log hormone-age) decrease in total testosterone and a 1.3% per annum decline in free testosterone (fT) [8]. Late onset hypogonadism is the term frequently used to describe this phenomenon and the detection of hypogonadism in adulthood, in particular. Evidence has documented that several associated diseases and chronic co-morbidity can interfere with the HPG axis leading to development of primary hypogonadism or, more frequently, secondary hypogonadism in adulthood, thus significantly influencing the physiological age-dependent decline of testosterone. By combining the data from three different waves of the Massachusetts Male Aging Study (MMAS), a population-based, observational study including 1,709 men aged 40–70 years showed that associated comorbidity and obesity significantly decreased, whereas smoking tended to increase total, free and bio-available testosterone concentrations [78]. Similarly, data derived from the EMAS study confirm these findings [8, 57]. Based upon these data and other evidence, the concept of functional and organic hypogonadism has been recently introduced [59]. The diagnosis of functional hypogonadism is based on the exclusion of a classical (organic) aetiology. The main causes of functional hypogonadism are obesity, co-morbidity and ageing with the first two accounting for most cases. Inflammatory cytokines released in chronic inflammation, adipocytokines and oestradiol in obesity, can suppress the HPG axis. The role of ageing up to age 80 years seems relatively small [59]. Considering that suppression of HPG axis activity is functional, and potentially reversible by empiric measures, such as weight loss, the need for testosterone therapy has been questioned [59].

#### 3.5.1 Diagnostic evaluation

The phenotype of the hypogonadal patient appears independent of the aetiology causing the problem, but is more often affected by the age of onset of hypogonadism. When androgen deficiency is complete and develops during foetal life, symptoms can be dramatic, spanning from an almost complete female phenotype (complete androgen insensitivity or enzymatic defects blocking androgen synthesis) to various defects in virilisation and ambiguous genitalia (micropenis, hypospadias and cryptorchidism) [5, 36]. Delay in puberty with an overall eunochoidal phenotype (scant body hair, high-pitched voice and small testes, penis and prostate) is typical of defects manifesting over the pre- or peri-pubertal period due to milder central (isolated HH) or peripheral defects (such as in Klinefelter syndrome) [5, 36]. When hypogonadism occurs in adulthood, especially functional hypogonadism, symptoms can often be mild, difficult to recognise and frequently confused with the ageing process [5, 36] or with chronic comorbidity. Several non-specific clinical features, such as fatigue, weakness, and decreased energy, as well as sexual impairment may be clinical manifestations.

The EMAS study showed that a triad of sexual symptoms, including low libido, reduced spontaneous erections...
and ED, are typically associated with a decrease in serum testosterone levels [10]. Conversely, psychological and physical symptoms were less informative [10].

The mainstay of LOH diagnosis includes signs and symptoms consistent with hypogonadism, coupled with biochemical evidence of low morning serum total testosterone levels on two or more occasions, measured with a reliable assay. Testosterone levels show a circadian variation, which persist in ageing men [79, 80]. Likewise, testosterone levels are potentially influenced by food intake [81]; hence, serum total testosterone should be measured in fasting conditions and in the morning (between 07.00 and 11.00 hours). A confirmatory measurement should always be undertaken in the case of a primary pathological value, and certainly before starting any testosterone therapy.

Liquid Chromatography-Tandem Mass Spectrometry (LC-MS/MS) represents the gold standard and most accurate method for sex steroid evaluation; however, standardised automated platform immuno-assays for total testosterone assessment demonstrate a good correlation with LC-MS/MS [82]. Conversely, available immuno-assays are not able to provide an accurate estimation of fT; therefore, direct fT evaluation with these methods is not recommended and should be avoided [41]. Liquid chromatography-tandem mass spectrometry remains the standard method for fT determination. Alternatively, fT can be derived from specific mathematical calculations taking into account serum SHBG and albumin levels [83] (http://www.issam.ch/freetesto.htm).

Data from available meta-analyses have documented that testosterone therapy is ineffective when baseline levels are > 12 nmol/L (3.5 ng/mL). Positive outcomes are documented when testosterone levels are < 12 nmol/L, being higher in symptomatic patients with more severe forms of hypogonadism (< 8 nmol/L). Hence, 12 nmol/L should be considered as a possible threshold for starting testosterone therapy in the presence of hypogonadal symptoms [84, 85]. As reported above, clinical conditions that may interfere with SHBG levels, evaluation of fT should be considered to better estimate actual androgen levels (Figure 2). Unfortunately, despite its potential clinical value [86], no validated thresholds for fT are available from clinical studies and this represents an area of uncertainty; however, some data indicate that fT levels < 225 pmol/L (6.5 ng/dL) are associated with hypogonadal symptoms [10, 51, 87, 88].

The determination of LH must be performed along with prolactin (PRL) when pathological total testosterone levels are detected, in order to correctly define the underlying conditions and exclude possible organic causes (Figure 2). Due to its negative influence on libido, PRL can also be considered as first-line screening in patients with reduced sexual desire. In addition, pituitary magnetic resonance imaging (MRI) scanning, as well as other pituitary hormone evaluations, is required in the presence of specific symptoms such as visual disturbances, headache [89, 90] or when hyperprolactinemia is confirmed. Limited evidence suggests performing pituitary MRI also in the case of severe hypogonadism (< 6 nmol/L, 1.75 ng/mL) with inadequate gonadotropin levels (Figure 2) [89, 90].
Figure 2: Diagnostic evaluation of Late-Onset Hypogonadism

**Check symptoms and signs suggestive for hypogonadism**

- Check for drugs and substances that can interfere with T production/action
- Check for concomitant metabolic diseases: obesity/metabolic syndrome/diabetes
- Check for potential testosterone therapy contraindications

**Measure fasting and morning (7-11 am) total T**
- (consider PRL measurement if low desire or other suggestive symptoms are present)
- (consider SHBG and free-T calculation when indicated)
- (consider LH when T deficiency pathophysiology must be investigated)

- **TT < 12 nM**
  - Hypogonadism possible
  - Repeat TT measurements along with LH, PRL +/-SHBG, cFT

- **TT > 12 nM**
  - Hypogonadism unlikely
  - TT > 12 nM (reduced cFT) and LH reduced/inappropriate normal

- **TT < 12 nM** (reduced cFT) and LH elevated
  - Secondary hypogonadism
  - Check for drugs and substances that can interfere with T production/action. Check for comitant metabolic disease: obesity/metabolic syndrome/diabetes

- **TT < 8 nM**
  - Investigate if drugs or substances that may interfere with hypothalamic-pituitary axis can be eliminated. Suggest modifying potential interfering conditions obesity/underweight or other metabolic disturbances
  - Rule out testosterone therapy possible contraindications

- **TT < 6 nM**
  - Elevated PRL
  - Headache/visual disturbances
  - Perform pituitary MRI

- **TT < 6 nM**
  - Fertility desired
  - Possible specific therapy
  - Gonadotropin therapy

**TT = total testosterone; cFT = calculated free testosterone; PRL = prolactin; SHBG = sex hormone-binding globulin; LH = luteinising hormone; MRI = Magnetic resonance imaging.**
3.5.2 History taking

Specific symptoms associated with LOH are shown in Table 3. History of surgical intervention for cryptorchidism or hypospadias must be taken into account as possible signs of congenital defects. Likewise, chronic and systemic comorbidities must be comprehensively investigated in every patient. Use of drugs that potentially interfere with the HPG axis should be ruled out (Table 2). Acute diseases are associated with development of functional hypogonadism and determination of serum total testosterone levels should be avoided in these conditions. However, as detailed above, recent data derived from SARS-CoV-2 infected patients showing worse outcomes in hypogonadal subjects suggest that the role of testosterone in the case of acute illness should be clarified [63, 91]. Several self-reported questionnaires or structural interviews have been developed for screening of hypogonadism. Although these case-history tools have demonstrated clinical utility in supporting the biochemical diagnosis of hypogonadism, or in the assessment of testosterone therapy outcomes, their specificity remains poor and they should not be used for a systematic screening of hypogonadal men [92].

3.5.3 Physical examination

Since obesity is frequently associated with hypogonadism (mostly functional), the determination of body mass index (BMI) and the measurement of waist circumference are strongly recommended in all individuals. Testicular and penile size, as well the presence of sexual secondary characteristics can provide useful information regarding overall androgen status. In addition, upper segment/lower segment ratio (n.v. > 0.92) and arm-span to height ratio (n.v. < 1.0) can be useful to identify a eunuchoid body shape, especially in subjects with pre-pubertal hypogonadism or delayed puberty. Finally, digital rectal examination (DRE) should be performed in all subjects to exclude prostate abnormalities before testosterone therapy (any type) or to support suspicion of hypogonadism [93].

</tbody>
</table>
Check for concomitant diseases, drugs and substances that can interfere with testosterone production/action.  
Total testosterone must be measured in the morning (07.00 and 11.00 hours) and in the fasting state, with a reliable laboratory assay.  
Repeat total testosterone on at least two separate occasions when < 12 nmol/L and before starting testosterone therapy.  
12 nmol/L total testosterone (3.5 ng/mL) represents a reliable threshold to diagnose late onset hypogonadism (LOH).  
Consider sex hormone-binding globulin and free-testosterone calculation when indicated.  
Calculated free-testosterone < 225 pmol/L has been suggested as a possible cut-off to diagnose LOH.  
Analyse luteinising hormone and follicle-stimulating hormone serum levels to differentiate between primary and secondary hypogonadism.  
Consider prolactin (PRL) measurement if low sexual desire (or other suggestive signs/symptoms) and low or low-normal testosterone is present.  
Perform pituitary magnetic resonance imaging (MRI) in secondary hypogonadism, with elevated PRL or specific symptoms of a pituitary mass and/or presence of other anterior pituitary hormone deficiencies.  
Perform pituitary MRI in secondary severe hypogonadism (total testosterone < 6 nmol/L).

3.5.5 Recommendations for screening men with LOH

Screen for late onset hypogonadism (LOH) (including in T2DM) only in symptomatic men.  
Do not use structured interviews and self-reported questionnaires for systematic screening for LOH as they have low specificity.

3.6 Treatment of LOH

3.6.1 Indications and contraindications for treatment of LOH

Patients with symptomatic hypogonadism (total testosterone < 12 nmol/L) without specific contraindications are suitable candidates to receive testosterone therapy (Table 4).

Absolute contraindications are untreated breast and prostate cancer (PCa). Acute cardiovascular events as well as uncontrolled or poorly controlled congestive heart failure and severe lower urinary tract symptoms (LUTS) [International Prostate Symptom Score (IPSS) score > 19] represent other contraindications, as there is insufficient information on the long-term effects of testosterone therapy in these patients [66]. A positive family history for venous thromboembolism requires further analysis to exclude a condition of undiagnosed thrombophilia-hypofibrinolysis [94]. These patients need to be carefully counselled prior to testosterone therapy initiation. A haematocrit (HCT) > 54% should require testosterone therapy withdrawal, reduction in dose, change of formulation and venesection depending on the clinical situation to avoid any potential cardiovascular complications. Lower baseline HTC (48-50%) should be carefully evaluated before testosterone therapy initiation, to avoid pathological increases during treatment, especially in high-risk men such as those with chronic obstructive pulmonary disease (COPD) or Obstructive Sleep Apnoea Syndrome (OSAS). Accordingly, the Framingham Heart Study showed that HCT > 48% represented a condition associated with increased risk of coronary artery disease (CAD) and mortality and was associated with cardiovascular disorders [95]. Finally, testosterone therapy suppresses gonadotropin and endogenous testosterone secretion as well as spermatogenesis. Hence, testosterone therapy is contraindicated in individuals who desire fertility [96]. Secondary hypogonadism is characterised by low or inappropriately normal gonadotropin levels; therefore, the rationale is to substitute the gonadotropin deficiency with FSH and LH analogues, if fertility is desired [97].

3.6.2 **Testosterone therapy outcomes**

3.6.2.1 **Sexual dysfunction**

Sexual concerns are the main symptoms of the hypogonadal patient [5, 10, 98, 99]. A consistent body of evidence shows that testosterone therapy in hypogonadal men (total testosterone < 12 nmol/L) may have a beneficial effect on several aspects of sexual life; in contrast, there is no evidence of benefits in using testosterone therapy for treating sexual dysfunction in eugonadal men [53, 85, 100, 101]. The beneficial effect on sexual function seems to be more related to testosterone level normalisation than the specific testosterone formulations used [101, 102].

A recent meta-analysis of only placebo-controlled RCTs using the International Index of Erectile Function (IIEF) [103] as a possible tool for outcome evaluation, showed that testosterone therapy significantly improves erectile function (as measured by IIEF-Erectile Function domain score) and that patients with more severe hypogonadism (i.e., total testosterone < 8 nmol/L) are more likely to achieve better improvement than patients with milder hypogonadism (i.e., total testosterone < 12 nmol/L). Similar results were observed for sexual desire; however, the presence of metabolic comorbidity (such as diabetes and obesity) decreased the magnitude of these improvements. In particular, testosterone therapy alone resulted in a clinically effective outcome only in patients with milder ED [85]. Other sexual function parameters, such as intercourse, orgasm and overall satisfaction, were all improved compared with placebo [85]. Men with comorbidity such as diabetes usually show modest improvements in terms of sexual function after testosterone therapy and may potentially require concomitant phosphodiesterase type 5 inhibitors (PDE5Is) to improve effectiveness [5, 101]. However, the specific beneficial effect derived from the combined use of testosterone therapy and PDE5Is is not completely clear [53]. Similarly, information related to the combined use of testosterone therapy with other ED drug therapies is lacking [5, 101].

The Sexual Function Trial of the Testosterone Trials (TTrials) (one of the largest placebo-controlled trials on testosterone therapy) documented consistent improvements in 10 of 12 measures of sexual activities in older (≥ 65 years) hypogonadal men, particularly in frequency of intercourse, masturbation and nocturnal erections (as measured by PDQ-Q4) [104]. The magnitude in improvement was shown to be proportional to the increase in serum total testosterone, fT and oestradiol levels, it was not possible to demonstrate a threshold level [105]. A study of 220 men with MetS with or without T2DM also found that sexual function improved in men who reported sexual problems with improvement in IIEF scores with specific increases in libido and sexual satisfaction [24].

3.6.2.2 **Body composition and metabolic profile**

Late onset hypogonadism is associated with a greater percentage fat mass and a lesser lean mass compared to testosterone-replete men [88]. The major effect of low testosterone is to increase visceral adiposity but also leads to deposition of lipids in the liver and muscle and is associated with atherosclerosis [19]. Some published data have suggested that testosterone therapy reduces percentage body fat and increases lean mass [106]. Testosterone therapy has also been found to decrease waist circumference, body weight and BMI, with these effects more predominant after 12 months of treatment [106-108]. The T4DM randomised controlled trial over 2 years reported that men on testosterone therapy and lifestyle programme had a greater reduction in waist circumference, total and abdominal fat mass and an increase in total and arm muscle mass and an increased strength in the non-dominant hand compared to a lifestyle programme alone [30]. There was a trend toward reduction in body weight although this approached significance but did not reach significance. The latter result is probably compounded by the increase in muscle mass as well as the decrease in fat mass. It should be recognised, however, that the results of previous studies are mainly derived from registry and observational trials, which have important limitations due to the risk of selection bias for the non-random assignment of testosterone exposure. Accordingly, data derived from RCTs showed only an improvement of fat mass and lean mass of the same amount without any modifications in body weight [84].
3.6.2.3 Mood and cognition

Several observational studies have documented a relationship between depressive symptoms, reduced QoL and hypogonadism [109, 110]. However, the specific relationship between hypogonadism and the incidence of depression is still unclear [110]. Only a few placebo-controlled RCTs have investigated the role of testosterone therapy in improving depressive symptoms. Data derived from TTrials showed that testosterone therapy improved mood, and depressive symptoms as continuous measures using several instruments [104]. However, the final effect was small in magnitude. In line with these data, the largest meta-analysis of available studies, including 1,890 hypogonadal men (baseline total testosterone < 12 nmol/L or fT < 225 pmol/L) men from 27 RCTs, documented that the positive effect of testosterone therapy was particularly evident in patients with milder symptoms [111]. The BLAST study of testosterone therapy in T2DM reported that those men with depression were less likely to respond with regard to symptoms of sexual dysfunction compared to men without depression [29].

Robust data on the effect of testosterone therapy on QoL are limited. Although recent meta-analyses suggest a significant effect of testosterone therapy over placebo, the magnitude is low and the heterogeneity high, therefore reducing the scientific value of the effect [102, 112].

The role of testosterone therapy in patients with cognitive impairment is even more uncertain. The TTrials evaluated the effect of testosterone therapy in 493 individuals with age-associated memory impairment in order to assess possible improvement of several aspects of cognitive function. However, the final results failed to demonstrate any beneficial effect of testosterone therapy in improving cognitive function [104].

3.6.2.4 Bone

Evidence suggests that bone mineralisation requires circulating sex steroids within the normal range [113]. The possible association between mild hypogonadism and osteopenia/osteoporosis is weak, whereas severe hypogonadism (total testosterone < 3.5 nM) is frequently associated with bone loss and osteoporosis, independent of patient age [113]. Two independent meta-analyses showed a positive effect of testosterone therapy on bone mineral density (BMD), with the highest effect at the lumbar level [114, 115]. Similarly, data derived from TTrials and the T4DM studies confirmed that testosterone therapy increased BMD in hypogonadal ageing men. The TTrial found increased BMD in trabecular bone at the lumbar level [104], whereas the T4DM study reported greater increases in cortical bone [116]. Changes in hip and spine BMD were similar in both studies. However, available data are insufficient to determine the effect of testosterone therapy alone on the risk of fractures [113]. The use of testosterone therapy as an adjunct to anti-resorptive treatment in hypogonadal patients at high risk of fractures has not been established. Therefore, anti-resorptive therapy must be the first-choice treatment in hypogonadal men at high risk for bone fractures. The combination of anti-resorptive treatment and testosterone therapy should be offered only in conjunction with hypogonadism-related symptoms.

3.6.2.5 Vitality and physical strength

The role of testosterone in stimulating muscle growth and strength is well established. Accordingly, androgenic-anabolic steroids (AAS) have been used as performance-enhancing agents to increase physical performance in competitive sport [117]. In this regard, testosterone therapy in hypogonadal men has been shown to increase muscle mass and reduce fat mass, with limited effects on final weight [84]. Despite this evidence, the role of testosterone therapy in older men with mobility limitations remains unclear. The National Health and Nutrition Examination Survey 1999-2004 [118] was unable to detect any association between overall circulating testosterone levels and the amount of physical activity. However, among non-obese men, those in the highest physical activity tertile were significantly less likely to have low or low-normal testosterone than those in the lowest tertile. Data from TTrials indicated that testosterone therapy did not substantially increase the fraction of men whose 6-minute walking distance increased > 50 m or the absolute increase in the distance walked by those enrolled in the physical function trial [104]. However, when the whole population of the TTrials was considered, a significant, although modest, positive effect on these two parameters was reported [104]. Similar data were derived from the Vitality Trial [104].

3.6.3 Choice of treatment

3.6.3.1 Lifestyle factors

As reported above, functional hypogonadism is frequently associated with obesity and metabolic disorders [119]. Therefore, weight loss and lifestyle changes should be the first approach for all overweight and obese men with hypogonadism. A previous meta-analysis documented that a low-calorie diet is able to revert obesity-associated secondary hypogonadism by increasing total testosterone and fT, reducing oestrogens and restoring normal gonadotropin circulating levels [120]. This was confirmed in a recent updated meta-analysis showing that the increase in testosterone is significantly associated with weight reduction [121]. Similar results can be obtained through physical activity, which is associated with the duration of scheduled exercise and weight loss obtained [121]. However, it should be recognised that the increase in testosterone levels observed after a low-calorie diet and physical activity is small (1-2 nmol) [120, 121]. It should also be recognised that 60-86% of weight lost is regained after 3 years and 75-121% after 5 years [122]. A greater testosterone increase can be achieved through bariatric surgery, which results in an average increase of about 10 nmol/L depending on the degree of weight loss [121]. Lifestyle changes represent an essential part of the management of obesity; however, some evidence suggests that when compared to lifestyle modifications alone, testosterone therapy-treated obese men benefit most from relief of their symptoms associated with testosterone deficiency, whereas those not treated did not benefit [97]. There is limited evidence to suggest that combination of lifestyle interventions and testosterone therapy in symptomatic hypogonadal men might result in better outcomes [88]. The T4DM study as described above has demonstrated that over 2-years testosterone therapy with lifestyle intervention was superior to lifestyle intervention alone in reducing waist circumference and total and abdominal fat content. There was no significant reduction in body weight when compared to lifestyle intervention alone [30].

3.6.3.2 Medical preparations

Several testosterone formulations are available (Table 5). Direct comparisons among different testosterone products are still lacking. Candidates for testosterone therapy should be adequately informed about the possible risks and benefits of all available testosterone preparations. The final choice should be based on the clinical situation, testosterone formulation availability, and patient needs and expectations [123].

3.6.3.2.1 Oral formulations

The esterification of testosterone with a long-chain fatty acid (testosterone undecanoate; TU) enables testosterone to be absorbed by the intestine through the lymphatic system, by-passing liver metabolism. This formulation has been available in oleic acid since the 1970s, and it has been recently reformulated in a mixture of castor oil and propylene glycol laureate (TU caps), to allow the drug to be maintained at room temperature without degradation [123]. The main limitation is related to the poor bioavailability, which is strongly dependent
on dietary fat content [123]. Recently, the US Food and Drug Administration (FDA) approved a new formulation of oral TU incorporating a liquid-filled hard capsule drug delivery system and a higher amount (225 mg) of the compound, which improves oral availability (https://www.fda.gov/media/110187/download). In an open label study of approximately 4 months’ duration (NCT02722278), 145 (87%) of 166 hypogonadal men enrolled who received the TU caps formulation had mean total testosterone concentration within the normal eugonadal range at the end of treatment (https://www.fda.gov/media/110187/download). However, the TU caps compound is not available in Europe.

Mesterolone is a 5α-DHT derivate available for oral administration. Along with DHT, mesterolone cannot be converted to oestrogens and can only be used for a limited period and specific indications, such as the presence of painful gynaecomastia. However, the lack of a full spectrum of testosterone bioactivity strongly limits its long-term use [123].

3.6.3.2.2 Parenteral formulations
Injectable testosterone preparations can be classified according to their half-lives (Table 5). Testosterone propionate is a short-term ester formulation requiring multiple fractionated doses (usually 50 mg, every 2-3 days), thus representing a major limitation for its use [123]. Cypionate and enanthate-T esters are short-term formulations, requiring administration every 2-4 weeks. A formulation containing mixed testosterone esters (TU, isocaproate, phenyl propionate, propionate - Sustanon®) which allows some benefit of a smoother release of testosterone into the circulation is available in some countries. The use of these older formulations is associated with wide fluctuations in plasma testosterone concentrations and is often reported as unpleasant by patients and potentially resulting in adverse effects, such as polycythaemia [123, 124]. A longer-lasting TU injectable formulation is widely available [123]; which has a good safety/benefit profile allowing the maintenance of normal stable testosterone levels at a dose of 1,000 mg initially every 12 weeks, following a 6-week loading dose, but can be adjusted to a frequency of 10-14 weeks dependent on the trough (pre-injection level) after 3-5 injections to maintain levels in the therapeutic range (usually > 12 and < 18 nmol/L) [123, 125].

3.6.3.2.3 Transdermal testosterone preparations
Among the available transdermal formulations, testosterone gels represent the most frequently used preparations. The gel is quickly absorbed by the stratum corneum, creating a reservoir within the subcutaneous tissues from where testosterone is continuously delivered for 24 hours, after a single daily application. These formulations have been shown to normalise serum testosterone levels with an excellent safety profile [123]. The introduction of specific devices and skin enhancers has resulted in better skin penetration of the drugs, thus reducing potential adverse effects. Local skin adverse effects are limited when compared to those with traditional testosterone patches, but they potentially allow transference of testosterone during close contact with the skin surface. The risk can be reduced by wearing clothing or by applying the gel on skin surfaces not usually touched (e.g., the inner thigh surface) [123]. To reduce the total amount of gel applied and residual quantities remaining on the skin, new formulations of testosterone gel have been introduced with a testosterone concentration of 1.62-2% [123]. Another transdermal testosterone formulation includes a topical, alcohol-based testosterone (2%) solution, which must be applied to the underarm once daily, using a metered dose applicator [123]. This testosterone formulation is not available in Europe. Testosterone levels should be monitored to optimise the testosterone dose. Blood collection is best taken at 2-4 hours after gel application to use the peak level of testosterone absorbed as a reference for adequate therapeutic levels. Levels of testosterone after application can vary and a repeat measurement may be indicated especially as sometimes, inadvertently, the skin over the vein-puncture site can be contaminated by the gel, leading to falsely elevated results.

In some European countries, DHT is available as a hydroalcoholic 2.5% gel. It is rapidly absorbed, reaching a steady state in 2-3 days. Similar to that reported for mesterolone, DHT is not aromatised but can be useful for treating particular conditions, such as gynaecomastia and microphallus [123].

3.6.3.2.4 Transmucosal formulations
3.6.3.2.4.1 Transbuccal testosterone preparations
A testosterone buccal system is still available in several countries. It consists on a sustained-release muco-adhesive buccal-testosterone-tablet requiring twice-daily application to the upper gums. The tablet does not dissolve completely in the mouth and must be removed after 12 hours. This formulation has been proven to restore testosterone levels within the physiological range with minimal or transient local problems, including gum oedema, blistering and gingivitis [123].

3.6.3.2.4.2 Transnasal testosterone preparations
A gel for intranasal administration is available in some countries, including the USA and Canada. It requires
administration two or three times daily using a specific metered-dose pump. The application is rapid, non-invasive, convenient, and avoids secondary transference observed with other topical products [123].

3.6.3.2.5 Subdermal depots
The implantation of testosterone pellets, available in the USA, UK and Australia, represents the longest available testosterone formulation lasting from 4-7 months. However, the procedure is invasive and may be unattractive to patients [123].

3.6.3.2.6 Anti-oestrogens
Anti-oestrogens, including selective oestrogen receptor (ER) modulators (SERMs) and aromatase inhibitors (AI) have been suggested as off-label treatments to restore testosterone levels and fertility in men with functional secondary hypogonadism or idiopathic infertility. They work by preventing down-regulation of the HPG axis by oestrogens and, for this reason are particularly useful in men with obesity and metabolic disorders [121]. In the latter case, the hypothesis is that the excess of adipose tissue leads to increased aromatase activity and oestrogens levels resulting in impairment of the HPG [119]. Due to their putative mechanism of action, they require an intact HPG axis and cannot work in primary hypogonadism or secondary hypogonadism due to organic damage of the HPG axis. Both types of SERMs, which bind ERs with an agonist or antagonist effect depending upon the target tissue, and AIs, which prevent androgens from being converted into oestrogens by aromatase, have been used in clinical practice [123]. The evidence published so far is poor; all these products are off-label treatments and SERMs, due to their agonistic effect on venous vessels, could predispose men to the development of venous thromboembolism [123]. In this context patients should be warned of the potential increased risk of venous thromboembolism, although data are lacking. Long-term use of these agents can lead to reduced bone density and development of osteoporosis, potentially increasing fracture risk.

3.6.3.2.7 Gonadotropins
Considering the aforementioned limitations regarding the use of anti-oestrogens, gonadotropin therapy should be considered the standard in men with secondary hypogonadism who desire paternity (Table 5) [123]. The treatment is based on the use of human chorionic gonadotropin (hCG), purified from the urine of pregnant women. The most expensive recombinant hCG (rhCG) and LH (rLH) formulations do not offer clinical advantages [123]. According to a meta-analysis of the available evidence, hCG should be administered with FSH as combined therapy results in better outcomes. Similar to recombinant hCG, recombinant FSH (rFSH) does not seem to offer any advantages compared to urinary-derived preparations [125]. More details on the use of gonadotropins are provided in Section 10.

3.6.3.3 Summary of evidence and recommendations for choice of treatment for LOH

### Summary of evidence

Weight loss obtained through a low-calorie diet and regular physical activity result in a small improvement in testosterone levels.

Testosterone gels and long-acting injectable TU represent T preparations with the best safety profile.

Gonadotropins treatment can be used to restore fertility in men with secondary hypogonadism.

3.7 Safety and follow-up in hypogonadism management

3.7.1 Hypogonadism and fertility issues

The aim of pharmacological management of hypogonadism is to increase testosterone levels. The first choice is to administer exogenous testosterone. However, while exogenous testosterone has a beneficial effect on
the clinical symptoms of hypogonadism, it inhibits gonadotropin secretion by the pituitary gland, resulting in impaired spermatogenesis and sperm cell maturation [126]. Therefore, testosterone therapy is contraindicated in hypogonadal men seeking fertility treatment [96]. When secondary hypogonadism is present, gonadotropin therapy may maintain normal testosterone levels and restore sperm production [5].

3.7.2 Male breast cancer
In vitro and in vivo studies have clearly documented that breast cancer growth is significantly influenced by testosterone and/or by its conversion to E2 through different mechanisms and pathways [127]. Accordingly, the use of SERMs still represents an important therapeutic option in the management of this cancer [127]. No information is available on the role of testosterone therapy in patients successfully treated for male breast cancer; therefore, treated and active male breast cancer should be recognised as absolute contraindications for testosterone therapy.

3.7.3 Lower urinary tract symptoms/benign prostatic hyperplasia
Based on the assumption that prostate growth is dependent on the presence of androgens, historically testosterone therapy has raised some concerns regarding the possibility of aggravating LUTS in patients affected by benign prostatic hyperplasia (BPH) associated with prostate enlargement [93, 128]. However, pre-clinical and clinical data have indicated that low rather than high androgen levels may decrease bladder capacity, alter tissue histology and decrease the ratio of smooth muscle to connective tissue, thus impairing urinary dynamics [93, 128].

A trial of 60 patients undergoing testosterone therapy for 6 months showed no significant differences in post-voidal residual urine and prostate volume, while storage symptoms as measured by IPSS significantly improved, despite an increase in prostate-specific antigen (PSA) level. A larger pre-treatment prostate volume was a predictive factor of improvement in LUTS [129]. A long-term study of 428 men undergoing testosterone therapy for 8 years demonstrated significant improvements in IPSS, no changes max flow rate (Qmax) and residual urine volume, but also a significant increase in prostate volume [130]. Similar data from the Registry of Hypogonadism in Men (RHYME), including 999 patients with a follow-up of 3 years, did not document any difference in PSA levels or total IPSS in men undergoing testosterone therapy, compared to untreated patients [131]. Similar results were reported in an Italian registry (SIAMO-NOI), collecting data from 432 hypogonadal men from 15 centres [132]. Meta-analyses have not found significant changes in LUTS between patients treated with testosterone or placebo [133-139]. According to the most recent literature, there are no grounds to discourage testosterone therapy in hypogonadal patients with BPH/LUTS and there is evidence of limited benefit from androgen administration. The only concern is related to patients with severe LUTS (IPSS > 19), as they are usually excluded from RCTs, therefore limiting the long-term safety data of testosterone therapy in this specific setting [93].

3.7.4 Prostate cancer (PCa)
A considerable number of observational studies have failed to demonstrate any association between circulating higher testosterone levels and PCa [140]. In contrast, studies investigating the relationship between low levels of testosterone and risk of PCa have found that men with very low levels of fT have a reduced risk of developing low-to-intermediate-grade PCa, but have a non-significantly increased chance of developing high-grade PCa [140]. This peculiar pattern was also reported in trials such as the Health Professionals Follow-up Study, the Prostate Cancer Prevention Trial (PCPT) and the Reduction by Dutasteride of Prostate Cancer Events (REDUCE), with varying magnitudes of significance [141].

The most recent meta-analysis, including 27 placebo-controlled, RCTs, found no evidence of increased PSA levels following testosterone therapy for one year. When considering 11 studies reporting on the occurrence of PCa, the meta-analysis found no evidence of increased risk of PCa. However, a 1-year follow-up may be considered too short to draw firm conclusions on the risks of developing PCa. Furthermore, the analysis was restricted to studies with > 1-year follow-up, but no significant changes in PSA levels nor increased risk of PCa were found [134]. After 5-years’ median follow-up in three independent registry studies with > 1,000 patients undergoing testosterone therapy, PCa occurrence remained at all times below the reported incidence rate in the general population [142]. Similar results were reported by a more recent large observational study including 10,311 men treated with testosterone therapy and 28,029 controls with a median follow-up of 5.3 years [143]. The same study, also showed that the risk of PCa was decreased for men in the highest tertile of testosterone therapy cumulative dose exposure as compared with controls [143].

With regards to PCa survivors, safety in terms of the risk of recurrence and progression has not yet been established. Limited data are available in the literature, with most case series not providing sufficient data to draw definitive conclusions (e.g., insufficient follow-up, small samples, lack of control arms, heterogeneity in study population and treatment regimen, etc.) [144]. More recently, a meta-analysis derived from 13 studies
including 608 patients, of whom 109 had a history of high-risk PCa, with follow-up of 1-189.3 months [145], suggested that testosterone therapy did not increase the risk of biochemical recurrence, but the available evidence is poor, limiting data interpretation [145]. Similar considerations can be derived from another, larger meta-analysis of 21 studies [146]. It is important to recognise that most of the studies analysed included low-risk patients with Gleason score < 8 [145].

In conclusion, recent literature does not support an increased risk of PCa in hypogonadal men undergoing testosterone therapy. Although it is mandatory to avoid testosterone administration in men with advanced PCa, insufficient long-term prospective data on the safety of androgen administration in PCa survivors [146], without recurrence should prompt caution in choosing to treat symptomatic hypogonadal men in this setting. Specifically, patients should be fully counselled that the long-term effects of testosterone therapy in this setting are still unknown and requires further investigation. If an occult PCa is not detected before initiation of testosterone therapy, treatment may unmask the cancer detected by an early rise in PSA over 6-9 months of therapy. Due to the lack of strong evidence-based data on safety, the possible use of testosterone therapy in symptomatic hypogonadal men previously treated for PCa should be fully discussed with patients and limited to low-risk individuals.

3.7.5 Cardiovascular Disease

Evidence suggests that hypogonadal men have an increased risk of CVD [75, 147]. Whether or not LOH is a cause or a consequence of atherosclerosis has not been clearly determined. Late-onset hypogonadism is associated with CV risk factors, including central obesity, insulin resistance and hyperglycaemia, dyslipidaemia (elevated total cholesterol, LDL-cholesterol, triglycerides and low HDL-cholesterol), pro-thrombotic tendency and chronic inflammatory state [147]. Atherosclerosis is a chronic inflammatory disease, that releases pro-inflammatory cytokines into the circulation, which are known to suppress testosterone release from the HPG axis. Evidence from RCTs of testosterone therapy in men with MetS and/or T2DM demonstrates some benefit in CV risk, including reduced central adiposity, insulin resistance, total cholesterol and LDL-cholesterol and suppression of circulating cytokines [14, 23-25, 29, 147]. However, due to the equivocal nature of these studies, testosterone therapy cannot be recommended for indications outside the specific symptoms.

Published data show that LOH is associated with an increase in all-cause and CVD-related mortality [12, 148-151]. These studies are supported by a meta-analysis that concluded that hypogonadism is a risk factor for cardiovascular morbidity [138] and mortality [152]. Importantly, men with low testosterone when compared to eugonadal men with angiographically proven coronary disease have twice the risk of earlier death [147]. Longitudinal population studies have reported that men with testosterone in the upper quartile of the normal range have a reduced number of CV events compared to men with testosterone in the lower three quartiles [148]. Androgen deprivation therapy for PCa is linked to an increased risk of CVD and sudden death [153]. Conversely, two long-term epidemiological studies have reported reduced CV events in men with high normal serum testosterone levels [154, 155]. Erectile dysfunction is independently associated with CVD and may be the first clinical presentation in men with atherosclerosis.

The knowledge that men with hypogonadism and/or ED may have underlying CVD should prompt individual assessment of their CV risk profile. Individual risk factors (e.g., lifestyle, diet, exercise, smoking, hypertension, diabetes and dyslipidaemia) should be assessed and treated in men with pre-existing CVD and in patients receiving androgen deprivation therapy. Cardiovascular risk reduction can be managed by primary care clinicians, but patients should be appropriately counselled by clinicians active in prescribing testosterone therapy [98]. If appropriate, they could be referred to cardiologists for risk stratification and treatment of co-morbidity.

No RCTs have provided a clear answer on whether testosterone therapy affects CV outcomes. The TTrial (n=790) in older men [156], the TIMES2 (n=220) [24], the BLAST studies in men with MetS and T2DM and the pre-frail and frail study in elderly men - all of 1-year duration and the T4DM 2-year study - did not reveal any increase in Major Adverse Cardiovascular Events (MACE) [24, 27, 30, 156, 157]. In this context, MACE is defined as the composite of CV death, non-fatal acute myocardial infarction, acute coronary syndromes, stroke and cardiac failure. Randomised controlled trials between 3 and 12 months in men with known heart disease treated with testosterone have not found an increase in MACE, but have reported improvement in cardiac ischaemia, angina and functional exercise capacity [158-160]. A large cohort study (n=20, 4,857 men) found that neither transdermal gels or intramuscular testosterone was associated with an increased risk of composite cardiovascular outcome in men with or without prevalent cardiovascular disease (mean follow up 4.3 years) [161]. The European Medicines Agency (EMA) has stated that 'The Co-ordination Group for Mutual recognition and Decentralisation Procedures-Human (CMDh), a regulatory body representing EU Member States, has agreed by consensus that there is no consistent evidence of an increased risk of heart problems with testosterone in men who lack the hormone (a condition known as hypogonadism). However, the product
information is to be updated in line with the most current available evidence on safety, and with warnings that
the lack of testosterone should be confirmed by signs and symptoms and laboratory tests before treating men
with these drugs [162].

As a whole, as for MACE, current available data from interventional studies suggest that there is no increased
risk with up to 3 years of testosterone therapy [163-166]. The weight of the currently published evidence has
reported that testosterone therapy in men with diagnosed hypogonadism has neutral or beneficial actions on
MACE in patients with normalised testosterone levels. The findings could be considered sufficiently reliable
for a 3-year course of testosterone therapy, after which no available study can exclude further or long-term CV
events [167, 168].

3.7.5.1 Cardiac Failure
Testosterone treatment is contraindicated in men with severe chronic cardiac failure because fluid retention
may lead to exacerbation of the condition. Some studies including one of 12 months’ duration have shown
that men with moderate chronic cardiac failure may benefit from low doses of testosterone, which achieve
mid-normal range testosterone levels [159, 169, 170]. If a decision is made to treat hypogonadism in men with
chronic cardiac failure, it is essential that the patient is followed up carefully with clinical assessment and both
testosterone and haematocrit measurements on a regular basis. An interesting observation is that untreated
hypogonadism increased the re-admission and mortality rate in men with heart failure [171].

3.7.6 Erythrocytosis
An elevated haematocrit is the most common adverse effect of testosterone therapy. Stimulation of
erythropoiesis is a normal biological action that enhances delivery of oxygen to testosterone-sensitive tissues
(e.g., striated, smooth and cardiac muscle). Any elevation above the normal range for haematocrit usually
becomes evident between 3 and 12 months after testosterone therapy initiation. However, polycythaemia
can also occur after any subsequent increase in testosterone dose, switching from topical to parenteral
administration and, development of co-morbidity, which can be linked to an increase in haematocrit (e.g.,
respiratory or haematological diseases).

There is no evidence that an increase of haematocrit up to and including 54% causes any adverse
effects. If the haematocrit exceeds 54% there is a testosterone independent, but weak associated rise in CV
events and mortality [95, 172-174]. Any relationship is complex as these studies were based on patients with
any cause of secondary polycythaemia, which included smoking and respiratory diseases. There have been no
specific studies in men with only testosterone-induced erythrocytosis.

Three large studies have not shown any evidence that testosterone therapy is associated with an increased risk
of venous thromboembolism [175, 176]. However, one study showed that an increased risk peaked at 6 months
after initiation of testosterone therapy, then declined over the subsequent period [177]. No study reported
whether there was monitoring of haematocrit, testosterone and/or E2 levels. High endogenous testosterone
or E2 levels are not associated with a greater risk of venous thromboembolism [178]. In one study venous
thromboembolism was reported in 42 cases and 40 of these had diagnosis of an underlying thrombophilia
(including factor V Leiden deficiency, prothrombin mutations and homocysteinuria) [179]. In a RCT of
testosterone therapy in men with chronic stable angina there were no adverse effects on coagulation, by
assessment of tissue plasminogen activator or plasminogen activator inhibitor-1 enzyme activity or fibrinogen
levels [180]. A meta-analysis of RCTs of testosterone therapy reported that venous thromboembolism was
frequently related to underlying undiagnosed thrombophilia-hypofibrinolysis disorders [94]. However, another
meta-analysis and systematic review of randomised controlled trials found that testosterone replacement
therapy was not associated with an increased risk of venous thromboembolism [181]. With testosterone
therapy an elevated haematocrit is more likely to occur if the baseline level is toward the upper limit of normal
prior to initiation. Added risks for raised haematocrit on testosterone therapy include smoking or respiratory
conditions at baseline. Higher haematocrit is more common with parenteral rather than topical formulations.
In men with pre-existing CVD extra caution is advised with a definitive diagnosis of hypogonadism before
initiating testosterone therapy and monitoring of testosterone as well as haematocrit during treatment.

Elevated haematocrit in the absence of co-morbidity or acute CV or venous thromboembolism can be managed
by a reduction in testosterone dose, change in formulation or if the elevated haematocrit is
very high by venesection (500 mL), even repeated if necessary, with usually no need to stop the testosterone
therapy.

3.7.7 Obstructive Sleep Apnoea
There is no evidence that testosterone therapy can result in onset or worsening of sleep apnoea. Combined
therapy with Continuous Positive Airway Pressure (CPAP) and testosterone gel was more effective than CPAP
alone in the treatment of obstructive sleep apnoea [182]. In one RCT, testosterone therapy in men with severe sleep apnoea reported a reduction in oxygen saturation index and nocturnal hypoxaemia after 7 weeks of therapy compared to placebo, but this change was not evident after 18 weeks’ treatment and there was no association with baseline testosterone levels [183].

3.7.8 Follow-up
Testosterone therapy alleviates symptoms and signs of hypogonadism in men in a specific time-dependent manner. The T Trials clearly showed that testosterone therapy improved sexual symptoms as early as 3 months after initiation [104]. Similar results have been derived from meta-analyses [53, 94]. Hence, the first evaluation should be planned after 3 months of treatment. Further evaluation may be scheduled at 6 months or 12 months, according to patient characteristics, as well as results of biochemical testing (see below). Table 6 summarises the clinical and biochemical parameters that should be monitored during testosterone therapy.

Trials were designed to maintain the serum testosterone concentration within the normal range for young men (280–873 ng/dL or 9.6-30 nmol/L) [104]. This approach resulted in a good benefit/risk ratio. A similar approach could be considered during follow-up. The correct timing for evaluation of testosterone levels varies according to the type of preparation used (Table 5). Testosterone is involved in the regulation of erythropoiesis [124] and prostate growth [93], hence evaluation of PSA and haematocrit should be mandatory before and during testosterone therapy. However, it is important to recognise that the risk of PCa in men aged < 40 years is low. Similarly, the mortality risk for PCa in men aged > 70 years is not considered high enough to warrant monitoring in the general population [184]. Hence, any screening for PCa through determination of PSA and DRE in men aged < 40 or > 70 years during testosterone therapy should be discussed with the patients.

Baseline and, at least, annually glyco-metabolic profile evaluation may be a reasonable consideration, particularly in the management of functional hypogonadism. Testosterone therapy may be beneficial for hypogonadal men with low or moderate fracture risk [113]; therefore, dual energy X-ray absorptiometry (DEXA) bone scan may also be considered at baseline and 18-24 months following testosterone therapy, particularly in patients with more severe hypogonadism [113].

Digital rectal examination may detect prostate abnormalities that can be present even in men with normal PSA values. Hence, DRE is mandatory in all men at baseline and during testosterone therapy.

The decision to stop testosterone therapy or to perform prostate biopsy due to PSA increase or prostate abnormalities should be based on local PCa guidelines. There is a large consensus that any increase of haematocrit > 54% during testosterone therapy requires therapy withdrawal and phlebotomy to avoid potential adverse effects including venous-thromboembolism and CVD, especially in high-risk individuals. In patients with lower risk of relevant clinical sequelae, the situation can be alternatively managed by reducing testosterone dose and switching formulation along with venesection. A positive family history of venous-thromboembolism should be carefully investigated and the patient counselled with regard to testosterone therapy to avoid/prevent thrombophilia-hypofibrinolysis [94]. Finally, caution should be exercised in men with pre-existing CVD or at higher risk of CVD.

## 4. EPIDEMIOLOGY AND PREVALENCE OF SEXUAL DYSFUNCTION AND DISORDERS OF MALE REPRODUCTIVE HEALTH

### 4.1 Erectile dysfunction

Epidemiological data have shown a high prevalence and incidence of ED worldwide [185]. Among others, the Massachusetts Male Aging Study (MMAS) [186] reported an overall prevalence of 52% ED in non-institutionalised men aged 40-70 years in the Boston area; specific prevalence for minimal, moderate, and complete ED was 17.2%, 25.2%, and 9.6%, respectively. In the Cologne study of men aged 30-80 years, the prevalence of ED was 19.2%, with a steep age-related increase from 2.3% to 53.4% [187]. The incidence rate of ED (new cases per 1,000 men annually) was 26 in the long-term data from the MMAS study [188] and 19.2 (mean follow-up of 4.2 years) in a Dutch study [189]. In a cross-sectional real-life study among men seeking first medical help for new-onset ED, one in four patients was younger than 40 years, with almost 50% of the young men complaining of severe ED [190]. Differences among these studies can be explained by differences in methodology, ages, and socio-economic and cultural status of the populations studied. The prevalence rates of ED studies are reported in Table 7.
4.2 Premature ejaculation

As evidenced by the highly discrepant prevalence rates reported in Table 8 [191], the method of recruitment for study participation, method of data collection and operational criteria can all greatly affect reported prevalence rates of premature ejaculation (PE). The major problem in assessing the prevalence of PE was the lack of a universally recognised definition at the time the surveys were conducted [192]. Vague definitions without specific operational criteria, different manners of sampling, and non-standardised data acquisition have led to heterogeneity in estimated prevalence [192-196]. The highest prevalence rate of 31% (men aged 18-59 years) was found by the National Health and Social Life Survey (NHSLS), which determines adult sexual behaviour in the USA [197]. Prevalence rates were 30% (18-29 years), 32% (30-39 years), 28% (40-49 years) and 55% (50-59 years). It is, however, unlikely that the PE prevalence is as high as 20-30% based on the relatively low number of men who seek medical help for PE. These high prevalence rates may be a result of the dichotomous scale (yes/no) in a single question asking if ejaculation occurred too early, as the prevalence rates in European studies have been significantly lower [198]. Two separate observational, cross-sectional surveys from different continents found that overall prevalence of PE was 19.8 and 25.8%, respectively [199, 200]. Further stratifying these complaints into the classifications defined by Waldinger et al. [201], rates of lifelong PE were 2.3 and 3.18%, acquired PE 3.9 and 4.48%, variable PE 8.5 and 11.38% and subjective PE 5.1 and 6.4% [199, 200].

Both studies showed that men with acquired PE were more likely to seek treatment compared to men with lifelong PE. Treatment-seeking behaviour may have contributed to errors in the previously reported rates of PE, as it is possible that men with lifelong PE came to terms with their problem and did not seek treatment. The additional psychological burden of a new change in ejaculatory latency in acquired PE may have prompted more frequent treatment seeking [202]. Thus, it is likely that there is disparity between the incidence of the various PE sub-types in the general community and in men actively seeking treatment for PE [203, 204]. This disparity could be a further barrier to understanding the true incidence of each sub-type of PE. An approximately 5% prevalence of acquired PE and lifelong PE in the general population is consistent with epidemiological data indicating that around 5% of the population have an ejaculation latency of < 2 minutes [205].

4.3 Other ejaculatory disorders

4.3.1 Delayed ejaculation

Due to its rarity and uncertain definitions, the epidemiology of delayed ejaculation (DE) is not clear [206]. However, several well-designed epidemiological studies have revealed that its prevalence is around 3% among sexually active men [197, 207]. According to data from the NHSLS, 7.78% of a national probability sample of 1,246 men aged 18-59 years reported inability achieving climax or ejaculation [197]. In a similar stratified national probability sample survey completed over 6 months among 11,161 men and women aged 16-44 years in Britain, 0.7% of men reported inability to reach orgasm [208]. In an international survey of sexual problems among 13,618 men aged 40-80 years from 29 countries, 1.1-2.8% of men reported that they frequently experience inability to reach orgasm [209]. Another study conducted in the United States (USA), in a national probability sample of 1,455 men aged 57-85 years, 20% of men reported inability to climax and 73% reported that they were bothered by this problem. [210]. Considering the findings of these epidemiological studies and their clinical experiences, some urologists and sex therapists have postulated that the prevalence of DE may be higher among older men [211-213]. Similar to the general population, the prevalence of men with DE is low among patients who seek treatment for their sexual problems. An Indian study that evaluated the data on 1,000 consecutive patients with sexual disorders who attended a psychosexual clinic demonstrated that the prevalence of DE was 0.6% and it was more frequent in elderly people with diabetes [214]. Nazareth et al. [215] evaluated the prevalence of International Classification of Diseases 10th edition (ICD-10) diagnosed sexual dysfunctions among 447 men attending 13 general practices in London, UK and found that 2.5% of the men reported inhibited orgasm during intercourse. Similar to PE, there are distinctions among lifelong, acquired and situational DE [216]. Although the evidence is limited, the prevalence of lifelong and acquired DE is estimated at 1 and 4%, respectively [217].

4.3.2 Anejaculation and Anorgasmia

Establishing the exact prevalence of anejaculation and anorgasmia is difficult since many men cannot distinguish between ejaculation and orgasm. The rarity of these clinical conditions further hampers the attempts to conduct epidemiological studies. In a report from the USA, 8% of men reported unsuccessfully achieving orgasm during the past year [197].

According to Kinsey et al. [218], 0.14% of the general population have anejaculation. The most common causes of anejaculation were spinal cord injury, diabetes mellitus and multiple sclerosis. Especially in most cases of spinal cord injury, medical assistance is the only way to ejaculate. While masturbation leads to the lowest rates of ejaculation, higher response rates can be obtained with penile vibratory stimulation or acetylcholine esterase inhibitors followed by masturbation in patients with spinal cord injury [219].
4.3.3 Retrograde ejaculation

Similar to anejaculation, it is difficult to estimate the true incidence of retrograde ejaculation (RE). Although RE is generally reported in 0.3-2% of patients attending fertility clinics [220], diabetes may increase these rates by leading to autonomic neuropathy. Autonomic neuropathy results in ED and ejaculatory dysfunctions ranging from DE to RE and anejaculation, depending on the degree of sympathetic autonomic neuropathy involved [221]. In 54 diabetic patients with sexual dysfunction, RE was observed with a 6% incidence [222]. In a controlled trial, RE was observed in 34.6% of diabetic men [223]. A more recent trial reported the rate of RE among 57 type-1 diabetes mellitus patients (aged 18-50 years) was at least 8.8% [224]. Retrograde ejaculation was also reported in studies of patients who had undergone transurethral resection of prostate (TURP) or open prostatectomy due to disrupted bladder neck integrity. A study of the effect of prostatectomy on QoL in 5,276 men after TURP, found that 68% reported post-surgical RE [225]. However, with the development of less invasive techniques, the incidence of RE decreases following the surgical treatment of LUTS [226-230].

4.3.4 Painful ejaculation

Painful ejaculation is a common but poorly understood clinical phenomenon, which is associated with sexual dysfunction. Several studies demonstrated its prevalence to range between 1-10% in the general population [231-233]; however, it may increase to 30-75% among men with chronic prostatitis/chronic pelvic pain syndrome (CP/CPPS) [234-238]. It should be noted that the design of most of these studies was not scientifically sound and the condition was probably under-reported due to the lack of an evidence-based definition and well-defined prognostic criteria.

4.3.5 Haemospermia

The exact incidence and prevalence of haemospermia are difficult to elucidate due to a number of factors including its covert presentation, usually self-limiting nature and patient embarrassment. The symptom represents 1-1.5% of all urological referrals and occurs in all age groups, with a mean age of 37 years [239, 240]. In a PCa screening study of 26,126 men, aged ≥ 50 years or older than 40 with a history of PCa or of black ethnicity, haemospermia was found in 0.5% on entry to the trial [241].

4.4 Low sexual desire

The global prevalence of low sexual desire in men is 3-28% [209, 242, 243]. Low solitary and dyadic sexual desires, have been reported in 68% and 14% of men, respectively [244]. Also, low sexual desire has been observed as a common complaint in gay men, with a prevalence of 19-57% [245, 246]. Despite its relationship with age, low sexual desire has been reported among young men (18-29 years), with prevalence of 6-19% [197, 247, 248].

2021 Calzo et al. [279] 2,660 sexually active men (USA) Not reported 18-31 Self-administered questionnaire (IIEF-5) Prevalence of mild ED was 11.3% and moderate-to-severe ED was 2.9% Demographic (age; marital status) Metabolic (body mass index; waist circumference; history of diabetes, hypertension, hypercholesterolaemia) Mental health (depression, anxiety, antidepressant, tranquiliser use)

2020 Goldstein et al. [280] 97,159 men from the 2015 and 2016 National Health and Wellness Surveys (Italy, France, China, Spain, Germany, US, UK, Brazil) Not reported > 18 Self-reported experiencing difficulty in achieving or maintaining an erection in the past 6 months (Erection difficulty was rated on a scale from 1= not at all to 5 = a great deal; those who selected a response of ≥ 2 were categorised as having ED and included in the study) Prevalence of ED by country among adult males ≥ 18 Age/BPH

2020 Molina-Vega et al. [281] 254 young non-diabetic obese men Not reported 18-49 Self-administered questionnaire (IIEF-5) Prevalence of ED was 42.1% Age, components of metabolic syndrome

Four baseline studies estimating the prevalence of Erectile Dysfunction:
MMAS = the Massachusetts Male Aging Study; NHSLS = the National Health of Social Life Survey; MALES = the multi-national men’s attitudes to life events and sexuality; GSSAB = Global Study of Sexual Attitudes and Behaviours.
BPH = Benign Prostate Hyperplasia; COPD = Chronic Obstructive Pulmonary Disease; ED = Erectile Dysfunction; IIEF = International Index of Erectile Function; IPSS = International Prostate Symptom Score; LUTS = Lower urinary tract symptoms.

5. MANAGEMENT OF ERECTILE DYSFUNCTION

5.1 Definition and classification

Penile erection is a complex physiological process that involves integration of both neural and vascular events, along with an adequate endocrine milieu. It involves arterial dilation, trabecular smooth muscle relaxation and activation of the corporeal veno-occlusive mechanism [310]. Erectile dysfunction is defined as the persistent inability to attain and maintain an erection sufficient to permit satisfactory sexual performance [311]. Erectile dysfunction may affect psychosocial health and have a significant impact on the QoL of patients and their partner’s [186, 312-314].

There is established evidence that the presence of ED increases the risk of future CV events including myocardial infarction, cerebrovascular events, and all-cause mortality, with a trend towards an increased risk of cardiovascular mortality [315]. Therefore, ED can be an early manifestation of coronary artery and peripheral vascular disease and should not be regarded only as a QoL issue, but also as a potential warning sign of CVD [316-319]. A cost analysis showed that screening men presenting with ED for CVD represents a cost-effective intervention for secondary prevention of both CVD and ED, resulting in substantial cost savings relative to identification of CVD at the time of presentation [320].

Erectile dysfunction is commonly classified into three groups based on aetiology: organic, psychogenic and mixed ED. However, this classification should be used, with caution as most cases are actually of mixed aetiology. It has therefore been suggested to use the terms “primary organic” or “primary psychogenic”.

5.2 Risk factors

Erectile dysfunction is associated with unmodifiable and modifiable common risk factors including age, diabetes mellitus, dyslipidaemia, hypertension, CVD, BMI/obesity/waist circumference, MetS, hyperhomocysteinemia, lack of exercise, and smoking (a positive dose-response association between quantity and duration of smoking has been demonstrated) [313, 317, 321-329]. Furthermore, an association between ED status and pharmaco-therapeutic agents for CVD (e.g., thiazide diuretics and β-blockers, except nebivolol), exert detrimental effects on erectile function, whereas newer drugs (i.e., angiotensin-converting enzyme-inhibitors, angiotensin-receptor-blockers and calcium-channel-blockers) have neutral or even beneficial effects [317, 330, 331]. Furthermore, the use of psychotropic drugs increases the risk of developing ED [332]. Atrial fibrillation [333], hyperthyroidism [20], vitamin D deficiency [334, 335], hyperuricemia [336], folic acid deficiency [337], depression [338] and anxiety disorders [339], chronic kidney disease [340], stroke [341] and chronic obstructive pulmonary disease [342] have also been reported as risks factors. Available data do not confirm a clear association between ED and hypothyroidism and hyperprolactinaemia [20]. Interestingly, a dual (cause-effect) association between ED and osteoporosis had been proposed, and therefore ED patients should be evaluated by bone mineral density or men with osteoporosis should be further assessed for erectile function [343]. Current evidence supports the fact that renal transplantation improves erectile function and the risk of ED is progressively reduced from before to after surgery [344, 345].

Further epidemiological data have also highlighted other potential risk factors associated with ED including sleep disorders [346], obstructive sleep apnoea [347], psoriasis [348-350], gouty arthritis [346] and ankylosing spondylitis [351], non-alcoholic fatty liver disease [352], other chronic liver disorders [353], chronic periodontitis [354], open-angle glaucoma [355], inflammatory bowel disease [356], chronic fatigue syndrome [357] and allergic rhinitis [358], and spina bifida [359]. Insufficient data are currently available to correlate primarily organic or primarily psychogenic ED with SARS-CoV-2 infection associated disease (COVID-19) [360, 361]. Similarly, although currently available data are scarce, a positive correlation between cycling and ED had been proposed, even if only after adjusting for age and several comorbidities [362]. Recent findings show that pelvic ring fractures are associated with onset of ED with important influence on QoL, especially in young patients [363, 364].

A recent meta-analysis showed that men partnered with women suffering from Female Sexual Dysfunction (FSD) present an increased risk of developing sexual impairment, in particular erectile and ejaculatory dysfunction [365].

Erectile dysfunction is also frequently associated with other urological conditions and procedures (Table 9). Epidemiological studies have demonstrated consistent evidence for an association between LUTS/BPH and sexual dysfunction, regardless of age, other co-morbidity and lifestyle factors [366]. The Multinational Survey on the Aging Male study, performed in the USA, France, Germany, Italy, Netherlands, Spain, and the UK, systematically investigated the relationship between LUTS and sexual dysfunction in > 12,000 men aged 50-80 years. In the 83% of men who were reported to be sexually active, the overall prevalence of LUTS was 90%, with an overall 49% prevalence of ED and a reported complete absence of erections in 10% of patients. The
overall prevalence of ejaculatory disorders was 46% [261]. Regardless of the employed technique, surgery for BPH-LUTS had no significant impact on erectile function at long-term (5 year) follow-up, while a slight advantage is demonstrated for prostate urethral lift (PUL) over conventional TURP at 24 months follow-up [367]. A post-operative improvement of erectile function was even found depending on the degree of LUTS improvement [368, 369]. An association has been confirmed between ED and CP/CPPS [369], and bladder pain syndrome/interstitial cystitis (BPS/IC), mostly in younger men [370]. An association between ED and PE has also been demonstrated (see Section 6.2) [371]. Recent evidence showed that ED is a mild, short-term and transient complication of prostate biopsy, regardless of the trans-rectal or trans-perineal approach employed [372].

An increased risk of ED is reported following [373] open urethroplasty, especially for correction of posterior strictures [374], with recent findings emphasising the importance of patient-reported outcome measures (PROMs) in urethral reconstructive surgery to better report actual sexual function outcomes [375, 376].

### Table 9: Urological conditions associated with ED

<table>
<thead>
<tr>

<td>Urethroplasty surgery for posterior urethral strictures [374]</td>
<td>OR of ED after posterior urethroplasty = 2.51 [1.82 – 3.45, 95% CI]</td>
</tr>
</tbody>
</table>

CI = confidence interval; OR = odds ratio; TURP = transurethral resection of the prostate; ED = erectile dysfunction; BPS/IC = bladder pain syndrome/interstitial cystitis; LUTS = lower urinary tract symptoms.

Several studies have shown that lifestyle modification [377], including physical activity [378], weight loss [379] and pharmacotherapy [331, 380, 381] for CVD risk factors may be of help in improving sexual function in men with ED. Meta-analytic data reveals a positive effect of lipid-lowering therapy with statins on erectile function [382, 383]. However, it should be emphasised that further controlled prospective studies are necessary to determine the effects of exercise or other lifestyle changes in the prevention and treatment of ED [377].

### 5.3 Pathophysiology

The pathophysiology of ED may be vasculogenic, neurogenic, anatomical, hormonal, drug-induced and/or psychogenic (Table 10) [310]. In most cases, numerous pathophysiological pathways can co-exist and may all negatively impact on erectile function.

The proposed ED etiological and pathophysiological division should not be considered prescriptive. In most cases, ED is associated with more than one pathophysiological factor and very often, if not always, will have a psychological component. Likewise, organic components can negatively affect erectile function with different pathophysiological effects. Therefore, Table 10 must be considered for diagnostic classifications only (along with associated risk factors for each subcategory).

GnRH = gonadotropin-releasing hormone; 5-ARIs = 5α-reductase inhibitors.

*A symmetry analysis showed that cardiovascular drugs do not strongly affect the risk of subsequently being prescribed as anti-erectogenic drug. The analysis only assessed the short-term risk [384].
5.3.1 Pelvic surgery and prostate cancer treatment

Pelvic surgery, especially for oncological disease (e.g., radical prostatectomy (RP) [385] or radical cystectomy [386] and colorectal surgery [387]), may have a negative impact on erectile function and overall sexual health. The most relevant causal factor is a lesion occurring in the neurovascular bundles that control the complex mechanism of the cavernous erectile response, whose preservation (either partial or complete) during surgery eventually configures the so-called nerve-sparing (NS) approach [388]. Therefore, surgery resulting in damage of the neurovascular bundles, results in ED, although NS approaches have been adopted over the last few decades. This approach is applicable to all types of surgery that are potentially harmful to erectile function, although to date, only the surgical treatment of PCa has enough scientific evidence supporting its potential pathophysiological association with ED [389, 390]. However, even non-surgical treatments of PCa (i.e., radiotherapy, or brachytherapy) can be associated with ED [391, 392]. The concept of active surveillance for the treatment of PCa was developed to avoid over-treatment of non-significant localised low-risk diseases, while limiting potential functional adverse effects (including ED). However, it is interesting that data suggest that even active surveillance has a detrimental impact on erectile function (and sexual well-being as a whole) [393-395].

To date, some of the most robust data on PROMs including erectile function, comparing treatments for clinically localised PCa come from the Prostate Testing for Cancer and Treatment (ProtecT) trial, in which 1,643 patients were randomised to active treatment (either RP or RT) and active monitoring and were followed-up for 6 years [396]. Sexual function, including erectile function, and the effect of sexual function on QoL were assessed with the Expanded Prostate Cancer Index Composite with 26 items (EPIC-26) instrument [397, 398]. At baseline, 67% of men reported erections firm enough for sexual intercourse but this fell to 52% in the active monitoring group, 22% in the RT group, and 12% in the RP group, at 6-months’ assessment. The worst trend over time was recorded in the RP group (with 21% erections firm enough for intercourse after 3 years vs. 17% after 6 years). In the RT group, the percentage of men reporting erections firm enough for intercourse increased between 6 and 12 months, with a subsequent decrease to 27% at 6-years assessment. The percentage declined over time on a yearly basis in the active monitoring group, with 41% of men reporting erections firm enough for intercourse at 3 years and 30% at 6 year evaluations [396].

Radical prostatectomy (open, laparoscopic or robot-assisted) is a widely performed procedure with a curative intent for patients presenting with clinically localised intermediate- or high-risk PCa and a life expectancy of > 10 years based on health status and co-morbidity [399]. This procedure may lead to treatment-specific sequelae affecting health-related QoL. Men undergoing RP (any technique) should be adequately informed before the operation that there is a significant risk of sexual changes other than ED, including decreased libido, changes in orgasm, anejaculation, Peyronie’s-like disease, and changes in penile length [390, 392]. These outcomes have become increasingly important with the more frequent diagnosis of PCa in both younger and older men [400, 401]. Research has shown that 25-75% of men experience post-RP ED [402], even though these findings had methodological flaws; in particular, the heterogeneity of reporting and assessment of ED among the studies [389, 403]. Conversely, the rate of unassisted post-operative erectile function recovery ranged between 20 and 25% in most studies. These rates have not substantially improved or changed over the past 17 years, despite growing attention to post-surgical rehabilitation protocols and refinement of surgical techniques [403-405].

Overall, patient age, baseline erectile function and surgical volume, with the consequent ability to preserve the neurovascular bundles, seem to be the main factors in promoting the highest rates of post-operative potency [390, 400, 402, 406]. Regardless of the surgical technique, surgeons’ experience may clearly impact on post-operative EF outcome; in particular when surgeons have a caseload greater than 25 radical prostatectomy cases per year or total cumulative experience of >1,000 prostatectomy cases results in better erectile function outcomes after RP [407]. Patients being considered for nerve-sparing RP (NSRP) should ideally be potent pre-operatively [400]. The recovery time following surgery is of clinical importance in terms of post-operative recovery of erectile function. Available data confirm that post-operative erectile function recovery can occur up to 48 months after RP [408]. Likewise, it has been suggested that post-operative therapy (any type) should be commenced as soon as possible after the surgical procedure [400, 402], although evidence suggests that the number of patients reporting return of spontaneous erectile function has not increased.

In terms of the effects of surgical interventions (e.g., robot-assisted RP [RARP] vs. other types of surgery), data are still conflicting. An early systematic review showed a significant advantage in favour of RARP in comparison with open retropubic RP in terms of 12-month potency rates [409], without significant differences between laparoscopic RP and RARP. Some recent reports confirm that the probability of erectile function recovery is
about twice as high for RARP compared with open RP [410]. More recently, a prospective, controlled, non-randomised trial of patients undergoing RP in 14 Swedish centres comparing RARP versus open retropubic RP, showed a small improvement in erectile function after RARP [411]. Conversely, a randomised controlled phase 3 study of men assigned to open RP or RARP showed that the two techniques yielded similar functional outcomes at 12 weeks [412]. More controlled prospective well-designed studies, with longer follow-up, are necessary to determine if RARP is superior to open RP in terms of post-operative ED rates [413]. To overcome the problem of heterogeneity in the assessment of erectile function, for which there is variability in terms of the PROMs used (e.g., International Index of Erectile Function [IIEF], IIEF-5, Expanded Prostate Cancer Index Composite with 26 items [EPIC 26], Sexual Health Inventory for Men, etc.) to measure potency or erectile function, the criteria used to define restoration of erectile function should be re-evaluated utilising objective and validated thresholds (e.g., normalisation of scores or return to baseline erectile function) [389].

Erectile dysfunction is also a common problem after both external beam radiation therapy (EBRT) and brachytherapy for PCa. A systematic review and meta-analysis including men treated with EBRT (65%), brachytherapy (31%) or both (4%) showed that the post-treatment prevalence of ED was 34% at 1 year and 57% at 5.5 years [414, 415]. Similar findings have been reported for stereotactic radiotherapy with 26-55% of previously sexually functioning patients reporting ED at 5 years [416].

Recently other modalities have emerged as potential therapeutic options in patients with clinically-localised PCa, including whole gland and focal (lesion-targeted) treatments, to ablate tumours selectively while limiting sexual toxicity by sparing the neurovascular bundles. These include high-intensity focused US (HIFU), cryo-therapeutic ablation of the prostate (cryotherapy), focal padeliporfin-based vascular-targeted photodynamic therapy and focal radiation therapy (RT) by brachytherapy or CyberKnife®. All these approaches have a less-negative impact on erectile function with many studies reporting a complete recovery at one-year follow-up [417]. However, prospective randomised controlled studies are needed to compare the functional and oncological outcomes using different treatment modalities [418, 419].

5.4 Diagnostic evaluation (basic work-up)

5.4.1 Medical and sexual history

The first step in evaluating ED is always a detailed medical and sexual history of patients and, when available, their partners [420]. It is important to establish a relaxed atmosphere during history-taking. This will make it easier to ask questions about erectile function and other aspects of the patient’s sexual history; and to explain the diagnosis and therapeutic approach to the patient and their partner. Figure 3 lists the minimal diagnostic evaluation (basic work-up) in patients with ED.

The sexual history must include information about previous and current sexual relationships, current emotional status, onset and duration of the erectile problem, and previous consultations and treatments. The sexual health status of the partner(s) (when available) can also be useful. A detailed description should be made of the rigidity and duration of both sexually-stimulated and morning erections and of problems with sexual desire, arousal, ejaculation, and orgasm [421, 422]. Validated psychometric questionnaires, such as the IIEF [103] or its short version (i.e., Sexual Health Inventory for Men; SHIM) [103], help to assess the different sexual function domains (i.e., sexual desire, erectile function, orgasmic function, intercourse satisfaction, and overall satisfaction), as well as the potential impact of a specific treatment modality. Similarly, structured interviews allow the identification and quantification of the different underlying factors affecting erectile function [423].

Psychometric analyses also support the use of the Erectile Hardness Score (EHS) for the assessment of penile rigidity in practice and in clinical trials research [424]. In cases of depressive mood, clinicians may use the Beck Depressive Inventory [425], which is one of the most recognised self-reported
measures in the field, takes approximately 10 minutes to complete, and assigns the patient to a specific level of depression (varying from “normal mood” to “extreme depression”).

Patients should always be screened for symptoms of possible hypogonadism (testosterone deficiency), including decreased energy and libido, and fatigue; potential cognitive impairment may be also observed in association with hypogonadism (see Sections 3.5 and 3.6), as well as for LUTS. In this regard, although LUTS/BPH in themselves do not represent contraindications to treatment for LOH, screening for LUTS severity is clinically relevant [7].

5.4.2 Physical examination

Every patient must be given a physical examination focused on the genitourinary, endocrine, vascular and neurological systems [426, 427]. A physical examination may reveal unsuspected diagnoses, such as Peyronie’s disease, pre-malignant or malignant genital lesions, prostatic enlargement or irregularity/nodularity, or signs and symptoms suggestive of hypogonadism (e.g., small testes or alterations in secondary sexual characteristics).

Assessment of previous or concomitant penile abnormalities (e.g., hypospadias, congenital curvature, or Peyronie’s disease with preserved rigidity) during the medical history and the physical examination is mandatory.

Blood pressure and heart rate should be measured if they have not been assessed in the previous 3-6 months. Likewise either BMI calculation or waist circumference measurement should be undertaken to assess patients for comorbid conditions (e.g., MetS).

5.4.3 Laboratory testing

Laboratory testing must be tailored to the patient’s complaints and risk factors. Patients should undergo a fasting blood glucose or haemoglobin A1c and lipid profile measurement if they have not been assessed in the previous 12 months. Hormonal tests should include early morning total testosterone in a fasting state. The bioavailable or calculated-free testosterone values may sometimes be needed to corroborate total testosterone measurements. However, the threshold of testosterone required to maintain an erection is low and ED is usually a symptom of more severe cases of hypogonadism (see Sections 3.5 and 3.6) [20, 53, 428-430]. Additional laboratory tests may be considered in selected patients with specific signs and associated symptoms (e.g., PSA) [431], prolactin and luteinising hormone [432]. Although physical examination and laboratory evaluation of most men with ED may not reveal the exact diagnosis, clinical and biochemical evaluation presents an opportunity to identify comorbid conditions [427].
5.4.4  **Cardiovascular system and sexual activity: the patient at risk**

Patients who seek treatment for sexual dysfunction have a high prevalence of CVDs. Epidemiological surveys have emphasised the association between cardiovascular/metabolic risk factors and sexual dysfunction in both men and women [433]. Overall, ED can improve the sensitivity of screening for asymptomatic CVD in men with diabetes [434, 435]. Erectile dysfunction significantly increases the risk of CVD, coronary heart disease and stroke. Furthermore, the results of a recent prospective cohort study showed that ED is an independent predictor for incident atrial fibrillation [436]. All of these cause mortality and the increase is probably independent of conventional cardiovascular risk factors [316, 317, 437, 438]. Longitudinal data from an observational population-based study of 965 men without CVD showed that younger men (especially those < 50 years) with transient and persistent ED have an increased Framingham CVD risk [439].

The EAU Guidelines for diagnosing and treating men with ED have been adapted from previously published recommendations from the Princeton Consensus conferences on sexual dysfunction and cardiac risk [440]. The Princeton Consensus (Expert Panel) Conference is dedicated to optimising sexual function and preserving cardiovascular health [440-442]. Accordingly, patients with ED can be stratified into three cardiovascular risk categories (Table 11), which can be used as the basis for a treatment algorithm for initiating or resuming sexual activity (Figure 3). It is also possible for the clinician to estimate the risk of sexual activity in most patients from their level of exercise tolerance, which can be determined when taking the patient’s history [381].

**ED = erectile dysfunction; IIEF = International Index of Erectile Function.**

Figure 4: Treatment algorithm for determining level of sexual activity according to cardiac risk in ED (based on 3rd Princeton Consensus) [440]

- Sexual activity is equivalent to walking 1 mile on the flat in 20 minutes or briskly climbing two flights of stairs in 10 seconds.
- Sexual activity is equivalent to 4 minutes of the Bruce treadmill protocol.
5.4.4.1 Low-risk category
The low-risk category includes patients who do not have any significant cardiac risk associated with sexual activity. Low-risk is typically implied by the ability to perform exercise of modest intensity, which is defined as, ≥ 6 metabolic equivalents of energy expenditure in the resting state, without symptoms. According to current knowledge of the exercise demand or emotional stress associated with sexual activity, low-risk patients do not need cardiac testing or evaluation before initiation or resumption of sexual activity or therapy for sexual dysfunction.

5.4.4.2 Intermediate- or indeterminate-risk category
The intermediate- or indeterminate-risk category consists of patients with an uncertain cardiac condition or patients whose risk profile requires testing or evaluation before the resumption of sexual activity. Based upon the results of testing, these patients may be moved to either the high- or low-risk group. A cardiology consultation may be needed in some patients to help the primary physician determine the safety of sexual activity.

5.4.4.3 High-risk category
High-risk patients have a cardiac condition that is sufficiently severe and/or unstable for sexual activity to carry a significant risk. Most high-risk patients have moderate-to-severe symptomatic heart disease. High-risk individuals should be referred for cardiac assessment and treatment. Sexual activity should be stopped until the patient’s cardiac condition has been stabilised by treatment, or a decision made by the cardiologist and/or internist that it is safe to resume sexual activity.

5.5 Diagnostic Evaluation (advanced work-up)
Most patients with ED can be managed based on the basis of medical and sexual history; conversely, some patients may need specific diagnostic tests (Tables 12 and 13).

5.5.1 Nocturnal penile tumescence and rigidity test
The nocturnal penile tumescence and rigidity (NPTR) test applies nocturnal monitoring devices that measure the number of erectile episodes, tumescence (circumference change by strain gauges), maximal penile rigidity, and duration of nocturnal erections. The NPTR assessment should be performed on at least two separate nights. A functional erectile mechanism is indicated by an erectile event of at least 60% rigidity recorded on the tip of the penis that lasts for > 10 minutes [443]. Nocturnal penile tumescence and rigidity monitoring is an attractive approach for objectively differentiating between organic and psychogenic ED (patients with psychogenic ED usually have normal findings in the NPTR test). However, many potential confounding factors (e.g., situational) may limit its routine use for diagnostic purposes [444].

5.5.2 Intracavernous injection test
The intracavernous injection test gives limited information about vascular status. A positive test is a rigid erectile response (unable to bend the penis) that appears within 10 minutes after the intracavernous injection and lasts for 30 minutes [445]. Overall, the test is inconclusive as a diagnostic procedure and a duplex Doppler study of the penis should be requested, if clinically warranted.

5.5.3 Dynamic duplex ultrasound of the penis
Dynamic duplex ultrasound (US) of the penis is a second-level diagnostic test that specifically studies the haemodynamic pathophysiology of erectile function. Therefore, in clinical practice, it is usually applied in those conditions in which a potential vasculogenic aetiology of ED (e.g., diabetes mellitus, renal transplantation, multiple concomitant CV risk factors and/or overt peripheral vascular disease, and poor responders to oral therapy) is suspected. Peak systolic blood flow > 30 cm/s, end-diastolic velocity < 3 cm/s and resistance index > 0.8 are considered normal [446, 447]. Recent data suggest that duplex scanning as a haemodynamic study may be better at tailoring therapy for ED, such as for low-intensity shock wave treatment (LI-SWT) and for diagnosing vasculogenic ED [448]. Further vascular investigation is unnecessary if a duplex US examination is normal.

5.5.4 Arteriography and dynamic infusion cavernosometry or cavernosography
Pudendal arteriography should be performed only in patients who are being considered for penile revascularisation [449]. Recent studies have advocated the use of computed tomography (CT) angiography as a diagnostic procedure prior to penile artery angioplasty for patients with ED and isolated penile artery stenosis [450]. Nowadays, dynamic infusion cavernosometry or cavernosography are infrequently used tools for diagnosing venogenic ED.
5.5.5 *Psychopathological and psychosocial assessment*

Mental health issues and psychological distress are frequently comorbid with ED [451]. This is most evident for depression and anxiety related disorders, but may also include transitory states of altered mood (i.e., dysfunctional affective states resulting from a specific life stressor or crisis) [338, 452, 453]. Relationship factors, including lack of satisfaction with the partner, poor sexual relationships, length of the relationship, or feeling emotionally disconnected from the partner during sex, have been related to erectile difficulties and dysfunction [452, 454, 455]. In contrast, intimacy was found to be a protective factor in ED [329, 456]. Additionally, the cognitive factors underpinning organic and non-organic ED must also be assessed. Cognitive factors include male dysfunctional thinking styles and expectations about sexuality and sexual performance. These expectations result from the sexuality norms and stereotypes, shared by a given culture. Expectations emphasising high sexual performance in men, result in anxiety, which acts as a maintenance factor for ED [457, 458]. Unrealistic expectations about male sexual performance may further align with internal causal attributions regarding the loss of erection (i.e., men attribute the loss of erection to themselves [sense of personal inadequacy]), thereby worsening ED [457, 459]. Likewise, poor self-esteem and cognitive distraction from erotic cues, are expected to negatively affect ED [460, 461].

Psychosexual assessment in ED cases include a clinical interview considering all the previous topics. Clinicians are expected to collect information on the individual’s psychopathological symptoms, life stressors, relationship dynamics, cognitive style, and cognitive distraction sources [460]. Also, self-reported measures are frequently used within the psychosocial context. These may include measurement scales such as the Brief Symptom Inventory [462] for measuring psychopathology symptoms, the Sexual Dysfunctional Beliefs Questionnaire [463] or the Sexual Modes Questionnaire [464] for measuring dysfunctional cognitive styles in men. It is worth noting that most literature follows a heteronormativity view. There is recent evidence suggesting that men who have sex with men present specific psychological risks associated with erectile capability regarding anal sex; minority stress, i.e. stress stemming from conflicting sexual identity, was associated with increased erectile difficulties in these men [465]. Therefore, professionals must tailor their assessment in the context of sexual minorities.

![Figure 5: Psychopathological and psychosocial assessment](image-url)

- Collect evidence for specific life stressors
- Evaluate psychosexual history and relationship factors
- Evaluate dysfunctional thinking style and expectations regarding sexuality and erectile function
- Decide on referral to (sexual) psychotherapy
- Include psychosexual aspects as outcomes for treatment efficacy
  - relationship/intimacy
  - sexual satisfaction
  - well-being
  - flexible thinking style and expectations
- Consider cultural background

5.6 Treatment of erectile dysfunction

5.6.1 Patient education - consultation and referrals

Educational intervention is often the first approach to sexual complaints, and consists of informing patients about the psychological and physiological processes involved in the individual’s sexual response, in ways the patient can understand. This first level approach has been shown to favour sexual satisfaction in men with ED [466]. Accordingly, consultation with the patient should include a discussion of the expectations and needs of the patient’s and their sexual partner. It should also review the patient’s and partner’s understanding of ED and the results of diagnostic tests, and provide a rationale for treatment selection [467]. Patient and partner education is an essential part of ED management [467, 468], and may prevent misleading information that can be at the core of dysfunctional psychological processes underpinning ED.

5.6.2 Treatment options

Based on the currently available evidence and the consensus of the Panel, a novel comprehensive therapeutic and decision-making algorithm (Figure 6) for treating ED, which takes into account the level of invasiveness of each therapy and its efficacy, has been presented. This newly-developed treatment algorithm was extensively discussed within the guidelines panel as an alternative to the traditional three-level concept, to better tailor a personalised therapy to individual patients, according to invasiveness, tolerability and effectiveness of the different therapeutic options and patients’ expectations. In this context, patients should be fully counselled with respect to all available treatment modalities.
Erectile dysfunction may be associated with modifiable or reversible risk factors, including lifestyle or drug-related factors [377]. These factors may be modified either before, or at the same time as, specific therapies are used. Likewise, ED may be associated with concomitant and underlying conditions (e.g., endocrine disorders and metabolic disorders such as diabetes, and some cardiovascular problems such as hypertension) which should always be well-controlled as the first step of any ED treatment [469]. Major clinical potential benefits of lifestyle changes may be achieved in men with specific co-morbid CV or metabolic disorders, such as diabetes or hypertension [377, 470].

As a rule, ED can be treated successfully with current treatment options, but it cannot be cured. The only exceptions are psychogenic ED, post-traumatic arteriogenic ED in young patients, and hormonal causes (e.g., hypogonadism) [53, 432], which potentially can be cured with specific treatments. Most men with ED are not treated with cause-specific therapeutic options. This results in a tailored treatment strategy that depends on invasiveness, efficacy, safety and cost, as well as patient preference [467]. In this context, physician-patient (partner, if available) dialogue is essential throughout the management of ED. Interesting insights come from a recent systematic review that showed a consistent discontinuation rate for all available treatment options (4.4-76% for PDE5Is; 18.6-79.9% for intracavernous injections; 32-69.2% for urethral suppositories; and 30% for penile prostheses). Men’s beliefs about ED treatment, therapeutic ineffectiveness, adverse effects, quality of men’s intimate relationships and treatment costs are the most prevalent barriers to treatment actual use [471].
**5.6.2.1 Oral pharmacotherapy**

Four potent selective PDE5Is have been approved by the EMA for treatment of ED [472]. Phosphodiesterase type 5 catalyses the hydrolysis of the second messenger cyclic guanosine monophosphate (cGMP) in the cavernous tissue; cGMP is involved in intra-cellular signalling pathways of cavernous smooth muscle. Accumulation of cGMP sets in motion a cascade of events at the intracellular level, which induces a loss of

---

*ED* = erectile dysfunction; *PDE5Is* = phosphodiesterase type 5 inhibitors; *LI-SWT* = low-intensity shockwave therapy.
contractile tone of the penile vessels by lowering cytosolic Ca²⁺. Nitric oxide (NO) has an essential role in promoting the formation of cGMP and other pathways leading to corporeal smooth muscle relaxation and erection of the penis [469, 473]. This is associated with increased arterial blood flow, eventually leading to compression of the sub-tunical venous plexus followed by erection [474]. Since they are not initiators of erection, PDE5Is require sexual stimulation to facilitate an erection. Efficacy is defined as an erection, with rigidity, sufficient for satisfactory intercourse [469].

Sildenafil
Sildenafil was launched in 1998 and was the first PDE5I available on the market [475]. It is administered in doses of 25, 50 and 100 mg. The recommended starting dose is 50 mg and should be adapted according to the patient’s response and adverse effects [475]. Sildenafil is effective 30-60 minutes after administration [475]. Its efficacy is reduced after a heavy, fatty meal due to delayed absorption. Efficacy may be maintained for up to 12 hours [476]. The pharmacokinetic profile for sildenafil is presented in Table 14. Adverse events (Table 15) are generally mild in nature and self-limited by continuous use. Pharmacokinetic data for sildenafil are presented in Table 14. Adverse effects (Table 15) are generally mild in nature and self-limited by continuous use. In pre-marketing studies, after 12 weeks of treatment in a dose-response study, improved erections were reported by 56%, 77% and 84% in a general ED population taking 25, 50 and 100 mg sildenafil, respectively, compared to 25% of men taking placebo [479]. Sildenafil significantly improved patient scores for IIEF, sexual encounter profile question 2 (SEP2), SEP question 3 (SEP3) and General Assessment Questionnaire (GAQ) and treatment satisfaction. The efficacy of sildenafil in almost every subgroup of patients with ED has been successfully established, irrespective of age [480]. Recently, an orally disintegrating tablet (ODT) of sildenafil citrate at a dose of 50 mg has been developed, mainly for patients who have difficulty swallowing solid dosage forms.

Tadalafil
Tadalafil was licensed for treatment of ED in February 2003 and is effective from 30 minutes after administration, with peak efficacy after about 2 hours [481]. Efficacy is maintained for up to 36 hours [481] and is not affected by food [482]. Usually, tadalafil is administered in on-demand doses of 10 and 20 mg or a daily dose of 5 mg. The recommended on-demand starting dose is 10 mg and should be adapted according to the patient’s response and adverse effects [481, 483]. Pharmacokinetic data for tadalafil are presented in Table 14. Adverse effects (Table 15) are generally mild in nature and self-limited by continuous use. In pre-marketing studies, after 12 weeks of treatment in a dose-response study, improved erections were reported by 67% and 81% of men with ED taking 10 and 20 mg tadalafil, respectively, compared to 35% of men in the placebo control group [481]. Tadalafil significantly improves patient scores for IIEF, SEP2, SEP3, and GAQ and treatment satisfaction [481].

Efficacy of tadalafil has been confirmed in post-marketing studies [472, 484] and in almost every subgroup of patients with ED, including difficult-to-treat subgroups (e.g., diabetes mellitus) [485]. Tadalafil has also been shown to have a net clinical benefit in the short-term on ejaculatory and orgasmic functions in ED patients [486]. Daily tadalafil 5 mg has also been approved and licensed as a monotherapy in men with BPH-related LUTS, due to its ability to significantly improve urinary symptoms [487]. Therefore, its use may be considered in patients with ED patients also complaining of concomitant LUTS, and wishing to benefit from a single therapy [488]. Data have confirmed that 40% of men aged > 45 years were combined responders for ED and LUTS/BPH to treatment with tadalafil 5 mg once daily, with symptom improvement after 12 weeks [489]. To date, the main limitation on the use of daily tadalafil 5 mg as a combined therapy for both ED and LUTS is conditioned by the fact that no data are available in terms of efficacy and tolerability beyond 12 months of treatment.

Vardenafil
Vardenafil became commercially available in March 2003 and is effective from 30 minutes after administration [490], with one of three patients achieving satisfactory erections within 15 minutes of ingestion [491]. Its effect is reduced by a heavy, fatty meal. Doses of 5, 10 and 20 mg have been approved for on-demand treatment of ED. The recommended starting dose is 10 mg and should be adapted according to the patient’s response and adverse effects [492]. Pharmacokinetic data for vardenafil are presented in Table 14. Adverse events (Table 15) are generally mild in nature and self-limited by continuous use [492]. After 12 weeks in a dose-response study, improved erections were reported by 66%, 76% and 80% of men with ED taking 5, 10 and 20 mg vardenafil, respectively, compared with 30% of men taking placebo [492, 493]. Vardenafil significantly improved patient scores for IIEF, SEP2, SEP3, and GAQ and treatment satisfaction.

Efficacy has been confirmed in post-marketing studies [492, 493]. The efficacy of vardenafil in almost every subgroup of patients with ED, including difficult-to-treat subgroups (e.g., diabetes mellitus), has been successfully established. An orodispersable tablet (ODT) formulation of vardenafil has been released [493]. Orodispersible tablet formulations offer improved convenience over film-coated formulations and...
may be preferred by patients. Absorption is unrelated to food intake and they exhibit better bio-availability compared to film-coated tablets [494]. The efficacy of vardenafil ODT has been demonstrated in several RCTs and did not seem to differ from the regular formulation [494-496].

Avanafil
Avanafil is a highly-selective PDE5I that became commercially available in 2013 [497]. Avanafil has a high ratio of inhibiting PDE5 as compared with other PDE subtypes, ideally allowing for the drug to be used for ED while minimising adverse effects (although head-to-head comparisons are not yet available) [498]. Doses of 50, 100 and 200 mg have been approved for on-demand treatment of ED [497]. The recommended starting dose is 100 mg taken as needed 15-30 minutes before sexual activity and the dose may be adapted according to efficacy and tolerability [497, 499, 500]. In the general population with ED, the mean percentage of attempts resulting in successful intercourse was approximately 47%, 58% and 59% for the 50, 100 and 200 mg groups, respectively, as compared with ~28% for placebo [497, 499]. Data from sexual attempts made within 15 minutes of treatment showed successful attempts in 64%, 67% and 71% of cases treated with avanafil 50, 100 and 200 mg, respectively. Dose adjustments are not warranted based on renal function, hepatic function, age or sex [499]. Pharmacokinetic data for avanafil are presented in Table 14 [497, 499]. Adverse effects are generally mild in nature (Table 15) [497, 499]. Pairwise meta-analytic data from available studies have suggested that avanafil significantly improved patient scores for IIEF, SEP2, SEP3 and GAQ, with an evident dose-response relationship [497, 501]. Administration with food may delay the onset of effect compared with administration in a fasting state but avanafil can be taken with or without food [502]. The efficacy of avanafil in many groups of patients with ED, including difficult-to-treat subgroups (e.g., diabetes mellitus), has been successfully established. As for dosing, 36.4% (28 of 77) of sexual attempts (SEP3) at ≤ 15 minutes were successful with avanafil vs. 4.5% (2 of 44) after placebo (P < 0.01) [503]. A recent meta-analysis confirmed that avanafil had comparable efficacy with sildenafil, vardenafil and tadalafil [502].

Choice or preference among the different PDE5Is
To date, no data are available from double- or triple-blind multicentre studies comparing the efficacy and/or patient preference for the most-widely available PDE5Is (i.e., sildenafil, tadalafil, vardenafil, and avanafil). Choice of drug depends on frequency of intercourse (occasional use or regular therapy, 3-4 times weekly) and the patient’s personal experience. Patients need to know whether a drug is short- or long-acting, its possible disadvantages, and how to use it. Two different network meta-analyses demonstrated that ED patients who prioritise high efficacy must use sildenafil 50 mg whereas those who optimise tolerability should initially use tadalafil 10 mg and switch to Udenafil 100 mg if the treatment is not sufficient (however, Udenafil 100 mg is not EMA or US Food and Drug Administration approved and is not available in Europe) [484, 504]. The results of another clinical trial have revealed that tadalafil 5 mg once daily may improve erectile function among men who have a partial response to on-demand PDE5I therapy [505].

Continuous use of PDE5Is
From a pathophysiological standpoint, animal studies have shown that chronic use of PDE5Is significantly improves or prevents the intracavernous structural alterations caused by age, diabetes or surgical damage [506-510]. No data exist in humans. In humans, a RCT has shown that there is no clinically beneficial effect on endothelial dysfunction measured by flow-mediated dilation deriving from daily tadalafil when compared to placebo [511]. From a clinical standpoint, in 2007, tadalafil 2.5 and 5 mg/day were approved by the EMA for treatment of ED. According to the EMA, a once-daily regimen with tadalafil 2.5 or 5 mg might be considered suitable, based on patients’ choice and physicians’ judgement. In these patients, the recommended dose is 5 mg, taken once daily at approximately the same time. Overall, tadalafil, 5 mg once daily, provides an alternative to on-demand tadalafil for couples who prefer spontaneous rather than scheduled sexual activities or who anticipate frequent sexual activity, with the advantage that dosing and sexual activity no longer need to be linked. Overall, treatment with tadalafil 5 mg once daily in men complaining of ED of various severities is well-tolerated and effective [512].

An integrated analysis showed that, regardless of the type of ED population, there is no clinically significant difference between a tadalafil treatment administered with continuous (once daily) vs. on-demand regimen [511]. The appropriateness of the continuous use of a daily regimen should be re-assessed periodically [512, 513].

Safety issues for PDE5Is

(i) Cardiovascular safety
Clinical trial results for the four PDE5Is and post-marketing data of sildenafil, tadalafil, and vardenafil have demonstrated no increase in myocardial infarction rates in patients receiving PDE5Is, as part of either RCTs or open-label studies, or compared to expected rates in age-matched male populations. None of the PDE5Is has an adverse effect on total exercise time or time-to-ischaemia during exercise testing in men with stable angina [472, 514]. Chronic or on-demand use is well-tolerated with a similar safety profile. The prescription of all PDE5Is in patients with CVD or in those with high CV risk should be based on the recommendations of the 3rd Princeton Consensus Panel [440].

(ii) Contraindication for the concomitant use of organic nitrates
An absolute contraindication to PDE5Is is use of any form of organic nitrate (e.g., nitroglycerine, isosorbide mononitrate, and isosorbide dinitrate) or NO donors (e.g., other nitrate preparations used to treat angina, as well as amyl nitrite or amyl nitrate such as “poppers” that are used for recreation). They result in cGMP accumulation and unpredictable falls in blood pressure and symptoms of hypotension. The duration of interaction between organic nitrates and PDE5Is depends upon the PDE5I and nitrate used. If a PDE5I is taken and the patient develops chest pain, nitroglycerine must be withheld for at least 24 hours if sildenafil (and probably also vardenafil) is used (half-life, 4 hours), or at least 48 hours if tadalafil is used (half-life, 17.5 hours), and for no less than 12 hours if avanafil is used (half-life, 6-17 hours) [515-518].

(iii) Use caution with antihypertensive drugs
Co-administration of PDE5Is with antihypertensive agents (e.g., angiotensin-converting enzyme inhibitors, angiotensin-receptor blockers, calcium blockers, β-blockers, and diuretics) may result in small additive decreases in blood pressure, which are usually minor [440]. In general, the adverse event profile of a PDE5I is not worsened by a background of antihypertensive medication, even when the patient is taking several antihypertensive agents [519].

(iv) Interaction with Nicorandil
In vitro studies in animals suggest that the potassium channel opener nicorandil may potentiate the vasorelaxation induced by isoproterenol in isolated rat aorta by increasing cyclic GMP levels [520]. This may be due to the nitric oxide donating properties of nicorandil. Therefore, concurrent use of nicorandil and PDE5Is is also contraindicated.
**α-Blocker interactions**

Tadalafil 5 mg is currently the only licensed drug for the treatment of both ED and LUTS with level 1 evidence confirming its overall good efficacy in relieving urinary symptoms and improving erectile function [488]. As such, this treatment should be considered in patients suffering from mild to moderate LUTS associated with ED either alone or in combination with alpha-blockers. To this regard, given that both drugs are vasodilators with a potential risk of hypotension, historically there has always been caution in the combination of alpha-blockers and PDE5I (any) because of the fear of possible cumulative effects on blood pressure, based on the evidence from some individual studies that reported the tolerability of combination therapy [476, 491, 521]. However, a recent meta-analysis concluded that a concomitant treatment with α-blockers [both non-uroselective (e.g., terazosin and doxazosin) and uro-selective (e.g., alfuzosin, tamsulosin and silodosin) and PDE5Is may produce changes in haemodynamic parameters, but it does not increase the rate of adverse events due to hypotension [520]. Therefore, there is no current limitation in the simultaneous use of α-blockers and PDE5I, prioritising the use of uro-selective drugs in order to further minimise the risk of dizziness or other adverse events, thus including hypotension.

**Dosage adjustment**

Drugs that inhibit the CYP34A pathway inhibit the metabolic breakdown of PDE5Is, thus increasing PDE5Is blood levels (e.g., ketoconazole, ritonavir, atazanavir, clarithromycin, indinavir, itraconazole, nefazodone, neflinavir, saquinavir and telithromycin). Therefore, lower doses of PDE5Is are necessary. However, other agents, such as rifampin, phenobarbital, phenytoin and carbamazepine, may induce CYP3A4 and enhance the breakdown of PDE5Is, so that higher doses of PDE5Is are required. Severe kidney or hepatic dysfunction may require dose adjustments or warnings.

**Management of non-responders to PDE5Is**

The two main reasons why patients fail to respond to a PDE5I are either incorrect drug use or lack of efficacy. Data suggest that an adequate trial involves at least six attempts with a particular drug [522]. The management of non-responders depends upon identifying the underlying cause [523].

Check that the medication has been properly prescribed and correctly used. The main reason why patients fail to use their medication correctly is inadequate counselling from their physician. The most common causes of incorrect drug use are: i) failure to use adequate sexual stimulation; ii) failure to use an adequate dose; and, iii) failure to wait an adequate amount of time between taking the medication and attempting sexual intercourse.

Check that the patient has been using a licensed medication. There is a large counterfeit market in PDE5Is. The amount of active drug in these medications varies enormously and it is important to check how and from which source the patient has obtained his medication.

PDE5I action is dependent on the release of NO by the parasympathetic nerve endings in the erectile tissue of the penis. The usual stimulus for NO release is sexual stimulation, and without adequate sexual stimulation (and NO release), the medication is ineffective. Furthermore, the reduced production of NO that occurs in diabetic patients due to peripheral neuropathy, is thought to be the justification for the higher failure rate of PDE5Is in this category of patients. Oral PDE5Is take different times to reach maximal plasma concentrations (C_{max}) [476, 478, 494, 501, 524-526]. Although pharmacological activity is achieved at plasma levels below the maximal plasma concentration, there will be a period of time following oral ingestion of the medication during which the drug is ineffective. Even though all four drugs have an onset of action in some patients within 15-30 minutes of oral ingestion [478, 494, 524-526], most patients require a longer delay between taking the medication [492, 501, 527, 528]. Absorption of both sildenafil and vardenafil can be delayed by a heavy, fatty meal [529]. Absorption of tadalafil is less affected, and food has negligible effects on its bioavailability [524]. When avanafil is taken with a high-fat meal, the rate of absorption is reduced with a mean delay in T_{max} of 1.25 hours and a mean reduction in C_{max} of 39% (200 mg). There is no effect on the extent of exposure (area under the curve). The small changes in avanafil C_{max} are considered to be of minimal clinical significance [497, 498, 501].

It is possible to wait too long after taking the medication before attempting sexual intercourse. The half-life of sildenafil and vardenafil is ~4 hours, suggesting that the normal window of efficacy is 6-8 hours following drug ingestion, although responses following this time period are recognised. The half-life of avanafil is 6-17 hours. Tadalafil has a longer half-life of ~17.5 hours, so the window of efficacy is longer at ~36 hours. Data from uncontrolled studies suggest patient education can help salvage an apparent non-responder to a PDE5I [523, 530-533]. After emphasising the importance of dose, timing, and sexual stimulation to the patient, erectile function can be effectively restored following re-administration of the relevant PDE5I [523, 530, 531].
A systematic review has addressed the association between genetic polymorphism, especially those encoding endothelial nitric oxide synthase, and the variability in response to PDE5Is [534]. Similar recent data have suggested that response to sildenafil treatment is also dependent on polymorphism in the PDE5A gene, which encodes the principal cGMP-catalysing enzyme in the penis, regulating cGMP clearance, and it is the primary target of sildenafil [535-537].

**Clinical strategies in patients correctly using a PDE5Is**

Overall, treatment goals should be individualised to restore sexual satisfaction for patients and/or couples, and improve QoL based on patients’ expressed needs and desires [538]. In this context, data suggests that almost half of patients abandon first-generation PDE5Is within 1 year, with no single specific factor playing a major role in dropout rates [539].

Uncontrolled trials have demonstrated that hypogonadal patients not responding to PDE5Is may improve their response to PDE5Is after initiating testosterone therapy [53, 469, 540]. Therefore, in the real-life setting most patients with ED will first be prescribed a PDE5i, which is usually effective; however, if diagnostic criteria suggestive for testosterone deficiency are present, testosterone therapy may be more appropriate even in ED patients [5, 53].

Modification of other risk factors may also be beneficial, as previously discussed. Limited data suggest that some patients might respond better to one PDE5i than to another [541], and although these differences might be explained by variations in drug pharmacokinetics, they do raise the possibility that, despite an identical mode of action, switching to a different PDE5i might be helpful. However it is important to emphasise that the few randomised studies have shown any difference in clinical outcomes with different drugs and intake patterns in patients with classic ED [542] and in special populations such as people with diabetics [543].

In refractory, complex, or difficult-to-treat cases of ED patients a combination therapy should be considered as a first-line approach. Although the available data are still limited, combining PDE5Is with antioxidant agents, shockwave therapy or a vacuum erection device (VED) improves efficacy outcomes, without any significant increase in adverse events [544]. Similarly, the association of daily tadalafil with a short-acting PDE5I (such as sildenafil) leads to improved outcomes, without any significant increase in adverse effects [545].

### 5.6.2.2 Topical/Intraurethral alprostadil

The vasoactive agent alprostadil can be administered intraurethrally with two different formulations. The first delivery method is topical, using a cream that includes a permeation enhancer to facilitate absorption of alprostadil (200 and 300 μg) via the urethral meatus [546, 547]. Clinical data are still limited. Significant improvement compared to placebo was recorded for IIEF-EF domain score, SEP2 and SEP3 in a broad range of patients with mild-to-severe ED [548]. Adverse effects include penile erythema, penile burning, and pain that usually resolve within 2 hours of application. Systemic adverse effects are rare. Topical alprostadil (VITAROS™) at a dose of 300 μg is available in some European countries. Recently, a randomised cross-over clinical trial has shown that, compared to the standard administration route, direct delivery within the urethral meatus can increase efficacy and confidence among patients, without increasing adverse effects [549].

The second delivery method is by intra-urethral insertion of a specific formulation of alprostadil (125-1000 μg) in a medicated pellet (MUSE™) [229]. Erections sufficient for intercourse are achieved in 30-65.9% of patients. In clinical practice, it is recommended that intra-urethral alprostadil is initiated at a dose of 500 μg, as it has a higher efficacy than the 250 μg dose, with minimal differences with regard to adverse events. In case of unsatisfactory clinical response, the dose can be increased to 1000 μg [550-552]. The application of a constriction ring at the root of the penis may improve efficacy [551, 552].

Overall, the most common adverse events are local pain (29-41%) and dizziness with possible hypotension (1.9-14%). Penile fibrosis and priapism are rare (< 1%). Urethral bleeding (5%) and urinary tract infections (0.2%) are adverse events related to the mode of administration. Efficacy rates are significantly lower than for intracavernous pharmacotherapy [553], with ~30% adherence to long-term therapy. Intraurethral pharmacotherapy provides an alternative to intracavernous injections in patients who prefer a less-invasive, although less- efficacious treatment.

### 5.6.2.3 Shockwave therapy

The use of LI-SWT has been increasingly proposed as a treatment for vasculogenic ED over the last decade, being the only currently marketed treatment that might offer a cure, which is the most desired outcome for most men suffering from ED [448, 554-561].

Overall, several single-arm trials have shown a beneficial effect of LI-SWT on patient-reported erectile function, but data from prospective randomised trials are conflicting, and many questions remain to be answered especially because of the heterogeneity among shockwave generators (i.e., electrohydraulic,
electromagnetic, piezoelectric and electropneumatic); type of shockwaves delivered (i.e., focused, linear, semi-focused and unfocused); set-up parameters (e.g., energy flux density and number of pulses per session) and treatment protocols (i.e., duration of treatment, number of sessions per week, total number of shockwave pulses delivered and penile sites of application) [562, 563]. In a recent trial trying to assess the best treatment parameters, no significant differences were observed between various energy flux density levels although a 0.10 mJ/mm² seems to perform slightly better than lower energies [564]. Most of the studies have suggested that LI-SWT can significantly increase the IIEF and EHS in patients with mild vasculogenic ED, although this improvement appears modest and the rates of patients reporting a satisfactory improvement range between 40-80% [448, 562]. Few studies have shown an improvement in penile haemodynamic parameters after LI-SWT, but the clinical meaning of this improvement remains unclear [562, 565]. Likewise, data suggest that LI-SWT could ameliorate erection quality even in patients with severe ED who are either PDE5is non-responders [559, 566, 567] or inadequate responders [568], thus reducing the immediate need for more invasive treatments. Treatment effect appears to be clinically evident starting from 1-3 months after treatment completion, with a subsequent progressive decrease of the achieved benefit in terms of erectile function over time, although some effects could be still detected up to 5 years after treatment [562, 564, 569]. Recently, the impact of LI-SWT has been also tested in the setting of penile rehabilitation after radical prostatectomy in 2 small, randomised trials showing only modest advantage compared to conventional PDE5is [570, 571].

Overall, larger prospective RCTs and longer-term follow-up data are necessary to provide clinicians with more confidence regarding the use and effectiveness of LI-SWT for ED. Further clarity is also needed in defining treatment protocols that can result in greater clinical benefits [572, 573].

As a whole, according to the available data and the novel treatment decision algorithm, LI-SWT may be offered to patients with vasculogenic ED, although they should be fully counselled before treatment.

5.6.2.4 Psychosocial intervention and therapy
Psychosocial interventions including different modalities (e.g., sexual skills training, marital therapy, psychosexual education) [466], and Cognitive and Behavioural Therapy (CBT - group or couple format), are recommended [460]. Cognitive and Behavioural Therapy is aimed at altering dysfunctional cognitive and behavioural patterns influencing ED, and increasing adjustment during the course of the disorder. Some of its techniques include identifying triggers preceding erectile difficulties, cognitive restructuring of dysfunctional thinking styles, learning coping skills aimed at dealing with erectile difficulties and emotional symptoms, improving communications skills with the partner, and relapse prevention. The CBT approach combined with medical treatment for ED has received empirical support and is considered an optimal procedure [574]. Moreover, there is preliminary evidence supporting the role of mindfulness-based therapy for ED and associated outcomes such as sexual satisfaction [575].

5.6.2.5 Hormonal treatment
The advice of an endocrinologist should be sought for managing patients with certain hormonal abnormalities or endocrinopathies [432]. Testosterone deficiency is either a result of primary testicular failure or secondary to pituitary/hypothalamic causes (e.g., a functional pituitary tumour resulting in hyperprolactinaemia) [432, 576]. When clinically indicated [577], testosterone therapy (intramuscular, transdermal, or oral) can be considered for men with low or low-normal testosterone levels and concomitant problems with their sexual desire, erectile function and dissatisfaction derived from intercourse and overall sex life (see Section 3.6 for a comprehensive discussion of testosterone therapy).

5.6.2.6 Vacuum erection devices
Vacuum erection devices (VED) provide passive engorgement of the corpus cavernosum, together with a constrictor ring placed at the base of the penis to retain blood within the corpus. Published data report that efficacy, in terms of erections satisfactory for intercourse, is as high as 90%, regardless of the cause of ED and satisfaction rates range between 27% and 94% [578, 579]. Most men who discontinue use of VEDs do so within 3 months. Long-term use of VEDs decreases to 50-64% after 2 years [580]. Treatment effect appears to be clinically evident starting from 1-3 months after treatment completion, with a subsequent progressive decrease of the achieved benefit in terms of erectile function over time, although some effects could be still detected up to 5 years after treatment [562, 564, 569]. Recently, the impact of LI-SWT has been also tested in the setting of penile rehabilitation after radical prostatectomy in 2 small, randomised trials showing only modest advantage compared to conventional PDE5is [570, 571].

Overall, larger prospective RCTs and longer-term follow-up data are necessary to provide clinicians with more confidence regarding the use and effectiveness of LI-SWT for ED. Further clarity is also needed in defining treatment protocols that can result in greater clinical benefits [572, 573].

As a whole, according to the available data and the novel treatment decision algorithm, LI-SWT may be offered to patients with vasculogenic ED, although they should be fully counselled before treatment.

5.6.2.7 Intracavernous injections therapy
Intracavernous administration of vasoactive drugs was the first medical treatment introduced for ED [533, 584]. According to invasiveness, tolerability, effectiveness and patients’ expectations (Figure 6), patients may be offered intracavernous injections. The success rate is high (85%) [553, 585].
5.6.2.7.1 Alprostadil

Alprostadil (Caverject™, Edex/Viridal™) was the first and only drug approved for intracavernous treatment of ED [533, 586]. Intracavernous alprostadil is most efficacious as a monotherapy at a dose of 5-40 μg (40 μg may be offered off label in some European countries). The erection appears after 5-15 minutes and lasts according to the dose injected, but with significant heterogeneity among patients. An office-training programme is required for patients to learn the injection technique. In men with limited manual dexterity, the technique may be taught to their partners. The use of an automatic pen that avoids a view of the needle may be useful to resolve fear of penile puncture and simplifies the technique.

Efficacy rates for intracavernous alprostadil of > 70% have been found in the general ED population, as well as in patient subgroups (e.g., men with diabetes or CVD), with reported satisfaction rates of 87-93.5% in patients and 86-90.3% in partners after the injections [533, 584]. Complications of intracavernous alprostadil include penile pain (50% of patients reported pain only after 11% of total injections), excessively-prolonged undesired erections (5%), priapism (1%), and fibrosis (2%) [533, 584, 587]. Pain is usually self-limited after prolonged use and it can be alleviated with the addition of sodium bicarbonate or local anaesthesia [533, 584, 588]. Cavernosal fibrosis (from a small haematoma) usually clears within a few months after temporary discontinuation of the injection programme. However, tunical fibrosis suggests early onset of Peyronie's disease and may indicate stopping intracavernous injections indefinitely. Systemic adverse effects are uncommon. The most common is mild hypotension, especially when using higher doses. Contraindications include men with a history of hypersensitivity to alprostadil, men at risk of priapism, and men with bleeding disorders. Despite these favourable data, drop-out rates of 41-68% have been reported for intracavernous pharmacotherapy [533, 584, 589, 590], with most drop-outs occurring within the first 2-3 months. In a comparative study, alprostadil monotherapy had the lowest discontinuation rate (27.5%) compared to overall drug combinations (37.6%), with an attrition rate after the first few months of therapy of 10% per year [591]. Reasons for discontinuation included desire for a permanent mode of therapy (29%), lack of a suitable partner (26%), poor response (23%) (especially among early drop-out patients), fear of needles (23%), fear of complications (22%), and lack of spontaneity (21%). Careful counselling of patients during the office-training phase as well as close follow-up are important in addressing patient withdrawal from an intracavernous injection programme [592-594].

5.6.2.7.2 Combination therapy

Table 16 details the available intracavernous injection therapies (compounds and characteristics). Combination therapy enables a patient to take advantage of the different modes of action of the drugs being used, as well as alleviating adverse effects by using lower doses of each drug.

- Papaverine (20-80 mg) was the first oral drug used for intracavernous injections. It is most commonly used in combination therapy because of its high incidence of adverse effects as monotherapy. Papaverine is currently not licensed for treatment of ED.
- Phentolamine has been used in combination therapy to increase efficacy. As monotherapy, it produces a poor erectile response.
- Sparse data in the literature support the use of other drugs, such as vasoactive intestinal peptide (VIP), NO donors (linsidomine), forskolin, potassium channel openers, moxisylyte or calcitonin gene-related peptide, usually combined with the main drugs [595, 596]. Most combinations are not standardised and some drugs have limited availability worldwide.
- Bimix, Trimix: papaverine (7.5-45 mg) plus phentolamine (0.25-1.5 mg) (also known as Bimix), and papaverine (8-16 mg) plus phentolamine (0.2-0.4 mg) plus alprostadil (10-20 μg) (also known as Trimix), have been widely used with improved efficacy rates, although they have never been licensed for ED [597, 598]. Trimix has the highest efficacy rates, reaching 92%; this combination has similar adverse effects as alprostadil monotherapy, but a lower incidence of penile pain due to lower doses of alprostadil. However, fibrosis is more common (5-10%) when papaverine is used (depending on total dose).
- Invicorp™: Vasoactive intestinal peptide (25 μg) plus phentolamine mesylate (1-2 mg Invicorp), currently licensed in Scandinavia, is a combination of two active components with complementary modes of action. Clinical studies have shown that the combination is effective for intracavernous injections in > 80% of men with ED, including those who have failed to respond to other therapies and, unlike existing intracavernous therapies, is associated with a low incidence of penile pain and a virtually negligible risk of priapism [599].

Despite high efficacy rates, 5-10% of patients do not respond to combination intracavernous injections. The combination of sildenafil with intracavernous injection of the triple combination regimen may salvage as many as 31% of patients who do not respond to the triple combination alone [600]. However, combination therapy is associated with an increased incidence of adverse effects in 33% of patients, including dizziness in 20% of patients. This strategy can be considered in carefully selected patients before proceeding to a penile implant.
There are currently several potential novel treatment modalities for ED, from innovative vasoactive agents and trophic factors to stem cell therapy and gene therapy. Most of these therapeutic approaches require further investigation in large-scale, blinded, placebo-controlled randomised studies to achieve adequate evidence-based and clinically-reliable recommendation grades [601-606]. A recent systematic review has concluded that five completed human clinical trials have shown promise for stem cell therapy as a restorative treatment for ED [607].

5.6.2.8 Other treatments
5.6.2.8.1 Platelet-Rich Plasma
The interest toward regenerative medicine for ED has significantly increased in the last decade [608]. Among these, intracavernous injection of platelet-rich plasma (PRP) has been recently investigated in several prospective and retrospective trials [609-615]. Platelet-rich plasma is obtained by centrifugation of patient autologous blood with subsequent extraction of a plasma fraction containing 3-7 times mean platelet concentration compared to the whole blood. The regenerative effect of PRP is deemed to be exerted through the high concentrations of platelets containing several growth factors including VEGF, EGF, IGF-1, PDGF and FGF [616]. These factors may be responsible for angiogenesis stimulation and stem cell recruitment [616]. Pre-clinical studies have shown a neuro-regenerative effect and an improved penile vascularisation in both cavernous nerve injury and diabetic rat-model [617]. In the clinical setting, the use of PRP has been previously investigated in the field of orthopaedics, plastic surgery and dermatology. To date, one randomised placebo controlled-trial [615], two prospective randomised trials [611, 612], two prospective cohort [609, 614] and two retrospective studies [610, 613] investigated the effect of intracavernous injection of PRP for ED. Overall, available findings demonstrate favourable outcomes of PRP injections in terms of IIEF-5 and SEP scores and peak systolic velocity on penile-duplex ultrasound [617]. In the only randomised placebo-controlled trial, 60 patients with mild to moderate vasculogenic ED were randomised to receive two injections of 10 mL PRP (n=30) or placebo (n=30) [615]. At 1, 3 and 6-month follow-up, the rate of patients reporting an MCID improvement in the IIEF-EF score was significantly higher in the treatment group, with 69% achieving minimal clinically important differences (MCID) 6 months after PRP compared to 27% in the placebo group (p < 0.001). IIEF-EF scores improved by a mean of 2.7 points at 1-month and 3.9 points at 6-month assessment after treatment. Regarding safety, the mean VAS score was higher as compared with placebo (2.8 vs. 2.2, respectively, p = 0.008) but no haemorrhagic events or other side effects were reported [615]. Despite these encouraging results, the available evidence is still insufficient to provide a recommendation regarding the use of PRP for ED treatment in clinical practice. Indeed, current studies are limited by the low number of patients included (ranging from 10-100), the lack of placebo comparison (except for 1 small RCT) and the heterogeneity in terms of the modality of PRP preparation. The concentration of platelets and growth factors could vary

according to the system used for preparation [618] and there is a lack of consensus concerning the optimal platelet concentration as well as the need for combining PRP with activating agents such as CaCl2 or thrombin to maximise the growth factors release [617, 618]. Intracavernous injection of PRP should be used only in a clinical trial setting.

5.6.2.8.2 Herbal medicine and natural supplements
In recent years there has been an exponential growth in the market of medicinal herbs and natural supplements for the treatment of ED, but with very little available evidence of robust scientific data to support their efficacy and safety. Recently, a Cochrane review showed that ginseng may only have trivial effects on erectile function or satisfaction with intercourse compared to placebo when assessed using validated tools [619]. Moreover, data suggested that daily administration of oral L-arginine, only when in combination with PDE5i use, improves sexual function [620].

5.6.2.9 Erectile dysfunction after radical prostatectomy
Use of pro-erectile drugs following RP is important in achieving post-operative erectile function and to allow patients to resume sexual activity. There is also some evidence in animal studies that this may avoid cavernous fibrosis and maintain penile length. Several trials have shown improvements in erectile function after RP in patients receiving drugs (any therapeutic or prophylactic) for ED. Early compared with delayed erectile function treatment affects the natural recovery time for potency [621], although there is a lack of data to support any specific regimen, which is either optimal for penile rehabilitation or may result in the achievement of spontaneous, non-pharmacologically assisted erections [390, 622, 623]. In prospective studies, there has been no evidence that penile rehabilitation itself increases the chances of spontaneous recovery of erectile function in men following nerve-sparing RP (NSRP) [623]. The currently available therapeutic armamentarium follows the treatment algorithm for ED, which is shown in Figure 4.

Management of post-RP ED has been revolutionised by the advent of PDE5Is, with their demonstrated efficacy, ease of use, good tolerability, excellent safety, and positive impact on QoL. In this context, it must be emphasised that post-RP, ED patients are poor responders to PDE5Is. Since their launch on the market, PDE5Is have been considered as the first-line therapy in patients who have undergone NS surgery, regardless of the surgical technique used [390, 400]. Several clinical parameters have been identified as potential predictors of PDE5Is outcomes in men undergoing RP. Patient age, baseline erectile function, and quality of NS technique are key factors in preserving post-RP erectile function [400, 409, 624].

The response rate to sildenafil treatment for ED after RP in different trials has ranged from 35-75% among those who underwent NSRP and from 0-15% among those who underwent non-NSRP [400, 625]. Early use of high-dose sildenafil after RP is associated with preservation of smooth muscle within the corpus cavernosum [626]. A single study demonstrated that daily sildenafil also results in a greater return of spontaneous normal erectile function after RP compared to placebo following bilateral NSRP in patients who were fully potent before surgery [627]. Conversely, a more recent prospective, randomised, placebo-controlled study, which assessed the effects of nightly sildenafil citrate therapy during penile rehabilitation using nocturnal penile rigidity score in addition to the IIEF-EF domain showed no therapeutic benefit for nightly sildenafil when compared to on-demand dosing in recovery of erectile function post-prostatectomy [628].

A large multicentre trial in Europe and the USA investigated the effects of tadalafil in patients with ED following bilateral NSRP. Erectile function was improved in 71% of patients treated with 20 mg tadalafil versus 24% of those treated with placebo, while the rate of successful intercourse attempts was 52% with 20 mg tadalafil vs. 26% with placebo [629]. Moreover, a randomised, double-blind, double-placebo trial in men < 68 years of age and with normal pre-operative erectile function who underwent NSRP at 50 centres from nine European countries and Canada, compared tadalafil once daily with placebo [623]. Tadalafil was most effective for drug-assisted erectile function in men with ED following NSRP and data suggested a potential role for tadalafil once daily (provided early after surgery) in contributing to the recovery of post-operative erectile function and maintaining penile length [623]. Conversely, unassisted or spontaneous recovery of erectile function was not improved after cessation of active therapy for 9 months [623]. However, tadalafil once daily improved QoL post-operatively, both at double-blind and open label treatment periods [630].

Similarly, vardenafil has been tested in patients with ED following NSRP in a randomised, multicentre, prospective, placebo-controlled study [631]. Following bilateral NSRP, erectile function improved by 71% and 60% with 10 and 20 mg vardenafil, respectively. An extended analysis of the same cohort of patients showed the benefit of vardenafil compared to placebo in terms of intercourse satisfaction, hardness of erection, orgasmic function, and overall satisfaction with sexual experience [632]. A randomised, double-blind, double-dummy,
multicentre, parallel-group study in 87 centres across Europe, Canada, South Africa and the USA, compared on-demand and nightly dosing of vardenafil in men with ED following bilateral NSRP [622]. In patients whose pre-operative erectile function domain score was > 26, vardenafil was efficacious when used on demand [622].

A double-blind, placebo-controlled, parallel-group study in 298 patients with ED after bilateral NSRP randomised to 100 or 200 mg avanafil or placebo (30 minutes before sexual activity) for 12 weeks showed significantly greater increases in SEP2 and SEP3 as well as in mean change of IIEF erectile function domain score with 100 and 200 mg avanafil versus placebo (P < 0.01) [442].

A recent Cochrane review analysed data from eight RCTs [633]. It showed that scheduled PDE5I may have little or no effect on short-term (up to 12 months) self-reported potency when compared to placebo or no treatment. In this study, daily PDE5i made little to no difference in short- and long-term erectile function. The authors conclude that penile rehabilitation strategies using PDE5I following RP do not increase self-reported potency and erectile function compared to on-demand use. Therefore, daily PDE5Is result in little to no difference in both short- and long-term (> 12 months) self-reported potency when compared to scheduled use. Finally, at short-term follow-up, daily PDE5I may result in little or no effect on self-reported potency when compared to scheduled intra-urethral application of prostaglandin E1.

Historically, the treatment options for post-RP ED have included intracavernous injections [634], urethral micro-suppository [400, 635], VED [390, 400, 636, 637], and penile implants [400, 638, 639]. Intracavernous injections and penile implants had been suggested as second- and third-line treatments, respectively, when oral PDE5Is are not adequately effective or not suitable for post-operative patients [390, 640]. A meta-analysis had shown that the early use of VED has an excellent therapeutic effect on post-RP patients and no serious adverse effects, therefore it should be considered as a therapeutic alternative [641]. Recent findings from two network meta-analyses show that: i) Sildenafil 100 mg regular dose (once daily or nightly) is the optimum penile rehabilitation strategy to improve erectile function recovery rates after RP, while the on-demand dose of PDE5Is should not be considered and recommended as a penile rehabilitation strategy [642]; ii) the combination therapy with VED and PDE5Is offers clear advantages over monotherapy, thus this combined approach should be considered in the clinical management of penile rehabilitation after RP [643].

Findings from a systematic review had suggested that pelvic floor muscle training (PFMT) combined with biofeedback is a promising alternative to pharmacological treatments, although there is a need for future well-powered, rigorously designed RCTs to draw strong conclusions [644].

5.6.2.10 Surgical management
5.6.2.10.1 Surgery for post-traumatic arteriogenic ED
In young patients with pelvic or perineal trauma, surgical penile revascularisation has a 60-70% long-term success rate [582, 645]. The stenosis must be confirmed by penile pharmaco-arteriography. Corporeal veno-occlusive dysfunction is a contraindication to revascularisation and must be excluded by dynamic infusion cavernosometry or cavernosography.

5.6.2.10.2 Venous ligation surgery
Venous ligation surgery for veno-occlusive dysfunction is no longer recommended because of poor long-term results [645].

5.6.2.10.3 Penile prostheses
The surgical implantation of a penile prosthesis may be considered in patients who i) are not suitable for different pharmacotherapies or prefer a definitive therapy; and, ii) do not respond to pharmacological therapies (Figure 6) [646]. A systematic review addressing cause and duration of symptoms before implantation has shown that most men receiving a penile prosthesis have an organic cause of ED, with vascular disease, diabetes, and previous pelvic surgery/trauma being the most common [647]. Similar findings have been reported by a prospective registry of penile prostheses with > 3-year collection period in the UK; the three commonest aetiological factors for ED were diabetes, prostate surgery and Peyronie's disease [648]. The mean duration of ED symptoms before surgical intervention ranges from 3-6 six years [647].

The two currently available classes of penile implants include inflatable (two- and three-piece) and semi-rigid devices (malleable, mechanical and soft flexible) [400, 638, 649-651]. Patients may prefer the three-piece inflatable devices due to the more “natural” erections obtained, although no prospective RCTs have compared satisfaction rates with both types of implants. The two-piece inflatable prosthesis can be a viable option among patients who are deemed at high-risk of complications with reservoir placements (e.g., previous abdominal
surgery). Semi-rigid prostheses result in a firm penis, which may be manually placed in an erect or flaccid state and offer the advantage of a simple implant technique, as well as easy use for the patient [400, 638, 649, 650]. Conversely, they can have the disadvantage of unnatural persistent erection and reduced concealability [650, 652]. They may also be an option in men with limited manual dexterity.

There are two main surgical approaches for penile prosthesis implantation: peno-scrotal and infrapubic [649, 650, 652, 653]. The peno-scrotal approach has been suggested to provide an excellent exposure; afford proximal crural exposure, avoid dorsal nerve injury, and permit direct visualisation of pump placement. However, with this approach, the reservoir is either placed blindly into the retropubic space, which can result in visceral injury in patients with a history of major pelvic surgery (mainly radical cystectomy) or a separate incision in the abdomen is placed under direct vision. A recent systematic review comparing the satisfaction and complication rates of the different surgical approaches has shown that there is no specific advantage between the two, but rather it is recommended that surgeons have knowledge of both techniques and are capable of tailoring the incision strategy for complex cases [654]. Revision surgery is associated with poorer outcomes and may be more challenging. Regardless of the indication, prosthesis implantation has one of the highest satisfaction rates (92-100% in patients and 91-95% in partners) among the treatment options for ED with appropriate counselling [400, 638, 649, 655-663]. In patients with favourable oncological prognosis after RP for PCa, a contemporary surgery to treat both ED, with the implant of a penile prosthesis, and stress urinary incontinence (male sling or artificial urinary sphincter) is effective and durable and has an established and definitive role to address both problems [400, 638, 664-666]. Structured psychosexual counselling may improve sexuality and sexual well-being in both patients and their partners after penile implant surgery [667].

5.6.2.10.4 Penile prostheses implantation: complications

Historically, the two main complications of penile prosthesis implantation are mechanical failure and infection. Several technical modifications of the most commonly used three-piece prostheses (e.g., AMS 700CX/CXR™ and Titan Zero degree™) resulted in mechanical failure rates of < 5% after 5 years of follow-up [638, 668, 669]. Careful surgical techniques with appropriate antibiotic prophylaxis against Gram-positive and Gram-negative bacteria reduced infection rates to 2-3% with primary implantation in low-risk patients and in high-volume centres, although the definition of a high-volume centre still needs clarification [670-673]. The infection rate may be further reduced to 1-2% by implanting an antibiotic-impregnated prosthesis (AMS Inhibizone™) or hydrophilic-coated prosthesis (Coloplast Titan™) [638, 670, 674-677]. Methods that decrease infections include using coated prostheses and strictly adhering to surgical techniques that avoid prolonged wound exposure and skin contact minimisation (i.e., no-touch technique).

Techniques that might prevent penile prostheses infection but lack definitive evidence include the use of prolonged post-operative antibiotics (> 24 hours), shaving with clippers, and preparation with chlorhexidine-alcohol [678, 679]. Identification and pre-treatment of patients who are colonised with nasal Staphylococcus aureus with mupirocin and chlorhexidine prior to surgery has been shown to reduce the incidence of post-operative surgical site infection from 4.4% to 0.9% in a placebo-controlled randomised trial [680]. On the whole, growing evidence suggests that the risk of penile prosthesis infection has reduced over the last few decades with device improvement and surgical expertise [681].

Higher-risk populations include patients undergoing revision surgery, those with impaired host defences (immunosuppression, diabetes mellitus, or spinal cord injury) or those with penile corporal fibrosis [638, 649, 671, 682-684]. A recent large database-study has shown that diabetes mellitus is a risk factor for penile prostheses infection, highlighting the need for optimal patient selection other than raising the question of whether lowering this risk by optimising glycaemic control before surgery [685]. Unfortunately, there are no RCTs determining the ideal and/or correct threshold of glycated haemoglobin that is acceptable prior to implant surgery in diabetic patients [686]. Recently, a large-cohort, multicentre, retrospective analysis in men with diabetes who received a Coloplast Titan™ implant demonstrated that vancomycin + gentamicin was the most efficacious combination of antibiotics used for implants dipping in terms of preventing postoperative infection and subsequent explantation and revision [687, 688].

Infection requires removal of the prosthesis and antibiotic administration. Alternatively, removal of the infected device with immediate salvage and replacement with a new prosthesis has been described using a wash-out protocol with successful salvages achieved in > 80% of cases [671, 683, 689, 690]. An absolute recommendation on how to proceed after explantation in this setting cannot be given and must be focused on the pros and cons of salvage therapy after full consultation with the patient. The majority of revisions are secondary to mechanical failure and combined erosion or infection [676, 678]. Ninety-three percent of cases are successfully revised, providing functioning penile prosthesis [671, 676, 689, 691, 692].
Besides infection and mechanical failure, impending erosion involving the distal corpora, urethra, glans or other structures can occur in 1-6% of cases after surgery [693]. Similarly, glans ischaemia and necrosis have been reported in about 1.5% of patients [693, 694]. Risk factors for these serious complications are higher in those patients with significant vascular impairment, such as patients with diabetes, or who have undergone concomitant lengthening procedures. Therefore, performing dual procedures at the time of implantation should be limited to mitigate the risks of serious complications.

5.6.2.10.5 Conclusions about penile prostheses implantation

Penile implants are an effective solution, usually for patients who do not respond to more conservative therapies. There is sufficient evidence to recommend this approach in patients not responding to less-invasive treatments due to its high efficacy, safety and satisfaction rate [695]. There are also currently no head to head studies comparing the different manufacturers’ implants, demonstrating superiority of one implant type over another [696].

Pro-erectile treatments should start at the earliest opportunity after radical prostatectomy/pelvic surgery and other curative treatments for prostate cancer. | Weak

5.6.4 **Follow-up**
Follow-up is important in order to assess efficacy and safety of the treatment provided. It is also essential to assess patient satisfaction since successful treatment for ED goes beyond efficacy and safety. Physicians must be aware that there is no single treatment that fits all patients or all situations as described in detail in the previous section.

### 6. DISORDERS OF EJACULATION

#### 6.1 Introduction
Ejaculation is a complex physiological process that comprises emission and expulsion processes and is mediated by interwoven neurological and hormonal pathways [697]. Any interference with those pathways may cause a wide range of ejaculatory disorders (Table 18).

#### 6.2 Premature ejaculation

##### 6.2.1 Epidemiology
Historically, the main problem in assessing the prevalence of PE has been the lack of a universally recognised definition at the time that surveys were conducted [192]. See Section 4.2 for a comprehensive discussion about epidemiology of PE.

##### 6.2.2 Pathophysiology and risk factors
The aetiology of PE is unknown, with few data to support suggested biological and psychological hypotheses, including anxiety [698-702], penile hypersensitivity [703-709] and 5-hydroxytryptamine (HT) receptor dysfunction [710-715]. The classification of PE into four subtypes [201] has contributed to a better delineation of lifelong, acquired, variable and subjective PE [716-718]. It has been hypothesised that the pathophysiology of lifelong PE is mediated by a complex interplay of central and peripheral serotonergic, dopaminergic, oxytocinergic, endocrinological, genetic and epigenetic factors [719]. Acquired PE may occur due to psychological problems - such as sexual performance anxiety, and psychological or relationship problems - and/or co-morbidity, including ED, prostatitis and hyperthyroidism [720-722].

A significant proportion of men with ED also experience PE [209, 373]. High levels of performance anxiety related to ED may worsen PE, with a risk of misdiagnosing PE instead of the underlying ED. According to the National Health and Social Life Survey (NHSLS), the prevalence of PE is not affected by age [197], unlike ED, which increases with age. Conversely, other data depicted an increased prevalence with ageing [702]; for instance, Verze et al. reported that PE prevalence based on the Premature Ejaculation Diagnostic Tool (PEDT) score (≥ 11) [723] proportionally increased with age [724]. Similarly, in a recent systematic review, PE was found to be more common in older age, with peak prevalence in men aged 60-69 years [725]. Premature ejaculation is not affected by marital or income status [197, 724]. However, PE is more common in Black men, Hispanic men, and men from regions where an Islamic background is common [196, 726] and prevalence may be higher in men with a lower educational level [197, 209]. Other risk factors include genetic predisposition [715, 727-730], poor overall health status and obesity [197], prostate inflammation [353, 731-734], hyperthyroidism [720], low prolactin levels [735], high testosterone levels [736], vitamin D and B12 deficiency [737, 738], diabetes [739,
6.2.3 Impact of PE on quality of life

Men with PE are more likely to report low satisfaction with their sexual relationship, low satisfaction with sexual intercourse, difficulty relaxing during intercourse, and less-frequent intercourse [284, 747, 748]. However, the negative impact of PE extends beyond sexual dysfunction. Premature ejaculation can have a detrimental effect on self-confidence and the relationship with the partner, and may sometimes cause mental distress, anxiety, embarrassment and depression [284, 749, 750]. Moreover, PE may also affect the partner's sexual functioning and their satisfaction with the sexual relationship decreases with increasing severity of the patient's condition [751-753]. Despite the possible serious psychological and QoL consequences of PE, few men seek treatment. In the Global Study of Sexual Attitudes and Behaviors survey, 78% of men who self-reported a sexual dysfunction sought no professional help or advice for their sexual problems [209], with men more likely to seek treatment for ED than for PE [209]. In the Premature Ejaculation Prevalence and Attitudes (PEPA) survey, only 9% of men with self-reported PE consulted a physician [198]. The main reasons for not discussing PE with their physician are embarrassment and a belief that there is no treatment. Physicians are often uncomfortable discussing sexuality with their patients usually because of embarrassment and a lack of training or expertise in treating PE [754, 755]. Physicians need to encourage their patients to talk about PE.

6.2.4 Classification

There is still little consensus about the definition and classification of PE [756]. It is now universally accepted that “premature ejaculation” is a broad term that includes several concepts belonging to the common category of PE. The most recent definition comes from the International Classification of Diseases 11th Revision, where PE was renamed as Early Ejaculation [757]: “Male early ejaculation is characterized by ejaculation that occurs prior to or within a very short duration of the initiation of vaginal penetration or other relevant sexual stimulation, with no or little perceived control over ejaculation. The pattern of early ejaculation has occurred episodically or persistently over a period of at least several months and is associated with clinically significant distress.”

This definition includes four categories: male early ejaculation, lifelong generalised and situational, acquired generalised and situational, unspecified.

In the Diagnostic and Statistical Manual of Mental Disorders V (DSM-V), PE is defined as a sexual disorder with:

- consistent ejaculation within 1 minute or less of vaginal penetration;
- over a period of at least 6 months;
- experienced 75–100% of the time;
- the condition results in clinically significant distress, sexual frustration, dissatisfaction, or tension between partners;
- this condition is not better accounted for by another non-sexual mental disorder, medication or illicit substance use, or medical condition [216].

The EAU Guidelines have adopted the definition of PE that was developed by the International Society for Sexual Medicine as the first evidence-based definition [758]. According to this definition, PE (lifelong and acquired) is a male sexual dysfunction characterised by the following:

- ejaculation that always or nearly always occurs prior to or within about 1 minute of vaginal penetration (lifelong PE) or a clinically significant and bothersome reduction in latency time, often to about 3 minutes or less (acquired PE);
- inability to delay ejaculation on all or nearly all vaginal penetrations;
- negative personal consequences, such as distress, bother, frustration, and/or the avoidance of sexual intimacy.

Two more PE syndromes have been proposed [717]:

- ‘Variable PE’ is characterised by inconsistent and irregular early ejaculations, representing a normal variation in sexual performance.
- ‘Subjective PE’ is characterised by subjective perception of consistent or inconsistent rapid ejaculation during intercourse, while ejaculation latency time is in the normal range or can even last longer. It should not be regarded as a symptom or manifestation of true medical pathology.
The addition of these new syndrome types may help in overcoming the limitations of each individual definition and it may support a more flexible view of PE for patient stratification, diagnosis and treatment [759].

6.2.5 Diagnostic evaluation

Diagnosis of PE is based on the patient’s medical and sexual history [205, 760, 761]. History should classify PE as lifelong or acquired and determine whether PE is situational (under specific circumstances or with a specific partner) or consistent. Special attention should be given to the duration time of ejaculation, degree of sexual stimulus, impact on sexual activity and QoL, and drug use or abuse. It is also important to distinguish PE from ED. Many patients with ED develop secondary PE caused by the anxiety associated with difficulty in attaining and maintaining an erection [373, 762]. Furthermore, some patients are not aware that loss of erection after ejaculation is normal and may erroneously complain of ED, while the actual problem is PE [763]. There are several overlapping definitions of PE, with four shared factors (Table 19), resulting in a multi-dimensional diagnosis [764].

</tr>
</tbody>
</table>

6.2.5.1 Intravaginal ejaculatory latency time (IELT)

Although it has been suggested as an objective diagnostic criterion and treatment outcome measure [765, 766], the use of IELT alone is not sufficient to define PE, as there is significant overlap between men with and without PE [767, 768]. Moreover, some men may experience PE in their non-coital sexual activities (e.g., during masturbation, oral sex or anal intercourse) thus measuring IELT will not be suitable for their assessment. Intravaginal ejaculatory latency time has a significant direct effect on perceived control over ejaculation, but not a significant direct effect on ejaculation-related personal distress or satisfaction with sexual intercourse [747]. In addition, perceived control over ejaculation has a significant direct effect on both ejaculation-related personal distress and satisfaction with sexual intercourse (each showing direct effects on interpersonal difficulty related to ejaculation) [769]. In everyday clinical practice, self-estimated IELT is sufficient [193]. Self-estimated and stopwatch-measured IELT are interchangeable and correctly assign PE status with 80% sensitivity and 80% specificity [770]. Specificity can be improved further to 96% by combining IELT with a single-item patient-reported outcome (PRO) scale on control over ejaculation and satisfaction with sexual intercourse (0 = very poor, to 4 = very good) and on personal distress and interpersonal difficulty (0 = not at all, to 4 = extremely). However, self-estimated IELT may be over-estimated by ~1 minute and therefore it must be carefully substituted with stopwatch-measured IELT while identifying men with the complaint of lifelong PE in a clinical setting [771].

Measurement of IELT with a calibrated stopwatch is mandatory in clinical trials. For any drug treatment study of PE, Waldinger et al. suggested using geometric mean instead of arithmetic mean IELT because the distributed IELT data are skewed. Otherwise, any treatment-related ejaculation delay may be overestimated if the arithmetic mean IELT is used instead of the geometric mean IELT [772].

6.2.5.2 Premature ejaculation assessment questionnaires

The need to assess PE objectively has led to the development of several questionnaires based on the use of PROs. Only two questionnaires can discriminate between patients who have PE and those who do not:

- Premature Ejaculation Diagnostic Tool (PEDT): A five-item questionnaire based on focus groups and interviews from the USA, Germany, and Spain assesses control, frequency, minimal stimulation, distress and interpersonal difficulty [773]. A total score > 11 suggests a diagnosis of PE, 9 or 10 suggests a probable diagnosis of PE, and < 8 indicates a low likelihood of PE.

- Arabic Index of Premature Ejaculation (AIPE): A seven-item questionnaire developed in Saudi Arabia assesses sexual desire, hard erections for sufficient intercourse, time to ejaculation, control, satisfaction of the patient and partner, anxiety or depression [774]. A cut-off score of 30 (range 7-35) discriminates PE diagnosis best. Severity of PE is classified as severe (score: 7-13), moderate (score: 14-19), mild-to-moderate (score: 20-25) and mild (score: 26-30).
Although it is widely used, some studies have reported a low correlation between a diagnosis provided by PEDT and a self-reported diagnosis. Only 40% of men with PEDT-diagnosed PE and 19% of men with probable PE self-reported the condition [301]. On the contrary, a recent study has shown that PEDT is valid in screening the presence of evidence-based-defined lifelong PE and acquired PE [62]. Questionnaires are a significant step in simplifying the methodology of PE drug studies, although further cross-cultural validation is needed [770].

Other questionnaires used to characterise PE and determine treatment effects include the Premature Ejaculation Profile (PEP) [768], Index of Premature Ejaculation (IPE) [775] and Male Sexual Health Questionnaire Ejaculatory Dysfunction (MSHQ-EjD) [776]. Currently, their role is optional in everyday clinical practice.

### 6.2.5.3 Physical examination and investigations

Physical examination may be part of the initial assessment of men with PE. It may include a focused examination of the urological, endocrine and neurological systems to identify underlying medical conditions associated with PE or other sexual dysfunctions, such as endocrinopathy, Peyronie’s disease, urethritis or prostatitis. Laboratory or physiological testing should be directed by specific findings from history or physical examination and is not routinely recommended [760].

### 6.2.5.4 Recommendations for the diagnostic evaluation of PE

### 6.2.6 Disease management

Before commencing any treatment, it is essential to define the subtype of PE and discuss patient’s expectations thoroughly. Pharmacotherapy must be considered as the first-line treatment for patients with lifelong PE, whereas treating the underlying cause (e.g., ED, prostatitis, LUTS, anxiety and hyperthyroidism) must be the initial goal for patients with acquired PE [205]. Various behavioural techniques may be beneficial in treating variable and subjective PE [777]. Psychotherapy can also be considered for PE patients who are uncomfortable with pharmacological therapy or in combination with pharmacological therapy [778, 779]. However, there is weak and inconsistent evidence regarding the effectiveness of these psychosexual interventions and their long-term outcomes in PE are unknown [780].

In lifelong PE, behavioural techniques are not recommended alone, and pharmacotherapy must be considered as the basis of treatment [205]. Dapoxetine (30 and 60 mg) is the first on-demand oral pharmacological agent approved for lifelong and acquired PE in many countries, except for the USA [781]. The metered-dose aerosol spray of lidocaine (150 mg/mL) and prilocaine (50 mg/mL) combination is the first topical formulation to be officially approved for on-demand treatment of lifelong PE by the EMA in the European Union [782]. All other medications used in PE are off-label indications [775]. Daily or on-demand use of selective serotonin re-uptake inhibitors (SSRIs) and clomipramine, and on-demand topical anaesthetic agents have consistently shown efficacy in PE [783-786]. Long-term outcomes of pharmacological treatments are unknown. An evidence-based analysis of all current treatment modalities was performed. Levels of evidence and grades of recommendation are provided, and a treatment algorithm is presented (Figure 7).
6.2.6.1 Psychological aspects and intervention

Only a few studies have addressed the psychological factors underpinning PE. Men with PE have been shown to present dysfunctional responsibility attribution patterns regarding their sexual experience. These men blame themselves for their dysfunctional sexual response, even when the negative sexual outcome is unrelated to early ejaculation; additionally, they take less credit for any positive sexual experience they might have [788, 789]. In addition to this style of internalised blame, men with PE focus on bodily sensations and their partners’ reactions during sex, to monitor potential signs of threat to their sexual performance. This monitoring process denotes a dysfunctional cognitive and attention style that contributes to the maintenance of PE [461].

Premature ejaculation is further related to increased levels of anxiety, including social anxiety [461, 769]. Yet, it is not known whether anxiety is a precursor or a consequence of PE [699]. Men with PE reported more caution, worry, less motivation toward novelty and exciting situations; that personality style may eventually intersect with PE dynamics [790]. The negative impact of PE on couples has been consistently mentioned. Female partners of men with PE present with an increased likelihood of sexual dysfunction [791, 792]; the intimate sphere, as well as the overall relationship quality, is compromised by PE [780]. An important trigger for seeking help in PE is partner dissatisfaction and the negative impact of PE on the general QoL of the couple [793].

Accordingly, psychosexual interventions, whether these are behavioural, cognitive, or focused on the couple, are aimed at teaching techniques to control/delay ejaculation, gaining confidence in sexual performance, reducing anxiety, and promoting communication and problem solving within the couple [777]. Interventions with a focus on sexual education or acceptance may be positive as well [794]. It is worth noting, however, that psychosexual interventions alone regarding PE lack empirical support. Recent evidence suggests that
start-stop exercises, combined with psycho-education and mindfulness techniques improve PE symptoms, as well as PE-associated distress, anxiety and depression [795]. The potential benefits of mindfulness have been reported [796]. Behavioural therapy may be most effective when used to 'add value' to medical interventions. Combination of dapoxetine and behavioural treatment was more effective than dapoxetine alone in patients with lifelong PE in a prospective, randomised trial [778]. Smartphone-delivered psychological intervention, aimed at improving behavioural skills for ejaculatory delay and sexual self-confidence, has positive effects, supporting E-health in the context of PE [797]. Validated assessment instruments need to be used as endpoints. Longer follow-up periods are necessary to confirm these findings.

6.2.6.2 Pharmacotherapy

6.2.6.2.1 Dapoxetine

Dapoxetine hydrochloride is a short-acting SSRI, with a pharmacokinetic profile suitable for on-demand treatment for PE [775]. It has a rapid $T_{\text{max}}$ (1.3 hours) and a short half-life (95% clearance rate after 24 hours) [798, 799]. It is approved for on-demand treatment of PE in European countries and elsewhere, but not in the USA. Both available doses of dapoxetine (30 mg and 60 mg) have shown 2.5- and 3.0-fold increases, respectively, in IELT overall, rising to 3.4- and 4.3-fold in patients with a baseline average IELT < 30 seconds [781, 800, 801].

In RCTs, dapoxetine, 30 mg or 60 mg 1-2 hours before intercourse, was effective at improving IELT and increasing ejaculatory control, decreasing distress, and increasing satisfaction [800]. Dapoxetine has shown a similar efficacy profile in men with lifelong and acquired PE [781, 802, 803]. Treatment-related adverse effects were dose-dependent and included nausea, diarrhoea, thirst, headache and dizziness [804]. Treatment-emergent adverse events (TEAEs) were responsible for study discontinuation in 4% (30 mg) and 10% (60 mg) of subjects [193]. There was no indication of an increased risk of suicidal ideation or suicide attempts and little indication of withdrawal symptoms with abrupt dapoxetine cessation [800, 805]. Dapoxetine is safer compared with formal anti-depressant compounds that are used for treatment of PE [806].
A low rate (0.1%) of vasovagal syncope was reported in phase 3 studies [807]. According to the summary of product characteristics, orthostatic vital signs (blood pressure and heart rate) must be measured prior to starting dapoxetine and dose-titration must be considered [808]. The EMA assessment report for dapoxetine concluded that the potentially increased risk for syncope has been proven manageable with adequate risk minimisation measures [809]. No cases of syncope were observed in a post-marketing observational study, which had identified patients at risk for orthostatic reaction using the patient’s medical history and orthostatic testing [810].

Many patients and physicians may prefer using dapoxetine in combination with a PDE5i to extend the time until ejaculation and minimise the risk of ED due to dapoxetine treatment. Phase 1 studies of dapoxetine have confirmed that it does not have any pharmacokinetic interactions with PDE5Is (i.e., tadalafil 20 mg and sildenafil 100 mg) [811]. When dapoxetine is co-administered with PDE5Is, it is well tolerated, with a safety profile consistent with previous phase 3 studies of dapoxetine alone [812]. A recent RCT including PE patients without ED, demonstrated that combination of dapoxetine with sildenafil can significantly improve IELT values and PROs compared with dapoxetine alone or sildenafil alone, with tolerable adverse events [813]. Efficacy and safety of dapoxetine/sildenafil combination tablets for the treatment of PE have also been reported [814].

Although dapoxetine is the only EMA approved oral drug for treatment of PE, discontinuation rates seem moderate-to-high. The cumulative discontinuation rates increase over time, reaching 90% at 2 years after initiation of therapy. The reasons for the high discontinuation rate are cost (29.9%), disappointment that PE was not curable and the on-demand nature of the drug (25%), adverse effects (11.6%), perceived poor efficacy (9.8%), a search for other treatment options (5.5%), and unknown (18.3%) [815]. Similarly, it was confirmed that a considerable number of patients who were on dapoxetine treatment spontaneously discontinue treatment, while this rate was reported 50% for other SSRIs and 28.8% for paroxetine [816]. In a Chinese cohort study, 13.6% of the patients discontinued dapoxetine due to lack of efficacy (62%), adverse effects (24%), and low frequency of sexual intercourse (14%) [817].

6.2.6.2.2 Off-label use of antidepressants: selective serotonin reuptake inhibitors and clomipramine

Ejaculation is commanded by a spinal ejaculation generator [818, 819] under excitatory or inhibitory influences from the brain and the periphery [739]. 5-hydroxytryptamine (5-HT or serotonin) is involved in ejaculatory control, with its ejaculation-retarding effects likely to be attributable to activation of 5-HT1B and 5-HT2C receptors, both spinally and supraspinally. By contrast, stimulation of 5-HT1A receptors precipitates ejaculation [820].

Selective serotonin re-uptake inhibitors are used to treat mood disorders but can delay ejaculation and therefore have been widely used ‘off-label’ for PE since the 1990s [821]. For depression, SSRIs must be given for 1-2 weeks to be effective for PE [820]. Administration of chronic SSRIs causes prolonged increases in synaptic cleft serotonin, which desensitises the 5-HT1A and 5-HT1B receptors [822]. Commonly used SSRIs include continuous intake of citalopram, fluoxetine, fluvoxamine, paroxetine and sertraline, all of which have a similar efficacy, whereas paroxetine exerts the strongest ejaculation delay [765, 823, 824]. A novel 5-HT1A receptor antagonist, GSK958108, significantly delayed ejaculation in a double-blind, placebo-controlled trial, recently [825].

Clomipramine, the most serotoninergic tricyclic antidepressant, was first reported in 1977 as an effective PE treatment [826, 827]. In a recent RCT, on-demand use of clomipramine 15 mg, 2-6 hours before sexual intercourse was found to be associated with IELT fold change and significant improvements in PRO measures in the treatment group as compared to the placebo group (4.66 ± 5.64 vs. 2.80 ± 2.19, P < 0.05). [828, 829]. The most commonly reported TEAEs were nausea in 15.7% and dizziness in 4.9% of men, respectively [828, 829].

Several systematic reviews and meta-analyses of drug treatment have reported that, despite methodological problems in most studies, there remain several, well-designed, double-blind, placebo-controlled trials supporting the therapeutic effect of daily SSRIs on PE [765, 783-786]. Based on these meta-analyses, SSRIs may increase the geometric mean IELT by 2.6-13.2-fold. Paroxetine is superior to fluoxetine, clomipramine and sertraline. Sertraline is superior to fluoxetine, whereas the efficacy of clomipramine is not significantly different from that of fluoxetine and sertraline. Paroxetine was evaluated in doses of 20-40 mg, sertraline 25-200 mg, fluoxetine 10-60 mg and clomipramine 25-50 mg. There was no significant relationship between dose and response among the various drugs. There is limited evidence that citalopram may be less efficacious compared to other SSRIs, while fluvoxamine may not be effective [830, 831].

Ejaculation delay may start a few days after drug intake, but it is more evident after 1-2 weeks as receptor desensitisation requires time to occur. Although efficacy may be maintained for several years, tachyphylaxis (decreasing response to a drug following chronic administration) may occur after 6-12 months [826]. Common TEAEs of SSRIs include fatigue, drowsiness, yawning, nausea, vomiting, dry mouth, diarrhoea and perspiration;
TEAEs are usually mild and gradually improve after 2-3 weeks of treatment [800, 826]. Decreased libido, anorgasmia, anejaculation and ED have also been reported.

Because of the risk of suicidal ideation or suicide attempts, caution is suggested in prescribing SSRIs to young adolescents aged ≤ 18 years with PE, and to men with PE and a comorbid depressive disorder, particularly when associated with suicidal ideation. Patients should be advised to avoid sudden cessation or rapid dose reduction of daily-dosed SSRIs, which may be associated with a SSRI withdrawal syndrome [193]. Moreover, PE patients who are trying to conceive should avoid using these medications because of their detrimental effects on sperm cells [832-835].

6.2.6.2.3 Topical anaesthetic agents
The use of local anaesthetics to delay ejaculation is the oldest form of pharmacological therapy for PE [836]. Several trials [706, 837, 838] support the hypothesis that topical desensitising agents reduce the sensitivity of the glans penis thereby delaying ejaculatory latency, but without adversely affecting the sensation of ejaculation. Meta-analyses have confirmed the efficacy and safety of these agents for the treatment of PE [839, 840]. In a recent meta-analysis, the efficacy of local anaesthetics was best among the other treatment options including SSRIs, dapoxetine 30 and 60 mg, PDE5Is and tramadol for < 8 weeks of therapy [841].

6.2.6.2.3.1 Lidocaine/prilocaine cream
In a randomised, double-blind, placebo-controlled trial, lidocaine/prilocaine cream increased IELT from one minute in the placebo group to 6.7 minutes in the treatment group [842]. In another randomised, double blind, placebo-controlled trial, lidocaine/prilocaine cream significantly increased the stopwatch-measured IELT from 1.49-8.45 minutes, while no difference was recorded in the placebo group (1.67-1.95 minutes) [843]. Although no significant TEAEs have been reported, topical anaesthetics are contraindicated in patients or partners with an allergy to any ingredient in the product. These anaesthetic creams/gels may be transferred to the partner and result in vaginal numbness. Therefore, patients are advised to use a condom after applying the cream to their penis. Alternatively, the penis can be washed to clean off any residual active compound prior to sexual intercourse. Since these chemicals may be associated with cytotoxic effects on fresh human sperm cells, couples seeking parenthood should not use topical lidocaine/prilocaine-containing substances [844].

6.2.6.2.3.2 Lidocaine/prilocaine spray
The eutectic lidocaine/prilocaine spray is a metered-dose aerosol spray containing purely base forms of lidocaine (150 mg/mL) and prilocaine (50 mg/mL), which has been officially approved by the EMA for the treatment of lifelong PE [845]. Compared to topical creams, the metered-dose spray delivery system has been proved to deposit the drug in a dose-controlled, concentrated film covering the glans penis, maximising neural blockage and minimising the onset of numbness [846], without absorption through the penile shaft skin [847].

To date, one phase 2 proof-of-concept [847] and two phase 3 RCTs [848, 849] have demonstrated the efficacy of lidocaine/prilocaine spray in improving both IELT and the Index of Ejaculatory Control of patients with primary PE, along with an improvement in scores assessing treatment satisfaction (IPE) [848, 849]. Based on these data, according to the patient information leaflet [850], the recommended dose of lidocaine/prilocaine spray is one dose (namely three sprays) to be applied on the glans penis at least 5 minutes before sexual intercourse [851]. Published data showed that lidocaine/prilocaine spray increases IELT over time up to 6.3-fold over 3 months, with a month-by-month improvement through the course of the treatment in long-term studies [852]. A low incidence of local TEAEs in both patients and partners has been reported, including genital hypoaesthesia (4.5% and 1.0% in men and females partners, respectively) and ED (4.4%), and vulvovaginal burning sensation (3.9%), but is unlikely to be associated with systemic TEAEs [850, 853].

Lidocaine-only sprays are also effective in the treatment of PE. In a recent RCT, PE patients were randomly allocated to receive either dapoxetine 60 mg or topical lidocaine 10% spray. The geometric mean IELTs were significantly better in the lidocaine compared with dapoxetine group (179.43 vs. 63.44, respectively). However, both groups showed significant improvement compared with baseline IELTs value (63.44 and 179.4 vs. 21.87, P < .05) [854]. In another RCT lidocaine 5% spray was compared with alcohol spray (placebo) in the treatment of lifelong PE for 8 weeks; the mean values of the AIPE scores, IELT, and sexual intercourse frequency in the lidocaine 5% spray group were significantly increased compared with the placebo group [855].

6.2.6.2.4 Tramadol
Tramadol is a centrally-acting analgesic agent that combines opioid receptor activation and re-uptake inhibition of serotonin and noradrenaline. Tramadol is a mild-opioid receptor agonist, but it also displays antagonistic properties on transporters of noradrenaline and 5-HT [856]. This mechanism of action distinguishes tramadol from
other opioids, including morphine. Tramadol is readily absorbed after oral administration and has an elimination half-life of 5-7 hours.

A large, randomised, double-blind, placebo-controlled, multicentre 12-week study was carried out to evaluate the efficacy and safety of two doses of tramadol (62 and 89 mg) by ODT in the treatment of PE [857].

A bioequivalence study has demonstrated equivalence between tramadol ODT and tramadol HCl. In patients with a history of lifelong PE and an IELT < 2 minutes, increases in the median IELT of 0.6 minutes (1.6-fold), 1.2 minutes (2.4-fold) and 1.5 minutes (2.5-fold) were reported for placebo, 62 mg of tramadol ODT, and 89 mg of tramadol ODT, respectively. It should be noted that there was no dose-response effect with tramadol. There are four RCTs comparing the efficacy of tramadol to paroxetine in the literature. On demand tramadol treatment yielded significantly higher IELTs compared to on demand paroxetine treatment arm in three of RCTs [858-860], whilst in the remaining RCT, daily paroxetine was found more effective to treat lifelong PE when compared with on-demand tramadol treatment [861]. A recent meta-analysis including these four RCTs and one single blind study implied that 50 mg tramadol had a significant improvement in the IELT compared with 20 mg paroxetine [862]. Adverse effects were reported at doses used for analgesic purposes (≤400 mg daily) and included constipation, sedation and dry mouth. In May 2009, the US FDA released a warning letter about tramadol's potential to cause addiction and difficulty in breathing [863]. The tolerability during the 12-week study period in men with PE was acceptable [859]. Several other studies have also reported that tramadol exhibits a significant dose-related efficacy along with potential adverse effects during treatment of PE [864]. The efficacy and safety of tramadol have been confirmed in systematic reviews and meta-analyses [859, 862, 865-868]. The Guidelines Panel considers tramadol as a potential alternative treatment to established first-line therapeutic options in men with PE; however, it should clearly outlined that the use of tramadol has to be considered with caution since there is a lack of data on long-term safety of the compound in this setting.

6.2.6.2.5 Phosphodiesterase type 5 inhibitors

One well-designed, randomised, double-blind, placebo-controlled study compared sildenafil to placebo in men with PE [869]. Although IELT was not significantly improved, sildenafil increased confidence, the perception of ejaculatory control and overall sexual satisfaction, reduced anxiety and the refractory time to achieve a second erection after ejaculation. Another RCT demonstrated that once-daily 5 mg tadalafil for 6 weeks was effective in improving PROs and was well tolerated by patients with PE [870]. Several open-label studies have shown that combination of PDE5Is and SSRIs is superior to SSRI monotherapy, which has also been recently confirmed by a Bayesian network meta-analysis [841]:

- Sildenafil combined with paroxetine improved IELT significantly and satisfaction vs. paroxetine alone [871];
- Sildenafil combined with sertraline improved IELT and satisfaction significantly vs. sertraline alone [872];
- Sildenafil combined with paroxetine and psychological and behavioural counselling significantly improved IELT and satisfaction in patients in whom other treatments failed [873];
- Sildenafil combined with dapoxetine (30 mg) improved IELT, satisfaction scores and PEDT vs. dapoxetine, paroxetine or sildenafil monotherapy [813];
- Tadalafil combined with paroxetine significantly improved IELT and satisfaction vs. paroxetine and tadalafil alone [874];
- Sildenafil combined with behavioural therapy significantly improved IELT and satisfaction vs. behavioural therapy alone [875].

Overall, there are limited data on the efficacy of other PDE5Is (tadalafil and vardenafil) [876, 877]. In a recent meta-analysis, PDE5Is were found to be significantly more effective than placebo in the treatment of patients with PE and without ED [878]. Some meta-analyses have demonstrated that the combined use of SSRIs and PDE5Is may be more effective than SSRI or PDE5I monotherapy [785, 879-883]. In a recent Bayesian meta-analysis, combined therapy of SSRI and PDE5I was found to be superior to other treatment modalities (including topical creams, tramadol, paroxetine or fluoxetine monotherapy, PDE5I monotherapy, dapoxetine 30 and 60 mg, clomipramine, citalopram, and placebo) lasting > 8 weeks [841].

6.2.6.2.6 Other drugs

In addition to the aforementioned drugs, there is continuous research into other treatment options. Considering the abundant α1a-adrenergic receptors in seminal vesicles and the prostate, and the role of the sympathetic system in ejaculation physiology, the efficacy of selective α-blockers in the treatment of PE has been assessed [884-886]. A recent study demonstrated that wake-promoting agent modafinil may be effective in delaying ejaculation and improving PROMs [887]. The efficacy of acupuncture was compared to dapoxetine for the treatment of PE and although acupuncture showed a significant ejaculation-delaying effect, this was less effective as compared with that of dapoxetine [888].
Decreasing penile sensitivity with glans penis augmentation using hyaluronic acid for the treatment of PE was initially proposed by Korean researchers in 2004 [889], and since then has gained popularity mainly in Asian countries [890, 891]. In a randomised controlled cross-over study, hyaluronic acid glans injections were safe with a modest but significant increase in IELT [892]. However, these procedures may result in serious complications and more safety studies must be conducted before recommending this treatment to PE patients [893].

Considering the importance of central oxytocin receptors in ejaculation reflex, several researchers have assessed the efficacy and safety of oxytocin receptor antagonists in the treatment of PE [894]. Epelsiban [895] and cligosiban [896-898] have been found to be safe and mildly effective in delaying ejaculation, but further controlled trials are needed [898].

Retarded ejaculation was associated with the use of pregabalin, a new generation of gapapentinoid, as a side-effect. In a double-blind, placebo-controlled randomised trial where the efficacy and tolerability of on-demand oral pregabalin (150 mg and 75 mg) in treatment of PE was trialled, it was found that IELTs of patients who received 150 mg pregabalin improved significantly (2.45 ± 1.43-fold) compared to those who received 75 mg pregabalin and placebo. Treatment-emergent side effects (blurred vision, dizziness, vomiting) were minimal and did not lead to drug discontinuation.

The role of other proposed treatment modalities for the treatment of PE such as penis-root masturbation [899], vibrator-assisted start-stop exercises [795], transcutaneous functional electric stimulation [900], transcutaneous posterior tibial nerve stimulation [901], and practicing yoga [902] need more evidence to be considered in the clinical setting.

6.3 Delayed Ejaculation

6.3.1 Definition and classification

The American Psychiatric Association defines DE as requiring one of two symptoms as follows: marked delay, infrequency, or absence of ejaculation on 75-100% of occasions, that persists for at least 6 months, and which causes personal distress [216]. However, in a recent study, while ejaculatory latency and control were significant criteria to differentiate men with DE from those without ejaculatory disorders, bother/distress did not emerge as a significant factor [903]. Similar to PE, there are distinctions among lifelong, acquired and situational DE [216]. Although the evidence is limited, the prevalence of lifelong DE and acquired DE is estimated around 1% and 4%, respectively [217].

6.3.2 Pathophysiology and risk factors

The aetiology of DE can be psychological, organic (e.g., incomplete spinal cord lesion or iatrogenic penile nerve damage), or pharmacological (e.g., SSRIs, antihypertensive drugs, or antipsychotics) [904, 905] (Table 20). Other factors that may play a role in the aetiology of DE include tactile sensitivity and tissue atrophy [794].
Although low testosterone level has been considered a risk factor in the past [55, 736], more contemporary studies have not confirmed any association between ejaculation times and serum testosterone levels [906, 907]. Idiosyncratic masturbation and lack of desire for stimuli are also proposed risk factors for DE [211-213].

6.3.3 **Investigation and treatment**

Patients should have a full medical and sexual history performed along with a detailed physical examination when evaluating for DE. It is not uncommon for clinicians to feel uncomfortable with the level of sexual information that is warranted in obtaining a full sexual history. Understanding the details of the ejaculatory response, sensation, frequency, and sexual activity/techniques; cultural context and history of the disorder; quality of the sexual response cycle (desire, arousal, ejaculation, orgasm, and refractory period); partner’s assessment of the disorder and if the partner suffers from any sexual dysfunction her/himself; and the overall satisfaction of the sexual relationship are all important to garner during history-taking [909]. Investigation by a sex therapist is often required to help obtain a complete psychological evaluation. It is incumbent on the clinician to diagnose medical pathologies that cause or contribute to DE, such as assessing the hormonal milieu, anatomy, and overall medical condition. Good communication between the sex therapist and medical practitioner is vital to successful diagnosis and treatment of DE.
6.3.3.1 Psychological aspects and intervention

There is scarce literature on the psychological aspects relating to DE, as well as on empirical evidence regarding psychological treatment efficacy. Studies on psychological aspects have revealed that men with DE show a strong need to control their sexual experiences. Delayed ejaculation is associated with difficulties surrendering to sexual pleasure during sex - i.e., the sense of letting go [910] - which denotes a psychological underlying mechanism influencing the reaching of orgasm [911]. As for psychological treatments, these may include, but are not limited to: increased genital-specific stimulation; sexual education; role-playing on his own and in front of his partner; retraining masturbatory practices; anxiety reduction on ejaculation and performance; and, re-calibrating the mismatch of sexual fantasies with arousal (such as with pornography use and fantasy stimulation compared to reality) [909]. A basic understanding of the sexual cycle for their respective partners can assist men and women in managing expectations and in evaluating their own sexual practices. Masturbation techniques that are either solo or partnered can be considered practice for the “real performance” which can eventually result in greater psychosexual arousal and orgasm for both parties [213]. Although masturbation with fantasy can be harmful when not associated with appropriate sexual arousal and context, fantasy can be supportive if it allows blockage of critical thoughts that may be preventing orgasm and ejaculation. Techniques geared towards reduction of anxiety are important skills that can help overcome performance anxiety, as this can often interrupt the natural erectile function through orgasmic progression. Referral to a sexual therapist, psychologist or psychiatrist is appropriate and often warranted.

6.3.3.2 Pharmacotherapy

Several pharmacological agents, including cabergoline, bupropion, alpha-1-adrenergic agonists (pseudoephedrine, midodrine, imipramine and ephedrine), buspirone, oxytocin, testosterone, bethanechol, yohimbine, amantadine, cyproheptadine and apomorphine have been used to treat DE with varied success [794]. Unfortunately, there is no FDA or EMA approved medications to treat DE, as most of the cited research is based on case-cohort studies that were not randomised, blinded, or placebo-controlled. Many drugs have been used as both primary treatments and/or as antidotes to other medications that can cause DE. A recent survey of sexual health providers demonstrated an overall treatment success of 40% with most providers commonly using cabergoline, bupropion or oxytocin [912]. However, this survey measured the anecdotal results of practitioners and there was no proven efficacy or superiority of any drug due to a lack of placebo-controlled, randomised, blinded, comparative trials [908]. In addition to pharmacotherapy, penile vibratory stimulation (PVS) is also used as an adjunct therapy for DE [913]. Another study that used combined therapy of midodrine and PVS to increase autonomic stimulation in 158 men with spinal cord injury led to ejaculation in almost 65% of the patients [914].

6.4 Anejaculation

6.4.1 Definition and classification

Anejaculation involves the complete absence of antegrade or retrograde ejaculation. It is caused by failure of semen emission from the seminal vesicles, prostate, and ejaculatory ducts into the urethra [915]. True anejaculation is usually associated with a normal orgasmic sensation and is always associated with central or peripheral nervous system dysfunction or with drugs [916].

6.4.2 Pathophysiology and risk factors

Generally, anejaculation shares similar aetiological factors with DE and retrograde ejaculation (Table 20).

6.4.3 Investigation and treatment

Drug treatment for anejaculation caused by lymphadenectomy and neuropathy, or psychosexual therapy for anorgasmia, is not effective. In all these cases, and in men who have a spinal cord injury, PVS (i.e., application of a vibrator to the penis) is the first-line therapy. In anejaculation, PVS evokes the ejaculation reflex [917], which requires an intact lumbosacral spinal cord segment. If the quality of semen is poor, or ejaculation is retrograde, the couple may enter an in vitro fertilisation program whenever fathering is desired. If PVS has failed, electro-ejaculation can be the therapy of choice [918]. When electro-ejaculation fails or cannot be carried out, other sperm-retrieval techniques may be used [919]. Anejaculation following either retroperitoneal surgery for testicular cancer or total mesorectal excision can be prevented using unilateral lymphadenectomy or autonomic nerve preservation [920], respectively.

6.5 Painful Ejaculation

6.5.1 Definition and classification

Painful ejaculation is a condition in which a patient feels mild discomfort to severe pain during or after ejaculation. The pain can involve the penis, scrotum, and perineum [921].
6.5.2 **Pathophysiology and risk factors**

Many medical conditions can result in painful ejaculations, but it can also be an idiopathic problem. Initial reports demonstrated possible associations of painful ejaculation with calculi in the seminal vesicles [922], sexual neurasthenia [923], sexually transmitted diseases [921, 924], inflammation of the prostate [237, 925], PCa [926, 927], BPH [235], prostate surgery [928, 929], pelvic radiation [930], herniorrhaphy [931] and antidepressants [932-934]. Further case reports have suggested that mercury toxicity or Ciguatera toxin fish poisoning may also result in painful ejaculation [935, 936]. Psychological issues may also be the cause of painful ejaculation, especially if the patient does not experience this problem during masturbation [937].

6.5.3 **Investigation and treatment**

Treatment of painful ejaculation must be tailored according to the underlying cause, if detected. Psychotherapy or relationship counselling, withdrawal of suspected agents (drugs, toxins, or radiation) [932, 933, 938] or the prescription of appropriate medical treatment (antibiotics, α-blockers or anti-inflammatory agents) may ameliorate painful ejaculation. Behavioural therapy, muscle relaxants, antidepressant treatment, anticonvulsant drugs and/or opioids, pelvic floor exercises, may be implemented if no underlying cause can be identified [939, 940].

6.5.3.1 **Surgical intervention**

If medical treatments fail, surgical operations such as TURP, transurethral resection of the ejaculatory duct and neurolysis of the pudendal nerve have been suggested [941, 942]. However, there is no strong supporting evidence that surgical therapy improves painful ejaculation and therefore it must be used with caution.

6.6 **Retrograde ejaculation**

6.6.1 **Definition and classification**

Retrograde ejaculation is the total, or sometimes partial, absence of antegrade ejaculation, as a result of semen passing backwards through the bladder neck into the bladder. Patients may experience a normal, or decreased, orgasmic sensation. The causes of retrograde ejaculation can be divided into neurogenic, pharmacological, urethral, or bladder neck incompetence [921].

6.6.2 **Pathophysiology and risk factors**

The process of ejaculation requires complex co-ordination and interplay between the epididymis, vas deferens, prostate, seminal vesicles, bladder neck and bulbourethral glands [943]. Upon ejaculation, sperm are rapidly conveyed along the vas deferens and into the urethra via the ejaculatory ducts. From there, the semen progresses in an antegrade fashion, in part maintained by coaptation of the bladder neck and rhythmic contractions of the periurethral muscles, co-ordinated by a centrally mediated reflex [943]. Closure of the bladder neck and seminal emission are initiated via the sympathetic nervous system from the lumbar sympathetic ganglia and subsequently hypogastric nerve. Prostatic and seminal vesicle secretion, as well as contraction of the bulbo-cavernosal, ischio-cavernosal and pelvic floor muscles are initiated by the S 2-4 parasympathetic nervous system via the pelvic nerve [943].

Any factor that disrupts this reflex and inhibits contraction of the bladder neck (internal vesical sphincter) may lead to retrograde passage of semen into the bladder. These can be broadly categorised as pharmacological, neurogenic, anatomic and endocrinal causes of retrograde ejaculation (Table 21).

SEXUAL AND REPRODUCTIVE HEALTH - LIMITED UPDATE 2022
### Disease management

Medical and surgical strategies exist for the treatment of retrograde ejaculation. In recent years the reliance on medical treatment as first-line management has become common practice.

#### 6.6.3.1 Pharmacological

Sympathomimetics stimulate the release of noradrenaline as well as activating $\alpha$- and $\beta$-adrenergic receptors, resulting in closure of the internal urethral sphincter, restoring the antegrade flow of semen. The most common sympathomimetics are synephrine, pseudoephedrine hydrochloride, ephedrine, phenylpropanolamine and midodrine [944]. Unfortunately, as time progresses their effect diminishes [945]. Many of the studies published about the efficacy of sympathomimetics in the treatment of retrograde ejaculation suffer from small sample size, with some represented by case reports.

A double-blind controlled study randomised patients to one of four $\alpha$-adrenergic agents (dextroamphetamine, ephedrine, phenylpropanolamine and pseudoephedrine) with or without histamine. The patients suffered from failure of ejaculation following retroperitoneal lymphadenectomy. They found that 4 days of treatment prior to ejaculation was most effective and that all the adrenergic agonists restored antegrade ejaculation [944]. In a systematic review, the efficacy of this group of medications was found to be 28% [220]. The adverse effects of sympathomimetics include dryness of mucous membranes and hypertension.

The use of antimuscarinics has been described, including brompheniramine maleate and imipramine, as well as in combination with sympathomimetics. The calculated efficacy of antimuscarinics alone or in combination with sympathomimetics is 22% and 39%, respectively [220]. Combination therapy appears to be more effective although statistical analysis is not yet possible due to the small sample sizes.

#### 6.6.3.2 Management of infertility

Infertility has been the major concern of patients with retrograde ejaculation. Beyond the use of standard sperm-retrieval techniques, such as testicular sperm extraction (TESE), three different methods of sperm acquisition have been identified for the management of infertility in patients with retrograde ejaculation. These include: i) centrifugation and resuspension of post-ejaculatory urine specimens; ii) the Hotchkiss (or modified Hotchkiss) technique; and, iii) ejaculation on a full bladder.

1. **Centrifugation and resuspension.** In order to improve the ambient conditions for the sperm, the patient is asked to increase their fluid intake or take sodium bicarbonate to dilute or alkalise the urine, respectively. Afterwards, a post-orgasmic urine sample is collected by introducing a catheter or spontaneous voiding. This sample is then centrifuged and suspended in a medium. The types of suspension fluids are heterogeneous and can include bovine serum albumin, human serum albumin, Earle’s/Hank’s balanced salt solution and the patient’s urine. The resultant modified sperm mixture can then be used in assisted reproductive techniques. A systematic review of studies in couples in which male partner had retrograde ejaculation found a 15% pregnancy rate per cycle (0–100%) [220].

2. **Hotchkiss method.** The Hotchkiss method involves emptying the bladder prior to ejaculation, using a catheter, and then washing out and instilling a small quantity of Lactated Ringers to improve the ambient condition of the bladder. The patient then ejaculates, and semen is retrieved by catheterisation or voiding [946]. Modified Hotchkiss methods involve variance in the instillation medium. Pregnancy rates were 24% per cycle (0–100%) [220].

3. **Ejaculation on a full bladder.** Few papers have described results using this technique [947, 948]. The patient is encouraged to ejaculate on a full bladder and semen is suspended in Baker’s Buffer. The pregnancy rate in the two studies, which included only five patients in total, was 60% [220].
6.7 Anorgasmia

6.7.1 Definition and classification
Anorgasmia is the perceived absence of orgasm and can give rise to anejaculation. Regardless of the presence of ejaculation, anorgasmia can be a lifelong (primary) or acquired (secondary) disorder [217].

6.7.2 Pathophysiology and risk factors
Primary anorgasmia is defined as starting from a man’s first sexual intercourse and lasts throughout his life, while for secondary anorgasmia patients should have a normal period before the problem starts [949]. Substance abuse, obesity and some non-specific psychological aspects, such as anxiety and fear, are considered risk factors for anorgasmia. Only a few studies have described anorgasmia alone and generally it has been considered as a symptom linked to ejaculatory disorders especially with DE, and therefore, they are believed to share the same risk factors. However, psychological factors are considered to be responsible for 90% of anorgasmia problems [950]. Causes of delayed orgasm and anorgasmia are shown in Table 22 [949].

</tbody>
</table>

6.7.3 Disease management
The psychological/behavioural strategies for anorgasmia are similar to those for DE. The patient and his partner should be examined physically and psychosexually in detail, including determining the onset of anorgasmia, medication and disease history, penile sensitivity and psychological issues. Adjunctive laboratory tests can also be used to rule out organic causes, such as testosterone, prolactin and TSH levels. Patients who have loss of penile sensitivity require further investigations [949].

6.7.3.1 Psychological/behavioural strategies
Lifestyle changes can be recommended to affected individuals including: changing masturbation style; taking steps to improve intimacy, and decreasing alcohol consumption. Several psychotherapy techniques or their combinations have been offered, including alterations in arousal methods, reduction of sexual anxiety, role-playing an exaggerated orgasm and increased genital stimulation [911, 951]. However, it is difficult to determine the success rates from the literature.

6.7.3.2 Pharmacotherapy
Several drugs have been reported to reverse anorgasmia, including cyproheptadine, yohimbine, buspirone, amantadine and oxytocin [952-957]. However, these reports are generally from case-cohort studies and drugs have limited efficacy and significant adverse effect profiles. Therefore, current evidence is not strong enough to recommend drugs to treat anorgasmia.

6.7.3.3 Management of infertility
If patients fail the treatment methods mentioned above, penile vibratory stimulation, electro-ejaculation or TESE are the choice of options for sperm retrieval in anorgasmia cases [949].

6.8 Haemospermia

6.8.1 Definition and classification
Haemospermia is defined as the appearance of blood in the ejaculate. Although it is often regarded as a symptom of minor significance, blood in the ejaculate causes anxiety in many men and may be indicative of underlying pathology [240].

6.8.2 Pathophysiology and risk factors
Several causes of haemospermia have been acknowledged and can be classified into the following subcategories; idiopathic, congenital malformations, inflammatory conditions, obstruction, malignancies, vascular abnormalities, iatrogenic/trauma and systemic causes (Table 23) [958].

</table>

The risk of any malignancy in patients presenting with haemospermia is approximately 3.5% (0-13.1%) [959]. In an observational study of 300 consecutive patients over a 30-month period, 81% had no identified cause of haemospermia. In those patients for whom a cause was identified, the diagnosis varied dependent upon the age of presentation. When the patients were divided into those under and those over 40 years of age, UTIs were more common among younger compared to older patients (15% vs. 10.3%). In the older group (> 40 years), stones (2.2% vs. 1.4%) and malignancy (6.2% vs. 1.4%) were more common when compared with the younger cohort. In the > 40 years group, 13 patients had PCa and one had low-grade urethral carcinoma. In the < 40 years group, one patient had testicular cancer [239]. In a recent study in which 342 patients with haemospermia were included, the most relevant aetiology for haemospermia was inflammation/infection (49.4%) while genitourinary cancers (i.e., prostate and testis) only accounted for 3.2% of the cases [960].

6.8.3 Investigations

As with other clinical conditions, a systematic clinical history and assessment to help identify the cause of haemospermia is undertaken. Although the differential diagnosis is extensive, most cases are caused by infections or other inflammatory processes [240].

The basic examination of haemospermia should start with a thorough symptom-specific and systemic clinical history. The first step is to understand if the patient has true haemospermia. Pseudo-haemospermia may occur as a consequence of haematuria or even suction of a partner’s blood into the urethra during copulation [921, 961, 962]. A sexual history should be taken to identify those whose haemospermia may be a consequence of a sexually transmitted disease. Recent foreign travel to areas affected by schistosomiasis or tuberculosis should also be considered. The possibility of co-existing systemic disease such as hypertension, liver disease and coagulopathy should be investigated along with systemic features of malignancy such as weight loss, loss of appetite or bone pain. Examination of the patient should also include measurement of blood pressure, as there have been several case reports suggesting an association between uncontrolled hypertension and haemospermia [963, 964].

Most authors who propose an investigative baseline agree on the initial diagnostic tests, but there is no consensus in this regard [958, 959, 961]. Urinalysis should be performed along with sending the urine for culture and sensitivity testing, as well as microscopy. If tuberculosis or schistosomiasis is the suspected cause, the semen or prostatic secretions should be sent for analysis. A full sexually-transmitted disease screen, including first-void urine as well as serum and genitourinary samples, should be tested for Chlamydia, Ureaplasma and Herpes Simplex virus. Using this strategy, it may be possible to find an infectious agent among cases that would have been labelled as idiopathic haemospermia [965].

Serum PSA should be taken in men aged > 40 years who have been appropriately counselled [241]. Blood work including a full blood count, liver function tests, and a clotting screen should be taken to identify systemic diseases. The question of whether further investigation is warranted depends on clinician judgment, patient age and an assessment of risk factors [958]. Digital rectal examination (DRE) should also be performed and the meatus re-examined after DRE for bloody discharge [966]. Detection of a palpable nodule in the prostate...
is important because an association between haemospermia and PCa has been postulated although not completely proven.

Magnetic resonance imaging is being increasingly used as a definitive means to investigate haemospermia. The multiplanar ability of MRI to accurately represent structural changes in the prostate, seminal vesicles, ampulla of vas deferens, and ejaculatory ducts has enabled the technique to be particularly useful in determining the origin of midline or paramedian prostatic cysts and in determining optimal surgical management [967]. The addition of an endorectal coil can improve the diagnostic accuracy for identifying the site and possible causes of haemorrhage [968].

Cystoscopy has been included in most suggested investigative protocols in patients with high-risk features (patients who are refractory to conservative treatment and who have persistent haemospermia). It can provide invaluable information as it allows direct visualisation of the main structures in the urinary tract that can be attributed to causes of haemospermia, such as: polyps, urethritis, prostatic cysts, foreign bodies, calcifications and vascular abnormalities [969, 970].

With the advancement of optics, the ability to create ureteroscopes of diameters small enough to allow insertion into the ejaculatory duct and seminal vesicles has been made possible [971]. In a prospective study, 106 patients with prolonged haemospermia underwent transrectal US and seminal vesiculoscopy. With both methods combined, diagnosis was made in 87.7% of patients. When compared head-to-head, the diagnostic yield for TRUS vs. seminal vesiculoscopy was 45.3% and 74.5%, respectively (P < 0.001) [972].

Melanospermia is a consequence of malignant melanoma involving the genitourinary tract and is a rare condition that has been described in two case reports [973, 974]. Chromatography of the semen sample can be used to distinguish the two by identifying the presence of melanin if needed.

### 6.8.4 Disease management

Conservative management is generally the primary treatment option when the patients are aged < 40 years and have a single episode of haemospermia. The primary goal of treatment is to exclude malignant conditions like prostate and bladder cancer and treat any other underlying cause. If no pathology is found, then the patient can be reassured [240, 958].

Patients with recurrent haemospermia who are middle-aged, warrant more aggressive intervention. Appropriate antibiotic therapy should be given to patients who have urogenital infections or STIs. Urethral or prostate varices or angiodysplastic vessels can be fulgurated, whereas cysts, either of the seminal vesicles or prostatic urethra, can be aspirated transrectally [240]. Ejaculatory duct obstruction is managed by transurethral incision at the duct opening [975, 976]. Systemic conditions should be treated appropriately [959, 962, 977, 978].

Defining a management algorithm for haemospermia is based on the patient age and degree of haemospermia. Patients often find blood in the ejaculate alarming, and investigations should be aimed at excluding a serious, despite infrequent, underlying cause (e.g., cancer), while at the same time preventing over-investigation and alleviating patient anxiety. The literature describes a multitude of causes for haemospermia, although many of these are not commonly found after investigation. However, men may be stratified into higher-risk groups according to several factors including: age > 40 years, recurrent or persistent haemospermia, actual risk for PCa (e.g., positive family history), and concurrent haematuria. Based upon the literature, a management algorithm is proposed (Figure 9) [959, 962, 977, 978].
Figure 9: Management algorithm for haemospermia [959, 962, 977, 978]

STI = Sexually transmitted infections; PSA = Prostate specific antigen; DRE = Digital rectal examination; US = Ultrasonography; TRUS = Transrectal ultrasonography; MRI = Magnetic resonance imaging.

7. LOW SEXUAL DESIRE AND MALE HYPOACTIVE SEXUAL DESIRE DISORDER

7.1 Definition, classification and epidemiology
It has always been a challenge to define sexual desire properly because it has a complicated nature and it can be conceptualised in many different ways. According to the International Classification of Diseases 10th edition (ICD-10), lack or loss of sexual desire should be the principal problem and not other sexual problems accompanying it such as ED [979]. In the DSM-V, male hypoactive sexual desire disorder (HSDD) is defined as “the persistent or recurrent deficiency (or absence) of sexual or erotic thoughts or fantasies and desire for sexual activity”. The judgment of deficiency is made by the clinician, taking into account factors that affect sexual functioning, such as age and general and socio-cultural contexts of the individual's life [216]. According to the fourth International Consultation on Sexual Medicine (ICSM), the definition of male HSDD was proposed as a “persistent or recurrent deficiency or absence of sexual or erotic thoughts or fantasies and desire for sexual activity (clinical principle)” [980]. Although the exact prevalence of low sexual desire (LSD) is unknown, a prevalence of 4.7% was reported in a survey of a population-based sample of middle-aged German men (n = 12,646) [981].

7.2 Pathophysiology and risk factors
Several aetiological factors are considered to contribute to the pathophysiology of LSD. Levine proposed three components of sexual desire as drive (biological), motivation (psychological) and wish (cultural) [982]. However, it is believed that both in the surveys and clinical practice those three components are usually found interwoven [983].

7.2.1 Psychological aspects
The endorsement of negative thoughts during sexual intercourse (i.e., concerns about erection, lack of erotic thoughts, and restrictive attitudes toward sexuality) predicts LSD in men [984, 985]. Furthermore, feeling shame during sexual intercourse, because of negative sexual thoughts (e.g., concern about achieving erection), characterises men with LSD as opposed to women with the same condition [986]. Psychopathological symptoms stemming from a crisis context negatively impacted male sexual desire [453], as well. In addition, dyadic male sexual desire was best accounted by sexual satisfaction [987]. It is worth noting that, despite LSD being less common in men than in women [980], it is the most frequent complaint in couples’ therapy [988]. Therefore, the role of relationship factors must be addressed. In addition, anxiety proneness has been associated with LSD in men and is expected to shift men’s attention from erotic cues to worrying thoughts, thereby decreasing sexual desire [989]. Finally, is worth noting that current approaches focus on sexual desire discrepancies between partners; the focus on discrepancies rather than on the partner who presents low desire not only reduces stigma, but also provides new opportunities for the management of desire in the relationship context [990].

7.2.2 Biological aspects
Testosterone seems to be essential for a man’s sexual desire; however, sexual desire does not directly relate to the circulating level of testosterone, especially in older men [991]. The biological and psychological components that take place in the pathophysiology of LSD are shown in Table 24 [983, 992]. In addition to these factors, there is some speculation about the role of thyroid and oxytocin hormones [720, 993].

In an international survey aimed at estimating the prevalence and correlates of sexual problems in 13,882 women and 13,618 men from 29 countries (Global Study of Sexual Attitudes and Behaviours), risk factors for male LSD were age 60-69 and 70-80 years, poor overall health, vascular diseases, being a current smoker, belief that ageing reduces sex, divorce in the past 3 years, financial problems in the last 3 years, major depression, being worried about the future of a relationship and less than one sexual relation in a week [209]. In a recent study that determined the factors associated with LSD in a large sample of middle-aged German men, PE, ED, and lower urinary tract symptoms were associated with LSD [981]. In contrast, men having more than two children, higher frequency of solo-masturbation, perceived importance of sexuality, and higher sexual self-esteem were less likely to have LSD [981].

7.3 Diagnostic work-up

7.3.1 Assessment questionnaires

Sexual Desire Inventory (SDI) evaluates different components influencing the development and expression of sexual desire [994]. This self-administered questionnaire consists of 14 questions that weigh the strength, frequency, and significance of an individual's desire for sexual activity with others and by themselves. The SDI suggests that desire can be split into two categories: dyadic and solitary desire. While dyadic desire refers to “interest in or a wish to engage in sexual activity with another person and desire for sharing and intimacy with another”, solitary desire refers to “an interest in engaging in sexual behaviour by oneself, and may involve a wish to refrain from intimacy and sharing with others” [994].

Physical examination and investigations

Similar to other forms of sexual dysfunctions, a thorough medical and sexual history must be obtained from men who complain of LSD. The depressive symptoms of the patients must be assessed [995] and relationship problems (e.g., conflict with the sexual partner) must be questioned. In the presence of accompanying symptoms suggestive of endocrinological problems, circulating total testosterone [996], prolactin [997] and thyroid hormones [720] levels can be evaluated.

7.4 Disease management

Treatment of LSD should be tailored according to the underlying aetiology.

7.4.1 Psychological intervention

Data on efficacy of psychological interventions for LSD are scarce. Accordingly, recommendations must be interpreted with caution. Psychological interventions with a focus on cognitive and behavioural strategies may be beneficial for LSD in men [460, 998] (Figure 10). Mindfulness treatments may be a strong candidate, as well [998]. Since both members of a couple may experience age-related changes concurrently and interdependently, it could be helpful to address the sexual health needs of the ageing couple (including LSD) as a whole rather than treating the individual patient [999]. Indeed, psychologists are putting more emphasis on the concept of sexual desire discrepancy. Sexual desire discrepancy is often found in couples or partners, and mirror a natural part of life and partners’ dynamics. Clinical approaches based on this lens are less stigmatising as they consider the normal variations in sexual desire that occur throughout the lifespan. This intervention option targets couples distressed by sexual desire discrepancies rather than a single individual targeted as the one presenting low sexual desire [990].
7.4.2 Pharmacotherapy

Low sexual desire secondary to low testosterone levels can be treated with different formulations of testosterone. The favourable effect of testosterone therapy on sexual motivation and the presence of sexual thoughts was shown in a meta-analysis [996]. The aim of treatment should be to reach the physiological range of testosterone (see Section 3.5).

Hyperprolactinaemia can also cause LSD and one of the most relevant aetiological factors is prolactin-secreting pituitary adenomas. These adenomas can be easily diagnosed with MRI of the pituitary gland and can be treated with dopamine agonist agents [1000]. The other accompanying endocrine disorders, such as hypothyroidism, hyperthyroidism and diabetes, should be treated accordingly.

Pharmacotherapy can also be used to treat major depression; however, it should be remembered that antidepressants may negatively affect sexual functioning; therefore, antidepressant compounds with less effect on sexual function should be chosen. Psychotherapy can increase the efficacy of pharmacotherapy, especially for patients whose LSD is due to depression [1001].

8. PENILE CURVATURE

8.1 Congenital penile curvature

8.1.1 Epidemiology/aetiology/pathophysiology

Congenital penile curvature (CPC) is a rare condition, with a reported incidence of < 1% [1002], although some studies have reported higher prevalence rates of 4-10%, in the absence of hypospadias [1003]. Congenital penile curvature results from disproportionate development of the tunica albuginea of the corporal bodies and is not associated with urethral malformation. In most cases, the curvature is ventral, but it can also be lateral and, more rarely, dorsal [1004].

Diagnostic evaluation

Taking a medical and sexual history is usually sufficient to establish a diagnosis of CPC. Patients usually present after reaching puberty as the curvature becomes more apparent with erections, and more severe curvatures can make intercourse difficult or impossible. Physical examination during erection (alternatively photographic or preferably after intracavernous injection [ICI] of vasoactive drugs) is important to document the curvature and exclude other pathologies [1004].

8.1.2 Disease management

The definitive treatment for this disorder remains surgical and can be deferred until after puberty, although a survey has suggested that men with probable untreated ventral penile curvature report more dissatisfaction with penile appearance, increased difficulty with intercourse, and psychological problems; therefore, supporting surgical correction of CPC in childhood [1005]. Surgical treatments for CPC generally share the same principles as in Peyronie's disease. Plication techniques (Nesbit, 16-dot, Yachia, Essed-Schröeder, and others) with or without neurovascular bundle elevation (medial/lateral) and with or without complete penile degloving, have been described [1006-1015]. Other approaches are based on corporal body de-rotation proposed by Shaer with different technical refinements that enable correction of a ventral curvature, with reported minimal narrowing and shortening [1016-1019]. There are no direct comparative studies therefore no single technique can be advocated as superior in terms of surgical correction.

8.2 Peyronie's Disease

8.2.1 Epidemiology/aetiology/pathophysiology

8.2.1.1 Epidemiology

Epidemiological data on Peyronie's disease (PD) are limited. Prevalence rates of 0.4-20.3% have been published, with a higher prevalence in patients with ED and diabetes [1020-1030], [1020-1028]. A recent survey has indicated that the prevalence of definitive and probable cases of PD in the USA is 0.7% and 11%, respectively, suggesting that PD is an under-diagnosed condition [1031]. Peyronie's disease often occurs in older men with a typical age of onset of 50-60 years. However, PD also occurs in younger men (< 40 years), but at a lesser prevalence than in older men (1.5-16.9%) [1024, 1032, 1033].

8.2.1.2 Aetiology

The aetiology of PD is unknown. However, repetitive microvascular injury or trauma to the tunica albuginea is still the most widely accepted hypothesis to explain the aetiology [1034]. Abnormal wound healing leads to
the remodelling of connective tissue into a fibrotic plaque [1034-1036]. Penile plaque formation can result in a curvature, which, if severe, may impair penetrative sexual intercourse. The genetic underpinnings of fibrotic diatheses, including PD and Dupuytren’s disease, are beginning to be understood, although much of the data are contradictory and we do not yet have the basis for predicting who will develop the disease or disease severity (Table 25) [1037, 1038].

8.2.1.3 Risk factors
The most commonly reported associated co-morbidity and risk factors are diabetes, hypertension, dyslipidaemias, ischaemic cardiopathy, autoimmune diseases [1039], ED, smoking, excessive alcohol consumption, low testosterone levels and pelvic surgery (e.g., radical prostatectomy) [390, 1024, 1028, 1040-1042]. Dupuytren’s contracture is more common in patients with PD affecting 8.3-39% of patients [1025, 1043-1045], while 4-26% of patients with Dupuytren’s contracture report PD [1044, 1046, 1047].

8.2.1.4 Pathophysiology
Two phases of the disease can be distinguished [1048]. The first is the active inflammatory phase (acute phase), which may be associated with painful erections and a palpable nodule or plaque in the tunica of the penis; typically, but not invariably, a penile curvature begins to develop. The second is the fibrotic phase (chronic phase) with the formation of hard, palpable plaques that can calcify, with stabilisation of the disease and of the penile deformity. With time, the penile curvature is expected to worsen in 21-48% of patients or stabilise in 36-67% of patients, while spontaneous improvement has been reported in only 3-13% of patients [1040, 1049-1051]. Overall, penile deformity is the most common first symptom of PD (52-94%). Pain is the second most common presenting symptom of PD, which presents in 20-70% of patients during the early
stages of the disease [1052]. Pain tends to resolve with time in 90% of men, usually during the first 12 months after the onset of the disease [1049, 1050]. Palpable plaques have been reported as an initial symptom in 39% of the patients and mostly situated dorsally [50, 1052].

In addition to functional effects on sexual intercourse, men may also suffer from significant psychological distress. Validated mental health questionnaires have shown that 48% of men with PD have moderate or severe depression, sufficient to warrant medical evaluation [1053].

<td>2a</td>
</tr>
</tbody>
</table>

8.2.2 Diagnostic evaluation

The aim of the initial evaluation is to obtain information on the presenting symptoms and their duration (e.g., pain on erection, palpable nodules, deformity, length and girth and erectile function). It is important to obtain information on the distress caused by the symptoms and the potential risk factors for ED and PD. A disease-specific questionnaire (Peyronie’s disease questionnaire [PDQ]) has been developed for use in clinical practice and trials. Peyronie’s disease questionnaire measures three domains, including psychological and physical symptoms, penile pain and symptom bother [1054].

Clinicians should take a focused history to distinguish between active and stable disease, as this will influence medical treatment or the timing of surgery. Patients who are still likely to have active disease are those with a shorter symptom duration, pain on erection, or a recent change in penile deformity. Resolution of pain and stability of the curvature for at least 3 months are well-accepted criteria of disease stabilisation as well as patients’ referral for specific medical therapy [1055, 1056] or surgical intervention, when indicated [1057].

The examination should start with a focused genital assessment that is extended to the hands and feet for detecting possible Dupuytren’s contracture or Ledderhosen scarring of the plantar fascia [1050]. Penile examination is performed to assess the presence of a palpable nodule or plaque. There is no correlation between plaque size and degree of curvature [1058]. Measurement of the stretched or erect penile length is important because it may have an impact on the subsequent treatment decisions and potential medico-legal implications [1059-1061].

An objective assessment of penile curvature with an erection is mandatory. According to current literature, this can be obtained by several approaches, including home (self) photography of a natural erection (preferably), using a vacuum-assisted erection test or an ICI using vasoactive agents. However, it has been suggested that the ICI method is superior, as it is able to induce an erection similar to or better than that which the patient would experience when sexually aroused [1062-1064]. Computed tomography and MRI have a limited role in the diagnosis of the curvature and are not recommended on a routine basis. Erectile function can be assessed using validated instruments such as the IIEF although this has not been validated in PD patients [1065]. Erectile dysfunction is common in patients with PD (30-70.6%) [1066, 1067]. It is mainly an arterial or cavernosal (veno-occlusive) dysfunction in origin [1040, 1058, 1068]. The presence of ED and psychological factors may also have a profound impact on the treatment strategy [1067].

Ultrasound measurement of plaque size is inaccurate but it could be helpful to assess the presence of the plaque and its calcification and location [1069, 1070]. Doppler US may be used for the assessment of penile haemodynamics and ED aetiology [1067].

8.2.3 Disease management

8.2.3.1 Conservative treatment

Conservative treatment of PD is primarily focused on patients in the early stage of the disease as an adjunct treatment to relieve pain and prevent disease progression or if the patient declines other treatment options during the active phase [1050, 1057]. Several options have been suggested, including oral pharmacotherapy, intralesional injection therapy, shockwave therapy (SWT) and other topical treatments (Table 26).

The results of the studies on conservative treatment for PD are often contradictory, making it difficult to provide recommendations in everyday, real-life settings [1071]. The Panel does not support the use of oral treatments for PD including pentoxifylline, vitamin E, tamoxifen, procarbazine, potassium para-aminobenzoate (potaba), omega-3 fatty acids or combination of vitamin E and L-carnitine because of their lack of efficacy (tamoxifen, colchicine, vitamin E and procarbazine) or evidence (potaba, L-carnitine and pentoxyfilline) [1057, 1072-1074]. This statement is based on several methodological flaws in the available studies. These include their uncontrolled nature, the limited number of patients treated, the short-term follow-up and the different outcome measures used [1075, 1076]. Even in the absence of adverse events, treatment with these agents may delay the use of other efficacious treatments.

</tr>
</tbody>
</table>
8.2.3.1.1 Oral treatment

**Phosphodiesterase type 5 inhibitors**

Phosphodiesterase type 5 inhibitors were first suggested as a treatment for PD in 2003 to reduce collagen deposition and increase apoptosis through the inhibition of transforming growth factor (TGF)-b1 [1077-1079]. A retrospective study of 65 men suggested the use of PDE5Is as an alternative for the treatment of PD. The results indicated that treatment with tadalafil was helpful in decreasing curvature and remodelling septal scars when compared to controls [1080]. Another recent study concluded that sildenafil was able to improve erectile function and pain in PD patients. Thirty-nine patients with PD were divided into two groups receiving vitamin E (400 IU) or sildenafil 50 mg for 12 weeks and significantly better outcomes in pain and IIEF score were seen in the sildenafil group [1081].

**Nonsteroidal anti-inflammatory drugs**

Nonsteroidal anti-inflammatory drugs (NSAIDs) may be offered to patients in active-phase PD in order to manage penile pain, which is usually present in this phase. Pain levels should be periodically reassessed in monitoring treatment efficacy.

8.2.3.1.2 Intralesional treatment

Injection of pharmacologically active agents directly into penile plaques represents another treatment option. It allows a localised delivery of a particular agent that provides higher concentrations of the drug inside the plaque. However, delivery of the compound to the target area is difficult to ensure, particularly when a dense or calcified plaque is present.

**Calcium channel antagonists: verapamil and nicardipine**

The rationale for intralesional use of channel antagonists in patients with PD is based on in vitro research [1082, 1083]. Due to the use of different dosing schedules and the contradictory results obtained in published studies, the evidence is not strong enough to support the clinical use of injected channel blockers verapamil and nicardipine and the results do not demonstrate a meaningful improvement in penile curvature compared to placebo [1084-1089]. In fact, most of the studies did not perform direct statistical comparison between groups.

**Collagenase of Clostridium histolyticum**

Collagenase of *Clostridium histolyticum* (CCH) is a chromatographically purified bacterial enzyme that selectively attacks collagen, which is known to be the primary component of the PD plaque [1090-1093]. Intralesional injection of CCH has been used in the treatment of PD since 1985. In 2014 the EMA approved CCH for the nonsurgical treatment of the stable phase of PD in men with palpable dorsal plaques in whom abnormal curvature of 30-90° and non-ventrally located plaques are present. It should be administered by a healthcare professional who is experienced and properly trained in the administration of CCH treatment for PD [1094, 1095].

The original treatment protocol in all studies consists of two injections of 0.58 mg of CCH 24-72 hours apart every 6 weeks for up to four cycles. Data from IMPRESS (Investigation for Maximal Peyronie’s Reduction Efficacy and Safety Studies) II and II studies [976], as well as post approval trials [1096], which demonstrated the efficacy and safety of this treatment, are summarised in Table 27.

SP = Stable phase; AP = Acute phase; N/S = Non-significant.

The average improvement in curvature was 34% compared to 18.2% in the placebo group. Three adverse events of corporeal rupture were surgically repaired. The greatest chance of curvature improvement is for curvatures between 30° and 60°, longer duration of disease, IIEF > 17, and no calcification [1056]. An 18.2% improvement from baseline in the placebo arm was also observed. These findings raise questions regarding the alleged role of plaque injection and penile modelling, regardless of the medication, in improving outcomes in men with PD as the placebo or modelling arm resulted in high curvature reduction compared to treatment.

The conclusion of the IMPRESS I and II studies is that that CCH improves PD both physically and psychologically [1097]. A post hoc meta-analysis of the IMPRESS studies demonstrated better results in patients with < 60° of curvature, > 2 years evolution, no calcification in the plaque and good erectile function [1096].

Thereafter, a modified short protocol consisting of administration of a single (0.9 mg, one vial) injection per cycle distributed along three lines around the point of maximum curvature up to three cycles, separated by 4-weekly intervals, has been proposed, and replaces the physician modelling with a multi-modal approach through penile stretching, modelling and VED at home [1102]. The results from this modified protocol were comparable to the results of the IMPRESS trials and appeared to decrease the cost and duration of treatment, although these represent non-randomised study protocols. These results were further explored in a prospective non-randomised multi-centre study [982]. In another large single-arm multi-centre clinical study using the shortened protocol, longer PD duration, greater baseline PC and basal and dorsal plaque location were identified as clinically significant predictors of treatment success [1104]. Accordingly, a nomogram developed to predict treatment success after CCH for PD showed that patients with longer PD duration, greater baseline
penile curvature and basal plaque location had a greater chance of treatment success [1104]; however, these findings need to be externally validated.

Regarding safety concerns, most PD patients treated with CCH experienced at least one mild or moderate adverse reaction localised to the penis (penile haematoma (50.2%), penile pain (33.5%), penile swelling (28.9%) and injection site pain (24.1%)), which resolved spontaneously within 14 days of injection [1105]. The adverse reaction profile was similar after each injection, regardless of the number of injections administered. Serious treatment-emergent adverse events (TEAEs) (0.9%) include penile haematoma and corporeal rupture that require surgical treatment. According to IMPRESS data and the shortened protocol, to prevent serious TEAEs men should be advised to avoid sexual intercourse in the 4 weeks following injection. Recent preliminary data suggest that treatment in the acute phase of the disease can be effective and safe [1065, 1099, 1100, 1106-1108].

In conclusion, CCH is a safe and established treatment for stable-phase disease. More recent evidence suggests that CCH also has a role in affecting the progression of active-phase disease, thus supporting the idea that the indications for CCH use could be expanded, although there is the possibility of a high placebo effect. It should also be noted that there is a large effect of traction or modelling in controlled studies, while studies reporting on modified protocols have small numbers of patients and are largely uncontrolled. Therefore, patients should be counselled fully on the efficacy of collagenase and the high cost of treatment.

It has been suggested that those patients with severe curvature may also benefit from CCH injections because of a potential downgrading of the penile curvature: a decrease in curvature may allow for a penile plication procedure instead of a plaque incision and grafting procedure, therefore avoiding the more negative impact on erectile function. However, further investigation is needed to validate these initial findings [1065, 1100].

The Panel has agreed to keep the whole set of information and recommendations regarding the use of CCH in men with PD despite the recent official withdrawal of the product from the European market by the company.

**Interferon α-2b**

Interferon α-2b (IFN-α2b) has been shown to decrease fibroblast proliferation, extracellular matrix production and collagen production by fibroblasts and improve the wound healing process from PD plaques in vitro [1109]. Intraleisional injections (5x10^6 units of IFN-α2b in 10 mL saline every 2 weeks over 12 weeks for a total of six injections) significantly improved penile curvature, plaque size and density, and pain compared to placebo. Additionally, penile blood flow parameters are benefited by IFN-α2b [1095, 1110, 1111]. Regardless of plaque location, IFN-α2b is an effective treatment option. Treatment with IFN-α2b provides a > 20% reduction in curvature in most men with PD, independent of plaque location [1112]. Given the mild adverse effects, which include sinusitis and flu-like symptoms, which can be effectively treated with NSAIDs before IFN-α2b injection, and the moderate strength of data available, IFN-α2b is currently recommended for treatment of stable-phase PD.

**Steroids, hyaluronic acid and botulinum toxin (botox)**

In the only single-blind, placebo-controlled study with intralesional administration of betamethasone, no statistically significant changes in penile deformity, penile plaque size, and penile pain during erection were reported [1113]. Adverse effects include tissue atrophy, thinning of the skin and immunosuppression [1114]. The effect of hyaluronic acid treatment in patients with PD was investigated in recent studies [1115-1118]. In a non-randomised study, intralesional injection of hyaluronic acid was compared to intralesional verapamil in acute phase PD and significant improvement of pain, curvature and IIEF-15 was observed [1117]. In a RCT, oral administration of hyaluronic acid combined with intralesional injection has been found superior to intralesional injection only and improvement of 7.8±3.9 degrees in curvature and reduction in plaque size of 3.0 mm was observed (LE:1b) [1118]. As only a single study evaluated intralesional botox injections in men with PD, the Panel conclude that there is no robust evidence to support these treatments [1119].

**Platelet Rich Plasma (PRP)**

In an experimental in-animal study investigating the effect of PRP on PD, no reduction in terms of plaque size has been shown, but the use of PRP resulted in increase in type III/type I collagen ratio and collagen/smooth muscle ratio [1120]. Few studies in humans have evaluated the effect of PRP on penile curvature, plaque size, PDQ and IIEF with low level of evidence (LE:3) (Table 28). Significant improvement has been found in penile curvature, and IIEF in two studies. Another two studies showed additional improvement in plaque size and PDQ. The effect of PRP in patients with Peyronie’s disease remains to be proven and should be considered as experimental.

8.2.3.1.3 Topical treatments

**Topical verapamil and H-100 Gel**

There is no sufficient and unequivocal evidence that topical treatments (verapamil, H-100 Gel [a compound with nicardipine, superoxide dismutase and emu oil] or steroids) applied to the penile shaft, with or without the use of iontophoresis (now known as transdermal electromotive drug administration), result in adequate levels of the active compound within the tunica albuginea [1125-1128]. Therefore, the Panel does not support the use of topical treatments for PD applied to the penile shaft.

**Extracorporeal shockwave treatment**

The mechanical shear stress provoked by low-intensity extracorporeal shock wave treatment (LI-ESWT) on the treated tissue was deemed to induce neovascularisation and to enhance local blood flow [1071]. The mechanism of action involved in ESWT for PD is still unclear, but there are two hypotheses: (i) SWT works by directly damaging and remodelling the penile plaque; and (ii) SWT increases the vascularity of the area by generating thermodynamic changes resulting in an inflammatory reaction, with increased macrophage activity causing plaque lysis and eventually leading to plaque resorption [1129, 1130].

Four RCTs and one meta-analysis [1131-1135] assessed the efficacy of ESWT for PD. Three were sham-controlled trials while one compared ESWT with the combination of ESWT and PDE5I (tadalafil) [1129].

All trials showed positive findings in terms of pain relief, but no effect on penile curvature and plaque size. Inclusion criteria varied widely among studies and further investigation is needed. The results are summarised in Table 29.

Penile traction therapy

In men with PD, potential mechanisms for disease modification with penile traction therapy (PTT) have been described, including collagen remodelling via decreased myofibroblast activity and matrix metalloproteinase up-regulation [1136, 1137]. The stated clinical goals of PTT are to non-surgically reduce curvature, enhance girth, and recover lost length, which are attractive to patients with PD. However, clinical evidence is limited due to the small number of patients included (267 in total), the heterogeneity in the study designs, and the non-standardised inclusion and exclusion criteria which make it impossible to draw any definitive conclusions about this therapy [1138-1142].

Most of the included patients will need further treatment to ameliorate their curvature for satisfactory sexual intercourse. Moreover, the effect of PTT in patients with calcified plaques, hourglass or hinge deformities which are, theoretically, less likely to respond to PTT has not been systematically studied. In addition, the treatment can result in discomfort and be inconvenient due to use of the device for an extended period (2-8 hours daily), but has been shown to be tolerated by highly-motivated patients. There were no serious adverse effects, including skin changes, ulcerations, hypo-aesthesia or diminished rigidity [1140, 1143].

In conclusion, PTT seems to be effective and safe for patients with PD, but there is still lack of evidence to give any definitive recommendation in terms of monotherapy for PD.

8.2.3.1.4 Multimodal treatment

There are some data suggesting that a combination of different oral drugs can be used for treatment of the acute phase of PD. However, there does not seem to be a consensus on which drugs to combine or the optimum drug dosage; nor has there been a comparison of different drug combinations.

A long-term study assessing the role of multimodal medical therapy (injectable verapamil associated with antioxidants and local diclofenac) demonstrated that it is efficacious to treat PD patients. The authors concluded that combination therapy reduced pain more effectively than verapamil alone, making this specific combination treatment more effective compared to monotherapy [1145]. Furthermore, combination protocols including injectable therapies, such as CCH, have been studied in controlled trials. The addition of adjunctive PTT and VED has been described; however, limited data are available regarding its use [1147].

Penile traction therapy has been evaluated as an adjunct therapy to intralesional injections with interferon, verapamil, or CCH [1085, 1148, 1149]. These studies have failed to demonstrate significant improvements in penile length or curvature, with the exception of one subset analysis identifying a 0.4 cm length increase among men using the devices for > 3 hours/day [1149]. A meta-analysis demonstrated that men who used PTT as an adjunct to surgery or injection therapy for PD had, on average, an increase in stretched penile length (SPL) of 1 cm compared to men who did not use adjunctive PTT. There was no significant change in curvature between the two groups [1150].

Data available on the combined treatment of CCH and the use of VED between injection intervals have shown significant mean improvements in curvature (-17°) and penile length (+0.4 cm) after treatment. However, it is not possible to determine the isolated effect of VED because of a lack of control groups [1102, 1150].

Recent data have suggested that combination of PDE5i (sildenafil 25 mg twice daily) after CCH treatment (shortened protocol combined with VED) is superior to CCH alone for improving penile curvature and erectile function. Further studies are necessary to externally validate those findings.

8.2.3.2 Surgical treatment

Although conservative treatment for PD may resolve painful erections in most men, only a small percentage experience significant straightening of the penis. The aim of surgery is to correct curvature and allow penetrative intercourse. Surgery is indicated in patients with significant penile deformity and difficulty with intercourse associated with sexual bother. Patients must have a stable disease for 3-6 months (or more than 9-12 months after onset of PD) [1048, 1057, 1151]. In addition to this requirement, there are other situations that may precipitate an indication for surgery, such as failed conservative or medical therapies, extensive penile plaques, or patient preference, when the disease is stable [1152, 1153].

Before considering reconstructive surgery, it is recommended to document the size and location of penile plaques, the degree of curvature, complex deformities (hinge or hourglass), the penile length and the presence or absence of ED. The potential aims and risks of surgery should be fully discussed with the patient so that he can make an informed decision [1151]. Specific issues that should be mentioned during this discussion are: risk of penile shortening; ED, penile numbness; and delayed orgasm, the risk of recurrent curvature, potential for palpation of knots and stitches underneath the skin, potential need for circumcision at the time of surgery, residual curvature and the risk of further penile wasting with shortening procedures [1057, 1154]. Selection of the most appropriate surgical intervention is based on penile length assessment, curvature severity and erectile function status, including response to pharmacotherapy in cases of ED [1057]. Patient expectations from surgery must also be included in the pre-operative assessment. The main objective of surgery is to achieve a “functionally straight” penis, and this must be fully understood by the patient to achieve the best possible satisfaction outcomes after surgery [1151, 1155].

Three major types of reconstruction may be considered for PD: (i) tunical shortening procedures; (ii) tunical lengthening procedures; and, (iii) penile prosthesis implantation, with or without adjunct straightening techniques in the presence of concomitant ED and residual curvature [1156, 1157].

Tunical shortening procedures achieve straightening of the penis by shortening the longer, convex side of the penis to make it even with the contralateral side. Tunical lengthening procedures are performed on the concave side of the penis after making an incision or partial excision of the plaque, with coverage of the defect with a graft. Although tunical lengthening procedures rarely lead to long-term penile length gain, they aim to minimise penile shortening caused by plication of the tunica albuginea, and correct complex deformities. In practice, tunical lengthening procedures are often combined with penile plication or shortening procedures to correct residual curvature [1158]. In patients with PD and ED not responding to medical treatments, penile prosthesis implantation can be considered with correction of the curvature including adjunct techniques (modelling, plication or incision/excision with grafting).

Penile degloving with associated circumcision (as a means of preventing post-operative phimosis) should be considered the standard approach for all types of procedures, although modifications have been described. Only one study has suggested that circumcision is not always necessary (e.g., in cases where the foreskin is normal pre-operatively) [1159]. Non-degloving techniques have been described that have been shown to prevent ischaemia and lymphatic complications after subcoronal circumcision [1160, 1161].

There are no standardised questionnaires for the evaluation of surgical outcomes. Data from well-designed prospective studies are scarce, with low levels of evidence. Data are mainly based on retrospective single-centre studies, typically non-comparative and non-randomised, or on expert opinion [1057, 1162]. Therefore, surgical outcomes must be treated with caution.

8.2.3.2.1 Tunical shortening procedures

For men with good erectile function, adequate penile length, without complex deformities, such as an hourglass or hinge type narrowing abnormality, and non-severe curvature, a tunical shortening procedure can be considered an appropriate surgical approach. Numerous different techniques have been described, although they can be classified as excisional, incisional and plication techniques.

In 1965, Nesbit was the first to describe the removal of tunical ellipses opposite to the point of maximum curvature with a non-elastic corporal segment to treat CPC [1163]. Thereafter, this technique became a successful treatment option for PD-associated penile curvature [1164]. This operation is based on a 5-10 mm
transverse elliptical excision of the tunica albuginea or ~1 mm for each 10° of curvature. The overall short- and long-term results of the Nesbit operation are excellent [1165-1169]. Some modifications of the Nesbit procedure have been described (partial thickness shaving instead of conventional excision; underlapped U incision) with similar results, although these are in non-randomised studies [1170-1174].

The Yachia technique is based on a completely different concept, as it utilises the Heinke-Mikowtiz principle for which a longitudinal tunical incision is closed transversely to shorten the convex side of the penis. This technique, initially described by Lemberger in 1984, was popularised by Yachia in 1990, when he reported a series of 10 cases [1175-1180].

Pure plication techniques are simpler to perform. They are based on single or multiple plications performed without making excisions or incisions, to limit the potential damage to the veno-occlusive mechanism [1059, 1181-1197]. Another modification has been described as the ‘16-dot’ technique that consists of application of two pairs of parallel Essed-Schroeder plications tensioned more or less depending on the degree of curvature [1174, 1198-1200]. The use of non-absorbable sutures or longer-lasting absorbable sutures may reduce recurrence of the curvature (Panel expert opinion). Results and satisfaction rates are both similar to the incision/excision procedures.

In general, using these tunical shortening techniques, complete penile straightening is achieved in > 85% of patients. Recurrence of the curvature and penile hypo-aesthesia is uncommon (~10%) and the risk of post-operative ED is low. Penile shortening is the most commonly reported outcome of these procedures. Shortening of 1-1.5 cm has been reported for 22-69% of patients, which is rarely the cause of post-operative sexual dysfunction and patients may perceive the loss of length as greater than it actually is. It is therefore strongly advisable to measure and document the penile length peri-operatively, both before and after the straightening procedure, whatever the technique used (Table 31).

As mentioned above, there are multiple techniques with small modifications and all of them have been reported in retrospective studies, most of them without comparison between techniques and therefore the level of evidence is not sufficient to recommend one method over another.

8.2.3.2.2 Tunical lengthening procedures

Tunical lengthening surgery is preferable in patients with significant penile shortening, severe curvature and/or complex deformities (hourglass or hinge) but without underlying ED. The definition of severe curvature has been proposed to be > 60°, although no studies have validated this threshold. However, it may be used as an informative guide for patients and clinicians in surgical counselling and planning, although there is no unanimous consensus based on the literature that such a threshold can predict surgical outcomes (Panel expert consensus opinion). On the concave side of the penis, at the point of maximum curvature, which usually coincides with the location of the plaque, an incision is made, creating a defect in the albuginea that is
covered with a graft. Complete plaque removal or plaque excision may be associated with higher rates of post-operative ED due to venous leak, but partial excision in cases of florid calcification may be permissible [1201, 1202]. Patients who do not have pre-operative ED should be informed of the significant risk of post-operative ED of up to 50% [1154].

Since 1974, when the first study using dermal grafting to treat PD was published [1203], a large number of different grafts have been used. The ideal graft should be resistant to traction, easy to suture and manipulate, flexible (not too much, to avoid aneurysmal dilations), readily available, cost-effective, and morbidity should be minimal, especially when using autografts. No graft material meets all of these requirements. Moreover, the studies performed did not compare different types of grafts and biomaterials and were often single-centre retrospective studies so there is not a single graft that can be recommended for surgeons [1204]. Grafting procedures are associated with long-term ED rates as high as 50%. The presence of pre-operative ED, the use of larger grafts, age > 60 years, and ventral curvature are considered poor prognostic factors for good functional outcomes after grafting surgery [1157]. Although the risk for penile shortening appears to be less than that compared to the Nesbit, Yachia or plication procedures, it is still an issue and patients must be informed accordingly [1156]. Higher rates (3-52%) of penile hypo-aesthesia have also been described after these operations, as damage of the neurovascular bundle with dorsal curves (in the majority) is inevitable. A recent prospective study showed that 21% of patients had some degree of sensation loss at 1 week, 21% at 1 month, 8% at 6 months, and 3% at 1 year [1205]. The use of geometric principles introduced by Egydio may help to determine the exact site of the incision, and the shape and size of the defect to be grafted [1206].

Grafts for PD surgery can be classified into four types (Table 31) [1049]:
- **Autografts**: taken from the individual himself, they include the dermis, vein, temporalis fascia, fascia lata, tunica vaginalis, tunica albuginea and buccal mucosa.
- **Allografts**: also of human origin but from a deceased donor, including the pericardium, fascia lata and dura mater.
- **Xenografts**: extracted from different animal species and tissues, including bovine pericardium, porcine small intestinal submucosa, bovine and porcine dermis, and TachoSil® (matrix of equine collagen).
- **Synthetic grafts**: these include Dacron® and Gore-Tex®.

All the autologous grafts have the inconvenience of possible graft harvesting complications. Dermal grafts are commonly associated with veno-occlusive ED (20%) due to lack of adaptability, so they have not been used in contemporary series [1203, 1204, 1207-1217]. Vein grafts have the theoretical advantage of endothelial-to-endothelial contact when grafted to underlying cavernosal tissue. The saphenous vein has been the most commonly used vein graft [1218-1233]. For some extensive albuginea defects, more than one incision may be needed. Tunica albuginea grafts have perfect histological properties but have some limitations: the size that can be harvested, the risk of weakening penile support and making future procedures (penile prosthesis implantation) more complicated [1234-1236]. Tunica vaginalis is easy to harvest and has little tendency to contract due to its low metabolic requirements, although better results can be obtained if a vascular flap is used [1237-1241]. Under the pretext that by placing the submucosal layer on the corpus cavernosum the graft feeds on it and adheres more quickly, the buccal mucosal graft has recently been used with good short-term results [1242-1248].

Cadaveric dura mater is no longer used due to concerns about the possibility of infection [1249, 1250]. Cadaveric pericardium (Tutoplast©) offers good results by coupling excellent tensile strength and multidirectional elasticity/expansion by 30% [1139, 1202, 1213, 1251, 1252]. Cadaveric or autologous fascia lata or temporalis fascia offers biological stability and mechanical resistance [1253-1255].

Xenografts have become more popular in recent years. Small intestinal submucosa (SIS), a type I collagen-based xenogenic graft derived from the submucosal layer of the porcine small intestine, has been shown to promote tissue-specific regeneration and angiogenesis, and supports host cell migration, differentiation and growth of endothelial cells, resulting in tissue structurally and functionally similar to the original [1256-1265]. As mentioned above, pericardium (bovine, in this case) has good traction resistance and adaptability, and good host tolerance [1233, 1266-1269]. Grafting by collagen fleece (TachoSil®) in PD has some major advantages such as decreased operating times, easy application and an additional haemostatic effect [1270-1275].

It is generally recommended that synthetic grafts, including polyester (Dacron®) and polytetrafluoroethylene (Gore-Tex®) are avoided, due to increased risks of infection, secondary graft inflammation causing tissue fibrosis, graft contractures, and possibility of allergic reactions [1178, 1276-1279].
Some authors recommend post-operative penile rehabilitation to improve surgical outcomes. Some studies have described using VED and PTT to prevent penile length loss of up to 1.5 cm [1280]. Daily nocturnal administration of PDE5I enhances nocturnal erections, encourages perfusion of the graft, and may minimise post-operative ED [1281]. Massages and stretching of the penis have also been recommended once wound healing is complete.

*Data are expressed as weighted average. Ranges are in parentheses.  
ED = Erectile dysfunction; SIS = Small intestinal submucosa.

The results of tunical shortening and lengthening approaches are presented in Tables 30 and 31. It must be emphasised that there have been no RCTs comparing surgical outcomes in PD. The risk of ED seems to be greater for penile lengthening procedures [1057]. Recurrent curvature is likely to be the result of failure to wait until the disease has stabilised, re-activation of the condition following the development of stable disease, or the use of early re-absorbable sutures (e.g., Vicryl) that lose their strength before fibrosis has resulted in acceptable strength of the repair. Accordingly, it is recommended that only non-absorbable sutures or slowly re-absorbable absorbable sutures (e.g., polydioxanone) should be used. With non-absorbable sutures, the knot should be buried to avoid troublesome irritation of the penile skin, but this issue may be alleviated by the use of slowly re-absorbable sutures (e.g., polydioxanone) [1165]. Penile numbness is a potential risk of any surgical procedure, involving mobilisation of the dorsal neurovascular bundle. This is usually a temporary neuropraxia, due to bruising of the dorsal sensory nerves. Given that the usual deformity is a dorsal deformity, the procedure most likely to induce this complication is a lengthening (grafting) procedure, or the association with (albeit rare) ventral [1156].

8.2.3.2.3 Penile prosthesis

Penile prosthesis (PP) implantation is typically reserved for the treatment of PD in patients with concomitant ED not responding to conventional medical therapy (PDE5i or intracavernous injections of vasoactive agents) [1057]. Although inflatable prostheses (IPPs) have been considered more effective in the general population with ED, some studies support the use of malleable prostheses in these patients with similar satisfaction rates [1057, 1284, 1285]. The evidence suggests that there is no real difference between the available IPPs [1286]. Surgeons can and should advise on which type of prosthesis best suits the patient but it is the patient who should ultimately choose the prosthesis to be implanted [692].

Most patients with mild-to-moderate curvature can expect an excellent outcome simply by cylinder insertion [1231, 1287]. If the curvature after placement of the prosthesis is < 30° no further action is indicated, since
the prosthesis itself will act as an internal tissue expander to correct the curvature during the subsequent 6-9 months. If, the curvature is > 30°, the first-line treatment would be modelling with the prosthesis maximally inflated (manually bent on the opposite side of the curvature for 90 seconds, often accompanied by an audible crack) [1288, 1289]. If, after performing this manoeuvre, a deviation > 30° persists, subsequent steps would be incision with collagen fleece coverage or without (if the defect is small, it can be left uncovered) or plaque incision and grafting [1290-1295]. However, the defect may be covered if it is larger, and this can be accomplished using grafts commonly used in grafting surgery (described above) which prevent herniation and recurrent deformity due to the scarring of the defect [1296]. The risk of complications (infection, malformation, etc.) is not increased compared to that in the general population. However, a small risk of urethral perforation (3%) has been reported in patients with ‘modelling’ over the inflated prosthesis [1288].

In selected cases of end-stage PD with ED and significant penile shortening, a lengthening procedure, which involves simultaneous PP implantation and penile length restoration, such as the “sliding” technique has been considered [1297]. Although the “sliding” technique is not recommended due to reported cases of glans necrosis because of the concomitant release of the neurovascular bundle and urethra, new approaches for these patients have been recently described, such as the MoST (Modified Sliding Technique), MUST (Multiple-Slit Technique) or MIT (Multiple-Incision Technique) techniques, but these should only be used by experienced high-volume surgeons and after full patient counselling [1298-1301].

While patient satisfaction after IPP placement in the general population is high, satisfaction rates have been found to be significantly lower in those with PD. Despite this, depression rates decreased after surgery in PD patients (from 19.3-10.9%) [1302]. The main cause of dissatisfaction after PPI in the general population is a shortened penile length. Therefore, patients with PD undergoing PP surgery must be counselled that the prostheses are not designed to restore the previous penile length [1302, 1303].

8.2.3.3 Treatment algorithm
As mentioned above, in the active phase of the disease, most therapies are experimental or with low evidence. In cases of pain, LI-ESWT, tadalafil and NSAIDs can be offered. In cases of curvature or penile shortening, traction therapy has demonstrated good responses.

When the disease has stabilised, intralesional treatments (mainly CCH) or surgery may be used. Intralesional treatments may reduce the indications for surgery or change the technique to be performed but only after full patient counselling, which should also include a cost-benefit discussion with the patient.

The decision on the most appropriate surgical procedure to correct penile curvature is based on pre-operative assessment of penile length, the degree of curvature and erectile function status. In non-complex and non-severe deformities, tunical shortening procedures are acceptable and are usually the method of choice. This is typically the case for CPC. If severe curvature or complex deformation is present (hourglass or hinge), or if the penis is significantly shortened in patients with good erectile function (preferably without pharmacological treatment), then tunical lengthening is feasible, using any of the grafts previously mentioned. If there is concomitant ED, which is not responsive to pharmacological treatment, the best option is the implantation of a penile prosthesis, with or without a straightening procedure over the penis (modelling, plication, incision or excision with or without grafting). The treatment algorithm is presented in Figure 11.
Figure 11: Treatment algorithm for Peyronie’s disease

**Treatment of Peyronie’s disease**

Discuss natural history of the disease
Reassure patient that Peyronie’s doesn’t lead to any form of malignancy

  - Residual curvature
    - > 30°
      - Tunical plication/Plaque incision + grafting
    - < 30°
      - No additional straightening procedures

**No**

- Short penis
- Severe curvature
- Complex deformities (hourglass, hinge)

**ED = erectile dysfunction; LI-ESWT = Low-intensity extracorporeal shockwave treatment; NSAIDs = non-steroidal anti-inflammatory drugs; CCH = Collagenase Clostridium histolyticum; IFN-α2b = Interferon-α2b.**
9. PRIAPISM

Evidence Acquisition and limitations
The Panel conducted systematic reviews on the medical and surgical management of ischaemic and non-ischaemic priapism and a dedicated systematic review on the overall management of priapism related to sickle cell disease. The results of these systematic reviews are presented below in the guidelines and the limitations of the studies that were assessed are highlighted.

Most studies had the same limitations and methodological bias: lack of published protocols, retrospective and usually single-arm design, lack of randomisation and blinding, incomplete outcome data, and selective reporting. Additionally, most studies included small numbers of patients, reported non-standardised patient characteristics, and had short (or even unreported) follow-up times and, in general, they reflected single-unit practices.

The definitions of priapism and outcomes (such as success and related complications) were inconsistent across the literature and few of the trials met the clear definitions that were set by the Panel for use in the systematic reviews. Hence, any attempt to draw clinically meaningful conclusions and offer evidence-based guidance based on systematic assessment of the literature was a challenging task. These limitations highlight the urgent need for clear and commonly accepted definitions of conditions and outcomes that should be used by researchers in the future so that robust evidence can be developed to support relevant guidelines and clinical practice recommendations.

The Panel acknowledged the evidence-related limitations, and in accordance with the GRADE approach endorsed by the European Association of Urology Guidelines Office, also took into consideration the benefits/harms balance and the patient ideals, views and preferences prior to finalising the relevant recommendations (for/against, weak/strong).

Priapism is a persistent or prolonged erection in the absence of sexual stimulation that fails to subside. It can be divided into ischaemic, non-ischaemic and stuttering priapism.

9.1 Ischaemic (Low-Flow or Veno-Occlusive) Priapism

9.1.1 Epidemiology, aetiology, pathophysiology and Diagnosis
Ischaemic priapism is a persistent erection marked by rigidity of the corpora cavernosa and by little or no cavernous arterial inflow [1304]. Ischaemic priapism is the most common subtype of priapism, accounting for > 95% of all episodes [1304, 1305]. It presents as a painful rigid erection that is characterised clinically by absent or reduced intracavernous arterial inflow, although proximally there is a compensated high velocity picture with little flow distally [1306]. In ischaemic priapism, there are time-dependent metabolic alterations within the corpus cavernosum progressively leading to hypoxia, hypercapnia, glucopenia and acidosis [1307, 1308].

Ischaemic priapism that lasts beyond 4 hours is similar to a compartment syndrome and characterised by the development of ischaemia within the closed space of the corpora cavernosa, which severely compromises the cavernosal circulation. Emergency medical intervention is required to minimise irreversible consequences, such as smooth muscle necrosis, corporal fibrosis and the development of permanent erectile dysfunction (ED) [1309, 1310]. The duration of ischaemic priapism represents the most significant predictor for the development of ED. In this context, interventions beyond 48-72 hours of onset may help to relieve the erection and pain, but have little clinical benefit in preventing long-term ED [1311].

Histological analysis of corporal smooth muscle biopsies shows that at 12 hours, there are features of interstitial oedema, progressing to destruction of the sinusoidal endothelium, exposure of the basement membrane and thrombocyte adherence by 24 hours. At 48 hours, thrombi in the sinusoidal spaces and smooth muscle necrosis with fibroblast-like cell transformation are evident [1312]. This implies that by 48 hours there appears to be smooth muscle necrosis and irreversibility of these ischaemic changes. A case-control study comparing corporal biopsies from patients with priapism lasting 48-72 hours with control penile tissues retrieved from autopsies demonstrated a significantly lower percentage of smooth muscle fibres, with an increase in elastic fibres and collagen [1309, 1313].

No specific pathophysiological causes of ischaemic priapism can be identified in most cases [1304, 1314], although the common aetiological factors include sickle cell disease (SCD), haematological dyscrasias, neoplastic syndromes, and several pharmacological agents (e.g., intracavernosal PGE1 therapy) (Table 32). Ischaemic priapism may occur (0.4-35%) after intracavernosal injection of erectogenic agents [585, 1304, 1309, 1315, 1316]. The risk is higher with papaverine-based combinations [1317], while the risk of priapism is < 1% following prostaglandin E1 injection [1318].
Second-generation antipsychotics (33.8%), other medications (11.3%), and alpha-adrenergic antagonists (8.8%) accounted for the greatest percentage of published drug-induced priapism cases [1319]. Isolated cases of priapism have been described in men who have taken PDE5Is [1304]. A recent study from the FDA Adverse Reporting System Public Dashboard showed that PDE5Is-induced priapism accounted for only 2.9% of drug-induced priapism. However, most of these men also had other risk factors for priapism, and it is unclear whether PDE5Is per se can cause ischaemic priapism [1304]. Since most men who experience priapism following PDE5I treatment have additional risk factors for ischaemic priapism, PDE5Is use is usually not regarded as a risk factor in itself. In terms of haemoglobinopathies, SCD is the most common cause of priapism in childhood, accounting for 63% of cases. It is the primary aetiology in 23% of adult cases [1318], and men with SCD have a lifetime probability of 29-42% of developing ischaemic priapism [1318, 1320, 1321] (LE: 4).

Mechanisms of SCD-associated priapism may involve derangements of several signalling pathways in the penis, resulting in disinhibited vasorelaxation of the cavernous smooth muscle by nitric oxide synthase (NOS) and Rho-associated protein kinase (ROCK) signalling, and increased oxidative stress associated with nicotinamide adenine dinucleotide phosphate (NADPH) oxidase-mediated signalling. Excessive adenosine and up-regulation of opiorphins in response to hypoxia reduce PDE5 gene expression and activity and impair NO bioavailability in the penis. Excessive oxidative/nitrosative stress and decreased activity of the RhoA/Rho-kinase contractile pathway further promotes priapism. Contrary to traditional belief, maintenance of physiological testosterone levels does not cause priapism, but rather preserves penile homeostasis and promotes normal erectile function [1322, 1323]. Testosterone deficiency is considered a controversial risk factor: it is prevalent in patients with SCD, but recent evidence indicates that it is not a risk factor per se for priapism [1324].

Priapism resulting from metastatic or regional infiltration by tumour is rare and usually reflects an infiltrative process, more often involving the bladder and prostate as the primary cancer sites [1325]. In a recent large retrospective study including 412 men with ischaemic priapism, eleven (3.5%) had malignant priapism, of which seven cases were a consequence of local invasion while the others were secondary to haematological malignancy [1326]. The conventional therapeutic recommendations for pharmacological treatment are unlikely to be effective and all of these men should have MRI of the penis and be offered supportive care and medical intervention for their primary cancer. In selected cases where palliative treatment options fail to control penile pain, a palliative penectomy can be considered.

Partial priapism, or idiopathic partial segmental thrombosis of the corpus cavernosum, is a rare condition. It is often classified as a subtype of priapism limited to a single crura without ischaemia, but rather a thrombus is present within the corpus cavernosum. Its aetiology is unknown, but bicycle riding, trauma, drug use, sexual intercourse, haematological diseases and α-blockers intake have all been associated with partial segmental thrombosis [1327]. The presence of a congenital web within the corpora is also a risk factor [1328].

9.1.2 Diagnostic evaluation

Figure 12: Differential diagnosis of priapism

9.1.2.1 History

Taking a comprehensive history is critical in priapism diagnosis and treatment [1304, 1329]. The medical history must specifically enquire about SCD or any other haematological abnormality [1330, 1331] and a history of pelvic, genital or perineal trauma. The sexual history must include the duration of the erection, the presence and degree of pain, prior drug treatment, history of priapism and erectile function prior to the last priapism episode (Table 33). The history can help to determine the underlying priapism subtype (Table 34). Ischaemic priapism is classically associated with progressive penile pain and the erection is rigid. However, non-ischaemic priapism is often painless and the erections often fluctuate in rigidity.

9.1.2.2 Physical examination

In ischaemic priapism, the corpora are fully rigid and tender, but the glans penis is soft. The patient complains of severe pain. Pelvic examination may reveal an underlying pelvic or genitourinary malignancy [1326].

9.1.2.3 Laboratory testing

Laboratory testing should include a complete blood count, white blood cell count with blood cell differential, platelet count and coagulation profile to assess anaemia and detect haematological abnormalities [1304, 1329].

A genome-wide association study on Brazilian patients identified four single nucleotide polymorphisms in LINC02537 and NAALADL2 significantly associated with priapism, although testing is not routinely recommended in clinical practice [1332].
Aspiration of blood from the corpora cavernosa usually reveals dark ischaemic blood (Table 33) (LE: 2b). Blood gas analysis is essential to differentiate between ischaemic and non-ischaemic priapism (Table 34). Further laboratory testing should be directed by the history, clinical examination and laboratory findings. These may include specific tests (e.g., haemoglobin electrophoresis) for diagnosis of SCD or other haemoglobinopathies.

9.1.2.4 Penile imaging

Colour Doppler US of the penis and perineum is recommended after clinical diagnosis and can differentiate ischaemic from non-ischaemic priapism as an alternative or adjunct to blood gas analysis [1306, 1333-1335] (LE: 2b). Colour Doppler US can identify the presence of the fistula as a blush with 100% sensitivity and 73% specificity [1335].

Ultrasound scanning of the penis should be performed before corporal blood aspiration in ischaemic priapism to prevent aberrant blood flow which can mimic a non-ischaemic picture or reperfusion picture after intervention for low-flow priapism [1336].

Following Colour Doppler US there will be an absence of blood flow in the cavernosal arteries in ischaemic priapism. Return of the cavernous artery waveform indicates successful detumescence [1304, 1335, 1337]. After aspiration, reactive hyperaemia may develop with a high arterial flow proximally that may be misleading and result in the diagnosis of non-ischaemic priapism.

Penile MRI can be used in the diagnostic evaluation of priapism and may be helpful in selected cases of ischaemic priapism to assess the viability of the corpora cavernosa and the presence of penile fibrosis. In particular, in cases of refractory priapism or delayed presentation (> 48 hours), smooth muscle viability can be indirectly assessed. In a prospective study of 38 patients with ischaemic priapism, the sensitivity of MRI in predicting non-viable smooth muscle was 100%, when correlated with corpus cavernosum biopsies [1336]. In this study, all patients with viable smooth muscle on MRI maintained erectile function on clinical follow-up with the non-viable group being offered an early prosthesis.

</tr>
</tbody>
</table>
Analise the blood gas parameters from blood aspirated from the penis to differentiate between ischaemic and non-ischaemic priapism.

Perform colour duplex ultrasound of the penis and perineum before aspiration to differentiate between ischaemic and non-ischaemic priapism.

In cases of prolonged ischaemic priapism or refractory priapism, magnetic resonance imaging of the penis may be used as an adjunct to predict smooth muscle viability.

Perform selected pudendal arteriogram when embolisation is planned for the management of non-ischaemic priapism.

### 9.1.3 Disease management

Acute ischaemic priapism is a medical emergency. Urgent intervention is mandatory and should follow a stepwise approach. The aim of any treatment is to restore penile detumescence, without pain, in order to prevent corporal smooth muscle fibrosis and subsequent ED.

**Figure 13: Medical and surgical management of ischaemic priapism**

The treatment is sequential and physicians should move on to the next stage if treatment fails.

**Initial conservative measures**
- Local anaesthesia of the penis
- Insert wide bore butterfly (16-18 G) through the glans into the corpora cavernosa
- Aspirate cavernosal blood until bright red arterial blood is obtained

**Cavernosal irrigation**
- Irrigate with 0.90% w/v saline solution

**Intracavernosal therapy**
- Inject intracavernosal adrenoceptor agonist
- Current first-line therapy is phenylephrine* with aliquots of 200 µg being injected every 3-5 minutes until detumescence is achieved (maximum dose of phenylephrine is 1mg within 1 hour) *

**Surgical therapy**
- Surgical shunting
- Consider primary penile implantation if priapism has been present for more than 48 hours

(*) Dose of phenylephrine should be reduced in children. It can result in significant hypertension and should be used with caution in men with cardiovascular disease. Monitoring of pulse and blood pressure is advisable in all patients during administration and for one hour afterwards. Its use is contraindicated in men with a history of cerebro-vascular disease and significant hypertension.

### 9.1.3.1 Medical Management

**Evidence Acquisition**

The studies that were identified after abstract screening and used for this literature review pertaining to medical management are reported in the table in Appendix 1. Most of these studies were retrospective case series without an available protocol. Additionally, several limitations were encountered during their assessment, including small study samples, unclear definitions of conditions, interventions and outcomes,
short or no reported follow-up and selective reporting of outcomes. As such, providing clinicians with clear recommendations based on robust evidence was not possible. Based on the studies included in the Panel's systematic review, medical management of priapism demonstrates a wide range of effectiveness, although it seems that sexual dysfunction and complication rates in medical management responders were not too high, when reported. It should be emphasised that most patients included in the surgical management studies that are discussed below represent medical non-responders. The selection bias that by definition existed in the surgical management in these single-arm studies makes the estimation of true effectiveness of medical intervention difficult to quantify.

9.1.3.1.1 First-line treatments
First-line medical treatments of ischaemic priapism of more than 4 hours duration are strongly recommended before any surgical treatment (LE: 4). Conversely, first-line treatments initiated beyond 48 hours, while relieving priapism, have little documented benefit in terms of long-term potency preservation (LE: 4). This is likely to be the consequence of irreversible smooth muscle damage that begins to be established by approximately 48 hours of tissue hypoxia [1309-1311]. An in-vitro model of priapism has shown that there is window of opportunity for therapeutic intervention beyond which the recovery of functional erectile tissue is unlikely due to irreversible smooth muscle cell dysfunction [1307]. In line with this finding it has been shown in a series of 50 patients with low-flow priapism who were successfully treated and followed-up for a mean 66 months, those with priapism lasting for more than 48 hours had a significant risk of ED [1309].

Historically, several first-line treatments have been described including exercise, ejaculation, ice packs, cold baths, and cold water enemas [1304]. However, there is limited evidence for the benefit of such measures and they may even exacerbate crisis in SCD patients. Success rates of these conservative measures alone have been rarely reported. In a small series, for instance, cold water enemas have been reported to induce detumescence in six out of ten cases [1338]. In another study 24.5% of 122 patients achieved detumescence following priapic episodes lasting for more than 6 hours by cooling of the penis and perineum, and walking upstairs [1320]. In SCD patients with priapism, it is recommended that the urology team works closely with the haematology team to optimise patient management.

Partial priapism usually resolves spontaneously with analgesic treatment while surgical intervention is rarely needed [1339].

9.1.3.1.2 Penile anaesthesia/analgesia
It is possible to perform blood aspiration and intracavernous injection of a sympathomimetic agent without any anaesthesia. However, anaesthesia may be necessary when there is severe penile pain. While it is recognised that the anaesthesia may not alleviate the ischaemic pain, cutaneous anaesthesia facilitates subsequent therapies. The treatment options for penile anaesthesia/systemic analgesia include:

- dorsal nerve block;
- circumferential penile block;
- subcutaneous local penile shaft block;
- oral conscious sedation (for paediatric patients).

9.1.3.1.3 Aspiration ± irrigation with 0.9% w/v saline solution
The first intervention for an episode of priapism lasting more than 4 hours consists of corporal blood aspiration (LE: 4) to drain the stagnant blood from the corporal bodies, making it possible to relieve the compartment-syndrome-like condition within the corpus cavernosum. Blood aspiration may be performed with intracorporeal access either through the glans or via percutaneous needle access to the lateral aspect of the proximal penile shaft, using a 16 or 18 G angio-catheter or butterfly needle. The needle must penetrate the skin, the subcutaneous tissue and the tunica albuginea to drain blood from the corpus cavernosum (LE: 4).

Some clinicians advocate using two angiocatheters or butterfly needles at the same time to accelerate drainage, as well as aspirating and irrigating simultaneously with a saline solution [1320] (LE: 4). Aspiration should be continued until bright red, oxygenated blood is aspirated (LE: 4).

Several case series have reported the outcomes from first-line treatments, although in most cases, aspiration and irrigation were combined with intracavernosal injection of sympathomimetic agents, thus making it difficult to draw conclusions about the success rate of aspiration + irrigation alone. In a RCT, 70 patients with ischaemic priapism secondary to intracavernosal injection and lasting more than 6 hours were treated with aspiration plus saline irrigation at different temperatures [1320]. The authors reported an 85% success rate with the optimum results achieved using a 10°C saline infusion after blood aspiration.
This approach has up to a 30% chance of resolving the priapism. There are insufficient data to determine whether aspiration followed by saline intracorporeal irrigation is more effective than aspiration alone (LE: 4).

9.1.3.1.4 Aspiration ± irrigation with 0.9% w/v saline solution in combination with intracavernous injection of pharmacological agents.

This combination is currently considered the standard of care for treatment of ischaemic priapism [1304, 1340, 1341] (LE: 4). Pharmacological agents include sympathomimetic drugs or α-adrenergic agonists. Intracavernous sympathomimetic agents include phenylephrine, etilephrine, ephedrine, epinephrine, norepinephrine and metaraminol with a resolution rate of up to 80% [1304, 1340, 1342-1349] (LE: 2b). The use of intracavernous adrenaline injection alone has also been sporadically reported [1350]. A literature review from the AUA reported that the use of a sympathomimetic agent combined with prior intracavernosal aspiration or irrigation had a resolution rate of 77% as compared with 58% in those who had a sympathomimetic injection alone [1341].

Phenylephrine

Adrenergic agonists act on the post-synaptic α-1-adrenergic receptors to stimulate cavernosal smooth muscle and arteriolar vasoconstriction, with a reduction in arteriolar inflow to the corporal bodies and smooth muscle contraction [1351]. Moreover, this class of drug also increases venous outflow through β2-adrenergic receptor activity [1348].

Phenylephrine is a selective α-1-adrenergic receptor agonist that has been observed in small case series to be effective at producing detumescence in priapism, when given as an intracavernosal injection, with few adverse effects [1348, 1352]. Therefore, phenylephrine is the recommended adrenergic agonist drug of choice due to its high selectivity for the α-1-adrenergic receptor, without concomitant β-mediated inotropic and chronotropic cardiac effects [1342, 1346, 1347] (LE: 4).

Phenylephrine is diluted in normal saline to a concentration of 100-500 μg/mL. Usually, 200 μg are given every three to five minutes directly into the corpus cavernosum. The maximum dosage is 1 mg within 1 hour (LE: 4). A lower concentration or volume is applicable for children and patients with severe cardiovascular diseases (LE: 4).

Higher doses of phenylephrine have been used in small retrospective case series [1346, 1347, 1353, 1354] without any adverse events, but further trials are needed to substantiate the efficacy of higher doses. There are in-vitro data suggesting that higher doses of phenylephrine are unlikely to be beneficial when conventional doses have failed because there is already significant apoptosis of the cavernosal smooth muscle [1355].

Phenylephrine has potential cardiovascular adverse effects [1304, 1340, 1342, 1343, 1346, 1347] and it is recommended that blood pressure and pulse are monitored every fifteen minutes for 1 hour after injection. This is particularly important in older men with pre-existing cardiovascular diseases. After injection, the puncture site should be compressed and the corpus cavernosum massaged to facilitate drug distribution.

The potential treatment-related adverse effects of intracavernous phenylephrine (and other sympathomimetic agents) include headache, dizziness, hypertension, reflex bradycardia, tachycardia and palpitations and sporadic subarachnoid haemorrhage [380]. Monitoring of blood pressure and pulse should be performed during intracavernous administration of sympathomimetic agents.

Given that intracavernous sympathomimetic agents can cause hypertension, the Panel is of the opinion that these agents are contraindicated in patients with malignant or poorly controlled hypertension, as there are case reports of significant cardiovascular and neurological complications following the use of these pharmacological agents for priapism [1343, 1356, 1357]. Similarly, there are data suggesting that sympathomimetic agents cause a hypertensive crisis when given with monoamine oxidase inhibitors, hence these medications should not be used together [1358] (LE: 4).

Etilephine

Etilephine is also an adrenergic agonist but directly stimulates both α and β adrenergic receptors [1341]. Most of the literature describing the use of etilephrine for treatment of priapism is related to men with SCD but there are small retrospective case series that have reported its benefits for priapism secondary to iatrogenic causes [1359, 1360]. Etilephine is the second most widely used sympathomimetic agent, administered by intracavernous injection at a concentration of 2.5 mg in 1-2 mL normal saline [1343] (LE: 3).
**Methylene blue**

Methylene blue is a guanylate cyclase inhibitor, that may be a potential inhibitor of endothelial-mediated cavernous smooth muscle relaxation. Small retrospective case series have reported its successful use for treating short-term pharmacologically-induced priapism [1361, 1362] (LE: 3). Methylene blue, 50-100 mg [1361], should be injected intracavernously and left for five minutes. It is then aspirated and the penis compressed for an additional five minutes [1362]. Treatment-related adverse effects include a transient burning sensation and blue discoloration of the penis.

**Adrenaline**

Adrenaline produces both α-adrenergic receptor agonist and α-adrenergic receptor activity. Intracavernosal adrenaline (2 mL of 1/100,000 adrenaline solution up to five times over a 20-minute period [1350]) has been used in patients with ischaemic priapism due to an intracavernous injection of vasoactive agents. The limited literature [1350, 1363] suggests that adrenaline can achieve detumescence in short-term priapism, with one small case series reporting a success rate of over 50% after a single injection, with an overall success rate of 95% with repeated injections [1350, 1363] (LE: 3).

**β-2-agonists**

Oral terbutaline is a β-2-agonist with minor β-1 effects and some α-agonist activity. A dose of 5 mg has been suggested to treat prolonged erections lasting more than 2.5 hours, after intracavernous injection of vasoactive agents, although the mechanism of action is not yet fully understood [1364-1366] (LE: 1b). The main use of terbutaline is for prevention of recurrent episodes of prolonged erection. Terbutaline should be given cautiously in patients with coronary artery disease, increased intravascular fluid volume, oedema or hypokalaemia [1366]. In a single multi-centre prospective study, another β-2-agonist, salbutamol, has been reported to induce detumescence in 34% of cases of prolonged erection (more than 3 hours) after intracavernous injection of erectogenic agents [1367]. However, more robust data are needed to recommend oral salbutamol for the treatment of ischaemic priapism.

**Anti-thrombotic agents**

Ramstein et al. reported retrospective data pertaining to the use of antithrombotic therapy (a single dose of subcutaneous heparin or aspirin 325 mg) in patients who had undergone corporeal aspiration with and without phenylephrine. Antithrombotic therapy was associated with a significant reduction in further episodes of priapism following aspiration and successful T-shunt insertions in those who failed aspiration. However, these findings were based on a small cohort size (n = 18), doses and types of antithrombotic therapy were heterogeneous, and exact timing of the priapism episodes was not measured precisely. In this setting, further prospective randomised trials are needed prior to the recommendation of antithrombotic agents for treatment or adjunctive therapy in the management of ischaemic priapism [1368].

**Management of priapism related to sickle cell disease**

The Panel conducted a systematic review on the overall management of priapism related to sickle cell disease. Unfortunately, few studies were conducted exclusively on patients with SCD and studies on mixed populations usually did not report separate data on SCD patients. Clear and systematic reporting of patient characteristics, interventions and outcomes was lacking, and the length of follow-up, if reported, varied significantly among the studies. Overall, the quality of studies was deemed poor for high-quality, evidence-based recommendations.
Urgent intervention is essential (LE: 4) and the general approach is similar to that described for other cases of ischaemic priapism and should be co-ordinated with a haematologist [1355, 1369, 1370] (LE: 4).

However, as with other haematological disorders, other therapeutic interventions may also need to be implemented [1369-1371]. Specific measures for SCD-related priapism include intravenous hydration and narcotic analgesia while preparing the patient for aspiration and irrigation. Additionally, supplemental oxygen administration and alkalinisation with bicarbonate can be helpful [1321, 1355].

Haemoglobin S (HbS) percentage should be measured in all SCD patients with acute priapism. Exchange blood transfusion has also been proposed, with the aim of increasing tissue delivery of oxygen [1372]. The transfused blood should be sickle cell haemoglobin negative and Rh and Kell antigen matched [1373]. However, the evidence is inconclusive as to whether exchange transfusion itself helps to resolve priapism. A systematic review reported that the mean time to detumescence was eleven days with exchange transfusions compared to eight days with conventional treatment. Moreover, there were 9 cases of ASPEN syndrome (association of sickle cell disease, priapism, exchange transfusion and neurological events) as a consequence of blood transfusion [1374].

Consensus recommendation: exchange transfusion should not be used as a primary treatment for ischaemic priapism in patients with SCD.

Several reports suggest that exchange transfusion may result in serious neurological sequelae [1374], although a series of 10 patients with SCD-related priapism showed that it was safe to perform exchange transfusion [1372]. Because of these considerations, routine use of exchange transfusion is not recommended as a primary treatment intervention in this group unless there is a risk of SCD-related symptoms (LE: 4). However, in patients who fail medical management, transfusion may be required to enable general anaesthesia to be safely administered prior to definitive surgery [1375].

9.1.3.2 Surgical management

Evidence acquisition
The majority of the identified studies for surgical management were retrospective and non-randomised. A significant proportion of the reports were case series reporting on one or two particular types of surgical procedures, often with low patient numbers (< 20) (Appendix 2). The studies showed a wide variation in data, including the proportion of patients who had prior conservative management, reporting of initial success, and duration of follow-up. Surgical complications were also not consistently reported. The systematic review captured specific end points of priapism resolution, sexual function and surgical adverse events when reported. However, due to the heterogeneity of the data, direct comparisons of success rates and long-term outcomes should be treated with caution.

9.1.3.2.1 Second-line treatments
Second-line intervention typically refers to surgical intervention in the form of penile shunt surgery and penile implant insertion for refractory or delayed ischaemic priapism, and should only be considered when other conservative management options fail (LE: 4). There is no evidence detailing the time frames before moving on to surgery after first-line treatment, although a period of at least 1 hour of first-line treatment without detumescence can be considered prior to moving to surgical intervention (LE: 4).

A number of clinical indicators suggest failure of first-line treatment including continuing corporal rigidity, cavernosal acidosis, anoxia, severe glucopenia, absence of cavernosal artery inflow by penile colour duplex US, and elevated intracorporal pressure [1376]. Colour duplex US of the penis in the ischaemic state may be helpful but it should be noted that blood flow may persist in the tumescent phase of erection [1377] (LE: 4).

9.1.3.2.1.1 Penile shunt surgery
Penile shunt surgery aims to produce an outflow for ischaemic blood from the corpus cavernosum thereby allowing restoration of normal circulation within these structures. Accordingly, a shunt creates an opening in the tunica albuginea, with either the glans, corpus spongiosum, or a vein for blood drainage (Table 37) [1304, 1340, 1378].

The type of shunt procedure is chosen according to the surgeon’s preference and familiarity with the procedure. It is conventional for distal shunt procedures to be tried before considering proximal shunting (LE: 4). Gadolinium-enhanced penile MRI [1336] and cavernosal smooth muscle biopsy have been used to diagnose smooth muscle necrosis (which, if present, would suggest that shunting is likely to fail) and may help
in decision-making and patient counselling in cases of refractory or delayed presentation (> 48 hours) that may be considered for immediate penile prosthesis insertion (see below).

It is important to assess the success of surgery by direct observation of penile rigidity or by repeated testing (e.g., cavernous blood gas testing) (LE: 4) [1304, 1340, 1379, 1380]. The use of penile colour US may not give appropriate information because of the hyperaemic (reperfusion) period that follows decompression after the ischaemic state [1377].

The recovery rates of erectile function in men undergoing shunt surgery following prolonged episodes of priapism are low and are directly related to the duration of priapism, pre-operative erectile status and age [1379-1381]. The exact duration of priapism for shunt surgery to preserve erectile function is not based on studies with high levels of evidence. If ischaemic priapism resolves within 24 hours of onset, it has been reported that 78-100% of patients regain spontaneous functional erections (with or without PDE5Is use). In contrast, other studies have shown that priapism for more than 36-48 hours appears to result in both structural and functional effects on corporal smooth muscle, with poorer outcomes (ED > 90%) [1379, 1382]. In general, shunt procedures undertaken after this time period (36-48 hours) may only serve to limit pain without any beneficial effects on erectile function and early prosthesis insertion can be considered [1311, 1383].

Four categories of shunt procedures have been reported [1304, 1341, 1378, 1383]. The limited available data preclude any overall recommendation for one procedure over another based upon outcomes, but distal shunts are less invasive and associated with lower rates of post-operative ED and therefore are recommended as the first surgical intervention of choice (Table 37) (LE: 4).

**Percutaneous distal (corpora-glanular) shunts**

Winter’s procedure uses a Trucut biopsy needle to create a fistula between the glans penis and each corpus cavernosum [1304, 1318, 1341, 1377, 1384] (LE: 3). Postoperative sequelae are uncommon [1385]. Winter’s shunt is easy to perform, but has been reported as the least successful operation to create a distal shunt [1380]. This is because the diameter of the Trucut needle is only 1.6 mm (14-18 g) and therefore cannot accommodate the increased blood flow from post-ischaemic hyperaemia, resulting in poor drainage, increased intracavernous pressure and consequent premature closure of the shunt [1377].

Ebbehoj’s technique involves making multiple tunical incision windows between the glans and each tip of the corpus cavernosum by means of a size 11 blade scalpel passed several times percutaneously [1304, 1341, 1377, 1386, 1387] (LE: 3).

T-Shunt involves performing a bilateral procedure using a scalpel with a size 10 blade inserted through the glans just lateral to the urethral meatus until it enters the tip of the corpus cavernosum. The blade is then rotated 90° away (to the lateral side) from the urethral meatus and withdrawn [1304, 1341, 1377, 1388] (LE: 3). If unsuccessful, the procedure is repeated on the opposite side. The T-shunt can be followed by a tunnelling procedure using a size 8/10 Hegar dilator inserted through the glans and into the corpus cavernosum, which can also be performed using US guidance, mainly to avoid urethral injury [1388]. The entry sites in the glans are sutured following detumescence. Tunnelling with a 7 mm metal sound or 7/8 Hegar dilator is necessary in patients with priapism duration > 48 hours. Tunnelling is a potentially attractive procedure as it combines the features of distal and proximal shunts with proximal drainage of the corpus cavernosum and may ameliorate the profibrotic effect of sludged blood retained in the corpus cavernosum [1381, 1383, 1388].

**Open distal (corpora-glanular) shunts**

Al-Ghorab’s procedure consists of an open bilateral excision of circular cone segments of the distal tunica albuginea via the glans penis, along with subsequent glans closure by running suture with absorbable material. A transverse incision on the glans may compromise arterial blood flow because distal deep dorsal arteries run longitudinally in the glans [1304, 1341, 1377, 1389-1391] (LE: 3).

Burnett’s technique (Snake manoeuvre) is a modification of the Al-Ghorab corpora-glanular shunt. It involves retrograde insertion of a 7/8 Hegar dilator into the distal end of each corpus cavernosum through the original Al-Ghorab glanular excision. After removal of the dilator from the corpus cavernous, blood evacuation is facilitated by manual compression of the penis sequentially from a proximal to distal direction. After detumescence, the glans penis is closed as in the Al-Ghorab procedure [1304, 1341, 1377, 1392, 1393] (LE: 3). Reported complications include wound infection, penile skin necrosis and urethrocutaneous fistulae [1393].

ED = erectile dysfunction; h = hours; d = days.

Open proximal (corpora-spongiosal) shunts
Quackles’s technique uses a trans-scrotal or perineal approach; a proximal open shunt technique creates a communication between the corpus cavernosum and the corpus spongiosum. The most frequent complications include an unwanted urethro-cavernous fistula and urethral stricture or cavernositis [1304, 1341, 1378, 1394]. The risk of urethral injury is less with a perineal approach to the bulb of the corpus spongiosum (LE: 3). Proximal shunts are more invasive and ED rates are documented to be higher [1376].

Peno-scrotal decompression
More recently a proximal decompression technique with the aim to spare the glans with high success rates has been described. The technique is based upon opening of the proximal corpus cavernosum combined with proximal and distal tunnelling using a suction tip [1395]. In a cohort of 25 patients, 12 had undergone previous corpora-glanular shunt surgery. Recurrence was observed in two of 25 patients with unilateral peno-scrotal decompression. In the 15 patients who had follow-up data, 40% had ED. Whilst, representing a promising technique, PSD in cases of refractory priapism may further delay penile prosthesis insertion with detrimental effects on surgical outcomes including penile shortening and prosthetic infection.

Anti-thrombotic agents
Procedures for shunting require incision through the tunica albuginea and expose collagen to coagulation factors in the penile blood and thus activate the blood-clotting cascade. Peri-operative anti-coagulation is advocated to facilitate resolution of the priapism. There was an 84% decrease in priapism recurrence in the shunt group that received peri-procedural anti-thrombotic treatment (325 mg acetylsalicylic acid pre-operatively, and 5000 IU intraoperative heparin, post-operatively for 5 days (81 mg acetylsalicylic acid and 75 mg clopidogrel) compared with the group that did not receive peri-procedural anti-thrombotic treatment after failed aspiration [1368].

Vein anastomoses/shunts
Grayhack’s procedure mobilises the saphenous vein below the junction of the femoral vein and anastomoses the vein end-to-side onto the corpus cavernosum. Venous shunts may be complicated by saphenofemoral thrombus formation and by pulmonary embolism [1304, 1341, 1396-1398] (LE: 3).

Immediate penile prosthesis implantation
The literature pertaining to penile implantation surgery is shown in Appendix 3. The studies identified here were principally retrospective non-randomised case series. In all but one study, patients had prior non-surgical management. All of the studies described priapism resolution rate, sexual function and surgical adverse events although the follow-up period was variable.
Refractory, therapy-resistant, acute ischaemic priapism or episodes lasting more than 48 hours usually result in complete ED, possibly along with significant penile deformity in the long-term. In these cases, immediate penile prosthesis surgery is advocated [1399-1402] (LE: 3).

The immediate insertion of a malleable penile prosthesis is recommended to avoid the difficulty and complications of delayed prosthetic surgery in the presence of corporal fibrosis. Potential complications that could compromise immediate penile prosthesis implantation include distal erosion and infection [1399, 1401], along with a small rate of revision surgery [1399]. Early surgery also offers the opportunity to maintain penile length and girth and prevent penile curvature due to cavernosal fibrosis. The prosthesis can be exchanged for an inflatable prosthesis at a later date, which may allow up sizing of the implant cylinders [1403].

Currently, there are no clear indications for immediately implanting a penile prosthesis in men with acute ischaemic priapism, although this can be considered in men with delayed or refractory priapism (see below [1340]).

Consensus recommendation [1304] (LE: 4):
Relative indications include:

- Ischaemia that has been present for more than 48 hours;
- Failure of aspiration and sympathomimetic intracavernous injections in delayed priapism (> 48 hours);
- Magnetic resonance imaging or corporal biopsy evidence of corporal smooth muscle necrosis [1304, 1399] (LE: 4);
- Failure of a shunting procedure (although in delayed cases > 48 hours, implantation might be considered ahead of shunt surgery);
- Refractory priapism in patients who have undergone shunting procedures.

The optimal time for implantation is within the first three weeks from the priapism episode [1311, 1376, 1404]. If shunt surgery has been performed, penile prosthesis implantation can be further delayed in order to allow reduction of oedema, wound healing and risk of prosthetic infection. A vacuum device to avoid fibrosis and penile shortening may be used during this waiting period [1405].

The decision on which type of implant to insert is dependent on patient suitability, surgeons’ experience, and availability and cost of the equipment. There are no randomised trials comparing the efficacy and complication rates of malleable and inflatable penile prostheses. Despite the higher infection rate in priapism patients compared to those with virgin prosthesis, in patients who are well-motivated and counselled prior to the procedure, immediate inflatable penile prosthesis implantation may be undertaken, although in most cases a semi-rigid implant is more suitable as it is easier to implant and reduces operative time and hence the risk of prosthetic infection. A further issue with immediate insertion of an inflatable penile prosthesis is that the patient must begin cycling the device immediately to avoid a fibrous capsule forming and contracting. Early cycling of an inflatable penile prosthesis prevents penile curvature and shortening [1311].

Surgery for non-acute sequelae after ischaemic priapism
Structural changes may occur after ischaemic priapism including cavernosal tissue necrosis and fibrosis with consequent penile scarring, megalophallic deformities, penile shortening, and occasional penile loss [1378, 1399, 1406, 1407]. Erectile dysfunction is also often observed [1304, 1408]. Unfortunately, these outcomes can still occur despite apparently successful first-line or second-line treatment in detumescence of the penis.

Penile prosthesis implantation is occasionally indicated in SCD patients with severe ED because other therapeutic options, such as PDE5Is and intracavernous injections are avoided as they may provoke a further priapism event [1304, 1340]. In severe corporeal fibrosis, narrow-based prosthetic devices are preferable because they are easier to insert and need less dilatation [1399] (LE: 3). After severe priapism that has resulted in penile destruction with complicated deformities or even loss of penile tissue, it may be necessary to make changes to the surgical technique. Multiple corporotomies, corporal excavation, optical corporotomy-Shaeer technique, dilatation with Carrion-Rosello cavernotome, Uramix or Mooreville cavernotome, excision of scar tissue, and use of small-diameter prosthesis, or penile reconstruction using grafts can be utilised, if concomitant prosthesis implantation is considered [1382, 1409] (LE: 3). Early implantation of a penile prosthesis is associated with lower infection rates (6-7% vs. 19-30%), penile shortening (3% vs. 40%) and revision rates (9% vs. 27%) compared to late insertion. General satisfaction rate for early implantation is higher (96%) than for late implantation (60%) [1311] (Appendix 4).

9.1.5 Recommendations for the treatment of ischaemic priapism

<table>
<thead>
<tr>
<th>Recommendations</th>
<th>Strength rating</th>
</tr>
</thead>
<tbody>
<tr>
<td>Start management of ischaemic priapism as early as possible (within four to six hours) and follow a stepwise approach.</td>
<td>Strong</td>
</tr>
<tr>
<td>First, decompress the corpus cavernosum by penile aspiration and washout until fresh red blood is obtained.</td>
<td>Strong</td>
</tr>
<tr>
<td>In priapism secondary to intracavernous injections of vasoactive agents, replace blood aspiration with intracavernous injection of a sympathomimetic drug as the first step.</td>
<td>Strong</td>
</tr>
<tr>
<td>In priapism that persists despite aspiration, proceed to the next step, which is intracavernous injection of a sympathomimetic drug.</td>
<td>Strong</td>
</tr>
</tbody>
</table>
In cases that persist despite aspiration and intracavernous injection of a sympathomimetic drug, repeat these steps before considering surgical intervention.

Treat ischaemic priapism associated with sickle cell disease in the same fashion as idiopathic ischaemic priapism. Provide other supportive measures (intravenous hydration, oxygen administration with alkalinisation with bicarbonate, blood exchange transfusions), but do not delay initial treatment to the penis.

Proceed to surgical treatment only when blood aspiration and intracavernous injection of sympathomimetic drugs have failed.

Perform distal shunt surgical procedures first and combine them with tunnelling if necessary.

Proximal procedures may be used in cases of distal shunt failure (< 48 hours) or in patients who do not wish to proceed with immediate penile implant insertion.

Peri- and post-operative anticoagulation may decrease priapism recurrence.

A penile prosthesis may be preferred over proximal shunting particularly in delayed (> 48 hours) or refractory priapism.

Implantation of a prosthesis may be considered in delayed presentation (> 48 hours) and in those cases refractory to injection therapy and distal shunting.

If a shunt has been performed, then implantation of a penile prosthesis should be delayed to minimise the risk of infection and erosion of the implant.

The decision on which type of implant to insert is dependent on patient suitability, surgeons’ experience and availability and cost of the equipment. If malleable penile prosthesis is implanted it can be later exchanged to an inflatable penile implant.

Patients must be fully counselled regarding the risks and benefits of implant insertion in every case of delayed presentation of refractory priapism.

### 9.2 Priapism in Special Situations

#### 9.2.1 Stuttering (recurrent or intermittent) priapism

**Epidemiology/aetiology/pathophysiology**

Robust epidemiological studies of stuttering priapism are lacking [1410, 1411]. However, recurrent priapism episodes are common in men with SCD (42-64%) [1412, 1413] while in adolescents and young men the incidence of priapism is 35%, of whom 72% have a history of stuttering priapism [1410].

The aetiology of stuttering priapism is similar to that of ischaemic priapism. Whilst SCD is the most common cause, idiopathic cases and cases due to a neurological disorder have been reported. Men who have acute ischaemic priapism, especially which has been prolonged (for more than 4 hours) are at risk of developing stuttering priapism [1408].

Several studies have proposed alternative mechanisms for stuttering priapism including inflammation, cellular adhesion, NO metabolism, vascular reactivity and coagulation [1304, 1322, 1355, 1414, 1415]. Specifically, a deficiency in endothelial NO causes downregulation in a cyclic guanosine monophosphate (cGMP)-dependent protein kinase and PDE5, resulting in dysregulation in the corporal smooth muscle tone [1416]. Furthermore, decreased NO availability decreases RhoA (Ras homolog gene family) and Rho-kinase, which are important factors for penile detumescence, and disrupts adenosine signalling [1417]. The lack of mechanisms to regulate cGMP, along with reduced vasoconstriction, reduce cavernosal smooth muscle tone, leading to an increased and disproportionate response to stimuli. Adenosine, like NO, is a potent vasodilator and regulator of penile tumescence. It is increased in conditions of stress, hypoxia and ischaemia, suggesting an important role in the pathogenesis of the priapic state [1418]. Finally, although debated, androgens have also been observed to have an association with priapism [1419]. Androgens play an important role in the mediation of erections both centrally and peripherally. They are known to contribute toward the regulatory basis of both NO synthase and PDE5 expression and activity in various structures of the local erectile apparatus [1420]. Therefore, one of the options for the treatment of stuttering priapism is to reduce serum testosterone levels to hypogonadal levels, which then suppresses androgen-associated mechanisms believed to be involved in triggering recurrent priapism.
9.2.1.1 Summary of evidence on the epidemiology, aetiology and pathophysiology of stuttering priapism

<table>
<thead>
<tr>
<th>Summary of evidence</th>
<th>LE</th>
</tr>
</thead>
<tbody>
<tr>
<td>Stuttering priapism is similar to ischaemic priapism in that it is low-flow and ischaemic and, if left untreated, can result in significant penile fibrosis, with SCD being the most common cause.</td>
<td>3</td>
</tr>
</tbody>
</table>

9.2.1.2 Classification

Stuttering priapism, also termed intermittent or recurrent priapism, is a distinct condition that is characterised by repetitive and painful episodes of prolonged erections. Erections are self-limiting with intervening periods of detumescence [1355, 1414]. These are analogous to repeated episodes of ischaemic priapism. In stuttering priapism the duration of the erections is generally shorter than in ischaemic priapism [1341]. The frequency and/or duration of these episodes is variable and a single episode can sometimes progress into prolonged ischaemic priapism.

9.2.1.3 Diagnostic evaluation

9.2.1.3.1 History

A comprehensive history is mandatory and follows the same principles as described in Table 33. There is a history of recurrent episodes of prolonged erections. These episodes can occur from several daily to isolated incidents every few months, continuously or followed by incident-free periods, of unknown duration, even months and years [1421]. The onset of the priapic episodes usually occurs during sleep and detumescence does not occur upon waking. These episodes can be painful and may be the reason that the patient first seeks medical attention. Priapism can cause significant impairment of mental health with patients experiencing sadness, embarrassment, fear, and exhaustion [1422].

9.2.1.3.2 Physical examination

Erections are painful and the penis is rigid as in ischaemic priapism, but the duration of events is usually shorter. Between erections the penis is usually normal, but in some cases signs of fibrosis can be found. Rarely, the penis may become enlarged, a condition known as megalophallus.

9.2.1.3.3 Laboratory testing

There are no specific findings on imaging for stuttering priapism. Colour duplex US of the penis and perineum and MRI are recommended and can differentiate non-ischaemic from ischaemic forms of priapism.

9.2.1.3.4 Penile imaging

There are no specific findings on imaging for stuttering priapism. Colour duplex US of the penis and perineum and MRI are recommended and can differentiate non-ischaemic from ischaemic forms of priapism.

9.2.1.3.5 Recommendations for diagnosis of stuttering priapism

The same recommendations as described in Section 9.1.2.5 apply. Stuttering priapism is a recurrent or intermittent type of ischaemic priapism.

9.2.1.4 Disease management

The primary goal in the management of patients with stuttering priapism is the prevention of further episodes and limiting the chances of developing a prolonged ischaemic priapism that is refractory to conventional treatment options. In most cases, stuttering priapism can be managed by pharmacological treatment, the aim of which is to reduce the frequency and severity of stuttering episodes. The management of each acute episode is similar to that for ischaemic priapism; aspiration/irrigation in combination with intracavernous injections of \( \alpha \)-adrenergic agonists. Unfortunately, the efficacy and safety of the various treatment modalities suggested over the medical literature are poorly reported. Specifically, most reports are from small case series and the Panel is not aware of any published, well-designed, controlled studies on the efficacy and safety of these treatments [1321, 1355, 1414, 1421].

9.2.1.4.1 \( \alpha \)-Adrenergic agonists

Studies of oral \( \alpha \)-adrenergic agonists have suggested some prophylactic benefit for daily treatment with these agents [1423]. Adverse effects include tachycardia and palpitations. Pseudoephedrine is widely used as an oral decongestant and can be a first-line treatment option for stuttering priapism [1365]. However, its effect on corporal smooth muscle is not fully understood. Etilephrine has been used successfully to prevent stuttering priapism caused by SCD. It is usually taken orally at doses of 5-10 mg daily, with response rates of up to 72% [1424-1426]. In one randomised, placebo-controlled clinical study comparing medical prophylaxis with etilephrine and ephedrine, there was no difference in efficacy between the two drugs.
9.2.1.4.2 Hormonal manipulations of circulating testosterone
The aim of hormonal manipulation is to down-regulate circulating testosterone levels to suppress the action of androgens on penile erection [1321, 1355, 1427]. This can be achieved by GnRH agonists or antagonists, antiandrogens or oestrogens [1428, 1429] (LE: 4). Potential adverse effects may include hot flushes, gynaecomastia, ED, loss of libido, and asthenia. All approaches have a similar efficacy profile (LE: 4) while the potential cardiovascular toxicity of oestrogens limits their clinical use. Alternative endocrine approaches that have been used with some success include 5-α-reductase inhibitors [1430, 1431] (LE: 3) and ketoconazole; an anti-fungal agent that reduces adrenal and testicular androgen production [1427, 1432] (LE: 4).

The duration of hormonal treatment for effective suppression of recurrent priapism is problematic. It is not possible to draw any conclusions on the dose, duration of treatment and the efficacy. Caution is strongly advised when prescribing hormonal treatments to pre-pubertal boys and adolescents, and specialist advice from paediatric endocrinologists should be sought. Likewise, hormonal agents have a contraceptive effect and interfere with normal sexual maturation and spermatogenesis and affect fertility. Therefore, men who are trying with their partner to conceive should be comprehensively counselled before using hormonal treatment. Moreover, sperm cryopreservation may be considered to mitigate any potential effects of anti-androgen therapy on fertility.

9.2.1.4.3 Digoxin
Digoxin is a cardiac glycoside and positive inotrope that is used to treat congestive heart failure. Digoxin regulates smooth muscle tone through several different pathways leading to penile detumescence [1321, 1355, 1433]. The use of maintenance digoxin doses (0.25-0.5 mg/daily) in idiopathic stuttering priapism reduces the number of hospital visits and improves QoL [1355]. In a small, clinical, double-blind, placebo-controlled study, digoxin decreased sexual desire and excitement with a concomitant reduction in penile rigidity, regardless of any significant change in plasma levels of testosterone, oestrogens and LH [1433] (LE: 2b). Adverse effects include decreased libido, anorexia, nausea, vomiting, confusion, blurred vision, headache, gynaecomastia, rash and arrhythmia.

9.2.1.4.4 Terbutaline
Terbutaline is a β-agonist that causes vasodilation, resulting in vascular smooth muscle relaxation [1321, 1355] and has been used to prevent stuttering priapism with detumescence rates of 36% in patients with alprostadil-induced priapism [1365] (LE: 3). The only randomised, placebo-controlled study (n = 68) in patients with pharmacologically-induced priapism, demonstrated detumescence in 42% of the terbutaline-treated group compared to only 15% in the placebo-treated group [1366] (LE: 1b). Adverse effects include nervousness, shakiness, drowsiness, palpitations, headache, dizziness, hot flushes, nausea and weakness.

9.2.1.4.5 Gabapentin
Gabapentin has anticonvulsant, antinociceptive and anxiolytic properties and is widely used as an analgesic and anti-epileptic agent. Its proposed mechanism of action is to inhibit voltage-gated calcium channels, which attenuates synaptic transmission [1427], and reduces testosterone and FSH levels [1434]. It is given at a dose of 400 mg, four times daily, up to 2,400 mg daily, until complete penile detumescence occurs, with subsequent maintenance administration of 300 mg/daily [1435] (LE: 4). Adverse effects include anorgasmia and impaired erectile function.

9.2.1.4.6 Baclofen
Baclofen is a gamma-aminobutyric acid (GABA) derivative that acts as a muscle relaxant and anti-muscle spasm agent. It can inhibit penile erection and ejaculation through GABA activity and prevents recurrent reflexogenic erections or prolonged erections from neurological diseases [1321]. Oral baclofen has little efficacy and it is not usually used in stuttering priapism but intrathecal administration is more effective [1355, 1436-1438] (LE: 4). Adverse effects include drowsiness, confusion, dizziness, weakness, fatigue, headache, hypotension and nausea.

9.2.1.4.7 Hydroxyurea
Hydroxyurea blocks the synthesis of deoxyribonucleic acid (DNA) by inhibiting ribonucleotide reductase, which has the effect of arresting cells in the S-phase [1427, 1439]. Hydroxyurea is an established treatment for ameliorating SCD and improving life expectancy [1369, 1440]. For patients with recurrent priapism, there is limited evidence to suggest a prophylactic role of hydroxyurea (LE: 3), [1427, 1439, 1441]. Adverse effects include oligo-zoospermia and leg ulcers.
9.2.1.4.8 Phosphodiesterase type 5 inhibitors
Low doses of PDE5Is have a paradoxical effect in alleviating and preventing stuttering priapism; mainly in patients with idiopathic and SCD-associated priapism [1321, 1355, 1416, 1442-1446] (LE: 3). It is important to remember that therapy should be started when the penis is in its flaccid state and not during an acute episode. There is a delay of one week before treatment is effective. There are no reported impairments in male sexual function (LE: 3). Phosphodiesterase type 5 inhibitor treatment of stuttering priapism is possibly mediated by an increase in the concentration of cGMP in the smooth muscle in an NO dysfunctional state. This can occur in priapism and may result in a change in the NO pathway, with down-regulation of cavernosal PDE5 thereby preventing the complete degradation of cGMP in the corpus cavernosum [1321, 1355, 1416, 1442].

9.2.1.4.9 Intracavernosal injections
Some patients with stuttering priapism, who have been started on systemic treatment to prevent recurrence of unwanted erections, may not see therapeutic benefits immediately and temporarily require intracavernous self-injections at home with sympathomimetic agents [1321, 1355]. The most commonly used drugs are phenylephrine and etilephrine (as described in the treatment of ischaemic priapism) [1304, 1341, 1411, 1425] (LE: 3). Adverse effects include hypertension, coronary ischaemia and cardiac arrhythmias.

Phosphodiesterase type 5 inhibitors have a paradoxical effect in alleviating and preventing stuttering priapism, mainly in patients with idiopathic and sickle cell disease-associated priapism. The evidence with other systemic drugs (digoxin, α-adrenergic agonists, baclofen, gabapentin and terbutaline, hydroxyurea) is limited.

Follow-up

Follow-up for stuttering priapism includes history and clinical examination to assess the efficacy of treatment in preventing or alleviating erectile events as well as assessing erectile function and penile fibrosis.
9.2.2 Priapism in children

The classification of priapism in children is similar to that in adults. In addition to ischaemic, stuttering and non-ischaemic priapism, a fourth type, neonatal priapism is also described [1304]. Priapism in children is considered rare as no data on its prevalence exist. Sickle cell disease is the major cause of priapism in children, followed by leukaemia (10%), trauma (10%), idiopathic causes (19%) and drugs (5%) [1450]. One study showed that 25% of children experienced SCD-related priapism in a pre-pubertal period [1451]. Another study revealed that 90% of men with SCD had their first priapism episode before age 20 years [1413]. Priapism in children should be evaluated and treated in a timely manner, as untreated ischaemic priapism may lead to ED and psychosexual disorders in adulthood [1452]. A multi-disciplinary team approach should be utilised with specialist input from haematologists and paediatric endocrinologists.

9.3 Non-ischaemic (high-flow or arterial) priapism

Most of the identified studies were small retrospective case series reporting principally on the role of embolisation in post-traumatic non-ischaemic priapism (Appendix 5). This may reflect the uncommon nature of the condition. Success rates and erectile function were well documented across all reports. Some studies attempted to stratify outcomes based on the agent used for embolisation (e.g., microcoil or autologous clot), although care should be taken when interpreting case series with small patient numbers.

9.3.1 Epidemiology/aetiology/pathophysiology

Epidemiological data on non-ischaemic priapism are almost exclusively derived from small case series [1304, 1335, 1337, 1453, 1454]. Non-ischaemic priapism is significantly less common than the ischaemic type, comprising only 5% of all priapism cases [1304]. The most frequent cause of non-ischaemic priapism is blunt perineal or penile trauma [1455]. The injury results in a laceration in the cavernosal artery or branches, leading to a fistula between the artery and the lacunar spaces of the sinusoidal space [1454]. The resultant increased blood flow results in a persistent and prolonged erection [1456].

There is often a delay between the trauma and the development of the priapism that may be up to two to three weeks [1457]. This is suggested to reflect either spasm or ischaemic necrosis of the injured artery, with the fistula only developing as the spasm resolves or when the ischaemic segment “blows up”. The priapism typically occurs after a nocturnal erection or an erection related to sexual activity, resulting in the sudden increase of blood flow and pressure in the cavernous arteries [1458]. The patient typically reports an erection that is not fully rigid and is not associated with pain because the venous drainage is not compromised and the penile tissue does not become ischaemic [1459].

Non-ischaemic priapism can occur after acute spinal cord injury, presumably due to loss of sympathetic input, leading to predominant parasympathetic input and increased arterial flow [1460]. It has also been reported to occur following internal urethrotomy [1461], Nesbit procedure [1462], circumcision [1463], transrectal prostate biopsy [1464], and brachytherapy for prostate cancer [1465]. Some cases have also been described following shunting procedures performed for ischaemic priapism due to a lacerated cavernosal artery (conversion of low-flow to high-flow priapism) [1466-1468]. Although SCD is usually associated with ischaemic priapism, occasional cases of high-flow priapism have been reported; however, the pathophysiological mechanism remains unclear [1469]. Finally, metastatic malignancy to the penis can also rarely cause non-ischaemic priapism [1470, 1471] (Table 38).

</tbody>
</table>
9.3.2 **Classification**
Non-ischaemic priapism is a persistent erection caused by unregulated cavernous arterial inflow [1304]. According to aetiology, non-ischaemic priapism can be categorised into four types: traumatic, neurogenic, iatrogenic and idiopathic in origin.

9.3.3 **Diagnostic evaluation**
9.3.3.1 **History**
A comprehensive history is mandatory in non-ischaemic priapism diagnosis and follows the same principles as described in Table 33. Arterial priapism should be suspected when the patient reports a history of pelvic, perineal, or genital trauma; no penile pain (discomfort is possible); and a persistent, not fully rigid erection (Table 34). The corpus cavernosum can become fully rigid with sexual stimulation, so the sexual intercourse is usually not compromised. The onset of post-traumatic non-ischaemic priapism can be delayed by several hours to weeks following the initial injury [1304].

9.3.3.2 **Physical examination**
In non-ischaemic priapism, the corpora are tumescent but not fully rigid. Abdominal, penile and perineal examination may reveal evidence of trauma (Table 34) [1304]. Neurological examination is indicated if a neurogenic aetiology is suspected.

9.3.3.3 **Laboratory testing**
Laboratory testing should include a blood count with white blood cell differential and a coagulation profile to assess for anaemia and other haematological abnormalities. Blood aspiration from the corpus cavernosum shows bright red arterial blood in arterial priapism, while blood is dark in ischaemic priapism (Table 34) (LE: 2b). Blood gas analysis is essential to differentiate between non-ischaemic and ischaemic priapism. Blood gas values in high-flow priapism show normal arterial blood [1304] (Table 35).

9.3.3.4 **Penile imaging**
Colour duplex US of the penis and perineum is recommended and can differentiate non-ischaemic from ischaemic priapism [1333-1335]. Ultrasound must be performed without intracavernosal vasoactive drug injection [1472]. In non-ischaemic priapism, US helps to localise the fistula site and appears as a characteristic colour blush and turbulent high-velocity flow on Doppler analysis [1473]. Patients with non-ischaemic priapism have normal to high blood velocities in the cavernous arteries [1306, 1474].

Selective pudendal arteriography can reveal a characteristic blush at the site of injury in arterial priapism [1475, 1476]. However, due to its invasiveness, it should be reserved for the management of non-ischaemic priapism when embolisation is being considered [1304, 1329].

The role of MRI in the diagnostic evaluation of priapism is controversial. Its role in non-ischaemic priapism is limited because the small penile vessels and fistulae cannot be easily demonstrated [1477].

9.3.4 Disease management

Although the conventional belief is that the management of non-ischaemic priapism is not an emergency because the corpus cavernosum does not contain ischaemic blood, recent data indicate that the duration of non-ischaemic priapism can also affect erectile function. High-flow priapism was reproduced in an in vitro model using pre-contracted strips of rabbit corpus cavernosum superfused at high pO₂ levels. This showed that the smooth muscle tone reduced by 43% after super-fusion for twelve hours, indicating irreversible smooth muscle dysfunction [1478]. In a case series consisting of six patients with high-flow priapism after median follow-up of 4.5 (2-12) weeks, all patients reported development of ED or distal penile flaccidity [1403]. The goal of treatment is closure of the fistula. Non-ischaemic priapism can be managed conservatively or by direct perineal compression. Failure of conservative treatment requires selective arterial embolisation [1479]. The optimal time interval between conservative treatment and arterial embolisation is still under debate. Definitive management can be performed at the discretion of the treating physician and should be discussed with the patients so that they can understand the risks of treatment [1304, 1329].

9.3.4.1 Conservative management

Conservative management may include applying ice to the perineum or perineal compression, which is typically US-guided. The fistula occasionally closes spontaneously. Even in those cases where the fistula remains patent, intercourse is still possible [1335, 1453, 1480, 1481]. Androgen deprivation therapy (e.g., leuprolide injections, bicalutamide and ketoconazole) has been reported in case series to enable closure of the fistula reducing spontaneous and sleep-related erections [1482]. However, sexual dysfunction due to these treatments must be considered. Patients may develop ED or distal penile flaccidity while undergoing conservative treatment [1403].

Blood aspiration is not helpful for the treatment of arterial priapism and the use of α-adrenergic antagonists is not recommended because of potential severe adverse effects (e.g., such as transfer of the drug into the systemic circulation).

9.3.4.2 Selective arterial embolisation

Selective arterial embolisation can be performed using temporary substances, such as autologous blood clot [1483-1485] and gel foam [1484, 1486], or permanent substances such as microcoils [1484, 1486-1488], ethylene-vinyl alcohol copolymer (PVA), and N-butyl-cyanoacrylate (NBCA) [1489]. It is assumed that temporary embolisation provides a decreased risk of ED, with the disadvantage of higher failure/recurrence rates; this would be the consequence of artery recanalisation using temporary materials. However, there is insufficient evidence to support this hypothesis. A recent non-systematic review of the literature reported success rates ranging between 61.7 and 83.3%, and ED rates from 0-33.3% after the first arterial embolisation, showing that failure/recurrence may not be significantly higher with temporary embolisation materials, and preservation of erectile function may not be that different between the two modalities either [1458]. Other potential complications of arterial embolisation include penile gangrene, gluteal ischaemia, cavernositis, and perineal abscess [1304, 1490]. Repeated embolisation is a reasonable option for treating non-ischaemic priapism, both in terms of efficacy and safety [1458].

9.3.4.3 Surgical management

Surgical ligation of the fistula is possible through a transcoporeal or inguinoscrotal approach, using intra-operative Doppler US. Surgery is technically challenging and associated with significant risks, particularly of ED [1491]. Surgery is rarely performed and should only be considered when there are contraindications for selective embolisation, if embolisation is unavailable, or repeated embolisations have failed. If the patient desires more definitive treatment and is not sexually active or has pre-existing ED, surgical intervention can be an appropriate option [1458]. Erectile dysfunction rates ranging from 0-50% are reported following non-ischaemic priapism and its treatment, with surgical ligation having the highest reported rates [1458]. Patients can require penile prosthesis implantation for ED in the long-term [1382].

9.3.4.4 Summary of evidence for the treatment of arterial priapism

<table>
<thead>
<tr>
<th>Summary of evidence</th>
<th>LE</th>
</tr>
</thead>
<tbody>
<tr>
<td>Non-ischaemic priapism can cause erectile dysfunction over time and early definitive management should be undertaken.</td>
<td>3</td>
</tr>
<tr>
<td>Conservative management applying ice to the perineum or site-specific perineal compression is an option in all cases. The use of androgen deprivation therapy may enable closure of the fistula reducing spontaneous and sleep-related erections.</td>
<td>3</td>
</tr>
</tbody>
</table>
Selective artery embolisation, using temporary or permanent substances, has high success rates. No definitive statement can be made on the best substance for embolisation in terms of sexual function preservation and success rate.

Repeated embolisation is a reasonable option for the treatment of non-ischaemic priapism.

Selective surgical ligation of the fistula should be reserved as the last treatment option when multiple embolisations have failed.

### 9.3.4.5 Recommendations for the treatment of arterial priapism

<td>Weak</td>
</tr>
<tr>
<td>Reserve selective surgical ligation of a fistula as a final treatment option when repeated arterial embolisations have failed.</td>
<td>Weak</td>
</tr>
</tbody>
</table>

### 9.3.4.6 High-flow priapism in children

Non-ischaemic priapism is a rare condition, especially in children. The embarrassment that children may have in speaking about it to their parents can lead to misdiagnosis and underestimating the prevalence of this condition [1492]. The aetiology, clinical presentation and diagnostic and therapeutic principles are comparable with those of arterial priapism in adults. However, some differentiating features should be noted.

Idiopathic non-ischaemic priapism can be found in a significant percentage of children [1493]. Perineal compression with the thumb may be a useful manoeuvre to distinguish ischaemic and non-ischaemic priapism, particularly in children, where it may result in immediate detumescence, followed by the return of the erection with the removal of compression [1458]. Conservative management using ice applied to the perineum or site-specific perineal compression may be successful, particularly in children [1494, 1495]. Although reportedly successful, embolisation in children is technically challenging and requires treatment within a specialist paediatric vascular radiology department [1345, 1496].

### 9.3.4.7 Follow-up

During conservative management of non-ischaemic priapism, physical examination and colour duplex US can be useful tools to assess treatment efficacy. Close follow-up using colour duplex US and MRI can help detect distal penile fibrosis and be beneficial in clinical decision-making to intervene with embolisation earlier [1403]. Follow-up after selective arterial embolisation should include clinical examination, colour duplex US, and erectile function assessment. If in doubt, repeat arteriography is required. The goals are to determine if the treatment was successful, identify signs of recurrence, and verify any anatomical and functional sequelae [1472].

### 9.4 Controversies and future areas of focus in the management of priapism

Low-flow priapism should be considered as a surgical emergency. Although the treatment of high-flow priapism can be delayed, there is some evidence to suggest that a delay in intervention may result in long-term fibrosis of the corpus cavernosum.

The evidence in the literature mainly consists of retrospective single centre cohort studies and therefore is of low quality. Prospective multicentre studies are needed to develop high levels of evidence to support contemporary guidelines.

There are a number of controversial areas including the prophylaxis of stuttering priapism, with no real evidence suggesting the superiority of a single pharmaceutical agent over another. In particular, understanding of the time point at which irreversible corporal smooth muscle necrosis occurs due to low-flow priapism is limited; therefore, definitive management of delayed or refractory priapism remains controversial (i.e., immediate prosthesis implantation vs. penoscrotal decompression vs. shunting). Therefore, it is strongly recommended that multi-centre collaborative studies are performed to better understand this rare but devastating condition.
10. MALE INFERTILITY

10.1 Definition and classification
Infertility is defined by the inability of a sexually active, non-contraceptive couple to achieve spontaneous pregnancy within 1 year [1497]. Primary infertility refers to couples that have never had a child and cannot achieve pregnancy after at least 12 consecutive months having sex without using birth control methods. Secondary infertility refers to infertile couples who have been able to achieve pregnancy at least once before (with the same or different sexual partner). Recurrent pregnancy loss is distinct from infertility and is defined as two or more failed pregnancies [1498, 1499].

10.2 Epidemiology/aetiology/pathophysiology/risk factors

10.2.1 Introduction
About 15% of couples do not achieve pregnancy within 1 year and seek medical treatment for infertility. One in eight couples encounter problems when attempting to conceive a first child and one in six when attempting to conceive a subsequent child [1500]. In 50% of involuntarily childless couples, a male-infertility-associated factor is found, usually together with abnormal semen parameters [1497]. For this reason, all male patients belonging to infertile couples should undergo medical evaluation by a urologist trained in male reproduction.

Male fertility can be impaired as a result of [1497]:
- congenital or acquired urogenital abnormalities;
- gonadotoxic exposure (e.g., radiotherapy or chemotherapy);
- malignancies;
- urogenital tract infections;
- increased scrotal temperature (e.g., as a consequence of varicocele);
- endocrine disturbances;
- genetic abnormalities;
- immunological factors.

In 30-40% of cases, no male-associated factor is found to explain impairment of sperm parameters and historically was referred to as idiopathic male infertility. These men present with no previous history of diseases affecting fertility and have normal findings on physical examination and endocrine, genetic and biochemical laboratory testing, although semen analysis may reveal pathological findings (see Section 10.3.2). Unexplained male infertility is defined as infertility of unknown origin with normal sperm parameters and partner evaluation. Between 20 and 30% of couples will have unexplained infertility. It is now believed that idiopathic male infertility may be associated with several previously unidentified pathological factors, which include but are not limited to endocrine disruption as a result of environmental pollution, generation of reactive oxygen species (ROS)/sperm DNA damage, or genetic and epigenetic abnormalities [1501].

Advanced paternal age has emerged as one of the main risk factors associated with the progressive increase in the prevalence of male factor infertility [1502-1509]. Likewise, advanced maternal age must be considered over the management of every infertile couple, and the consequent decisions in the diagnostic and therapeutic strategy of the male partner [1510, 1511]. This should include the age and ovarian reserve of the female partner, since these parameters might determine decision-making in terms of timing and therapeutic strategies (e.g., assisted reproductive technology [ART] vs. surgical intervention) [1502-1505]. Table 40 summarises the main male-infertility-associated factors.

</thead>
<tbody>
<tr>
<td>Investigate both partners simultaneously to categorise the cause of infertility.</td>
<td>Strong</td>
</tr>
<tr>
<td>Infertility should be evaluated after 6 months of attempted conception when the female partner is aged &gt; 35 years.</td>
<td>Weak</td>
</tr>
<tr>
<td>Examine all men seeking medical help for fertility problems, including men with abnormal semen parameters for urogenital abnormalities.</td>
<td>Strong</td>
</tr>
</tbody>
</table>

10.3 Diagnostic work-up

Focused evaluation of male patients must always be undertaken and should include: a medical and reproductive history; physical examination; semen analysis – with strict adherence to World Health Organization (WHO) reference values for human semen characteristics [1513], and hormonal evaluation. Other investigations (e.g., genetic analysis and imaging) may be required depending on the clinical features and semen parameters.

10.3.1 Medical/reproductive history and physical examination

10.3.1.1 Medical and reproductive history

Medical history should evaluate any risk factors and behavioural patterns that could affect the male partner's
fertility, such as lifestyle, family history (including, testicular cancer), comorbidity (including systemic diseases; e.g., hypertension, diabetes mellitus, obesity, MetS, testicular cancer, etc.), genito-urinary infections (including sexually transmitted infections), history of testicular surgery and exclude any potential known gonadotoxins [1514].

Typical findings from the history of a patient with infertility include:
- cryptorchidism (uni- or bilateral);
- testicular torsion and trauma;
- genitourinary infections;
- exposure to environmental toxins;
- gonadotoxic medications (anabolic drugs, chemotherapeutic agents, etc.);
- exposure to radiation or cytotoxic agents.

10.3.1.2 Physical examination
Focused physical examination is compulsory in the evaluation of every infertile male, including presence of secondary sexual characteristics. The size, texture and consistency of the testes must be evaluated. In clinical practice, testicular volume is assessed by Prader’s orchidometer [1515]; orchidometry may overestimate testicular volume when compared with US assessment [1516]. There are no uniform reference values in terms of Prader’s orchidometer-derived testicular volume, due to differences in the populations studied (e.g., geographic area, nourishment, ethnicity and environmental factors) [1515-1517]. The mean Prader’s orchidometer-derived testis volume reported in the European general population is 20.0 ± 5.0 mL [1515], whereas in infertile patients it is 18.0 ± 5.0 mL [1515, 1518, 1519]. The presence of the vas deferens, fullness of epididymis and presence of a varicocele should be always determined. Likewise, palpable abnormalities of the testis, epididymis, and vas deferens should be evaluated. Other physical alterations, such as abnormalities of the penis (e.g., phimosis, short frenulum, fibrotic nodules, epispadias, hypospadias, etc.), abnormal body hair distribution and gynecomastia, should also be evaluated.

Typical findings from the physical examination of a patient with characteristics suggestive for testicular deficiency include:
- abnormal secondary sexual characteristics;
- abnormal testicular volume and/or consistency;
- testicular masses (potentially suggestive of cancer);
- absence of testes (uni-bilaterally);
- gynaecomastia;
- varicocele.

10.3.2 Semen analysis
A comprehensive andrological examination is always indicated in every infertile couple, both if semen analysis shows abnormalities, and even in the case of normal sperm parameters as compared with reference values [1520]. Important treatment decisions are based on the results of semen analysis and most studies evaluate semen parameters as a surrogate outcome for male fertility. However, semen analysis cannot precisely distinguish fertile from infertile men [1521]; therefore, it is essential that the complete laboratory work-up is standardised according to reference values (Table 41). There is consensus that modern semen analysis must follow these guidelines. Ejaculate analysis has been standardised by the WHO and disseminated by publication of the most updated version of the WHO Laboratory Manual for the Examination and Processing of Human Semen. Of note, the 6th edition the WHO Manual for the Examination and Processing of Human Semen [1522] has been published on July 2021 and reports some differences compared to the previous edition (5th edn.) [1523] that has been used throughout the last eleven years. Therefore, it is possible that the worldwide implementation in the everyday clinical practice of the newly-released version could be gradual. The 6th edn. of the WHO Manual is more like a technical guideline rather than a clinical guideline. Accordingly, it comprises three sections: i) semen examination; ii) sperm preparation and cryopreservation; and, iii) quality assessment and quality control.

Overall, the procedures for semen examination are divided into three chapters:
- Basic examinations, which contains fewer investigations than the previous edition that should be performed by every laboratory, based on step-wise procedures and evidence based techniques.
- Extended analyses, which are performed by choice of the laboratory or by special request from the clinicians.
- Advanced examinations, that are classified as focused on very specialized as well as mainly research methods and other emerging technologies.

Overall, a few relevant differences have been identified between 6th and 5th editions.
Basic examination:
- Assessment of sperm numbers: the laboratory should not stop assessing the number of sperm at low concentrations (2 million/mL), as suggested in the 5th edition, but report lower concentrations, noting that the errors associated with counting a small number of spermatozoa may be very high. In this edition, it is recognised that the total sperm numbers per ejaculate (sperm output) have more diagnostic value than sperm concentration; therefore, semen volume must be measured accurately.
- Assessment of sperm motility: the categorisation of sperm motility has reverted back to fast progressively motile, slow progressively motile, non-progressively motile and immotile (grade a, b, c or d) because presence (or absence) of rapid progressive spermatozoa is recognised to be clinically important.
- Assessment of sperm morphology: the 6th edition has recommended the Tygerberg strict criteria by sperm adapted Papanicolaou staining.

Moreover, vitality test should not be performed in all samples and only if few motile sperm are found.

Extended examinations
This chapter contains procedures to detect leukocytes and markers of genital tract inflammation, sperm antibodies, indices of multiple sperm defects, sequence of ejaculation, methods to detect sperm aneuploidy, semen biochemistry and sperm DNA fragmentation.

Advanced examinations
Obsolete tests such as the human oocyte and human zona pellucida binding and the hamster oocyte penetration tests have been completely removed. Research tests include assessment of ROS and oxidative stress, membrane ion channels, acrosome reaction and sperm chromatin structure and stability, computer-assisted sperm analysis (CASA).

Reference ranges and reference limits
In the 5th edition, the distribution of values from approximately 1,800 men who have contributed to a natural conception within 12 months of trying was presented and the lower fifth percentile of this distribution has been considered as a true cutoff limit for normal vs. abnormal sperm parameters [1513].

The 6th edn highlights that distribution of data from reference men do not represent limits between fertile and subfertile individuals [1522]. Indeed, in the latest edition of the WHO Manual, the data presented in the 5th edition have been further evaluated and complemented with data from around 3,500 men in 12 countries [1520]. Of note, the distributions do not differ much from the compilation of 2010. Table 41 reports the lower reference limits for semen characteristics according to the 2010 and 2021 version of the WHO Manual.

According to the new WHO Manual, the lower fifth percentile of data from men in the reference population (Table 41) does not represent a limit between fertile and infertile men. For a general prediction of live birth in vivo as well as in vitro, a multiparametric interpretation of the entire men’s and partner’s reproductive potential are needed.

It has also become clear from studies that more complex testing than semen analysis may be required in everyday clinical practice, particularly in men belonging to couples with recurrent pregnancy loss from natural conception or ART and men with unexplained male infertility. Although definitive conclusions cannot be drawn, given the heterogeneity of the studies, in these patients there is evidence that sperm DNA may be damaged, thus resulting in pregnancy failure [1501, 1524, 1525] (see below).

CIs = confidence intervals; MAR = mixed antiglobulin reaction; NP = non-progressive; PR = progressive (a+b motility).

* Distribution of data from the population is presented with one-sided intervals (extremes of the reference population data). The lower 5th percentile represents the level under which only results from 5% of the men in the reference population were found.

If semen analysis is normal according to WHO criteria, a single test is sufficient. If the results are abnormal on at least two tests, further andrological investigation is indicated. According to WHO reference criteria 5th edn., it is important to differentiate between the following [1523]:

- oligozoospermia: < 15 million spermatozoa/mL;
- asthenozoospermia: < 32% progressive motile spermatozoa;
- teratozoospermia: < 4% normal forms.

None of the individual sperm parameters (e.g., concentration, morphology and motility), are diagnostic per se of infertility. According to the WHO reference criteria 6th edn., this subdivision is not reported, although the EAU Guidelines panel considers this further segregation still clinically relevant in the everyday clinical practice.

Often, all three anomalies occur simultaneously, which is defined as oligo-astheno-terato-zoospermia (OAT) syndrome. As in azoospermia (namely, the complete absence of spermatozoa in semen), in severe cases of oligozoospermia (spermatozoa < 5 million/mL) [1526], there is an increased incidence of obstruction of the male genital tract and genetic abnormalities. In those cases, a more comprehensive assessment of the hormonal profile may be helpful to further and more accurately differentially diagnose among pathological conditions.

In azoospermia, the semen analysis may present with normal ejaculate volume and azoospermia after centrifugation. A recommended method is semen centrifugation at 3,000 g for 15 minutes and a thorough microscopic examination by phase contrast optics at ×200 magnification of the pellet. All samples can be stained and re-examined microscopically [1522]. This is to ensure that small quantities of sperm are detected, which may be potentially used for intra-cytoplasmic sperm injection (ICSI); therefore, removing the need for surgical intervention.

10.3.3 **Measurement of sperm DNA Fragmentation Index (DFI)**

Semen analysis is a descriptive evaluation and may be unable to discriminate between the sperm of fertile and infertile men. Therefore, it is now apparent that sperm DNA damage may occur in men with infertility. DNA fragmentation, or the accumulation of single- and double-strand DNA breaks, is a common property of sperm, and an increase in the level of sperm DNA fragmentation has been shown to reduce the chances of natural conception. Although no studies have unequivocally and directly tested the impact of sperm DNA damage on clinical management of infertile couples, sperm DNA damage is more common in infertile men and has been identified as a major contributor to male infertility, as well as poorer outcomes following ART [1527, 1528], including impaired embryo development [1527], miscarriage, recurrent pregnancy loss [1524, 1525, 1529], and birth defects [1527]. Sperm DNA damage can be increased by several factors including hormonal anomalies, varicocele, chronic infection and lifestyle factors (e.g., smoking) [1528].
Several assays have been described to measure sperm DNA damage. It has been suggested that current methods for assessing sperm DNA integrity still do not reliably predict treatment outcomes from ART and there is controversy whether to recommend them routinely for clinical use [1528, 1530]. Of those, terminal deoxynucleotidyl transferase mediated deoxyuridine triphosphate nick end labelling (TUNEL) and the alkaline comet test (COMET) directly measure DNA damage. Conversely, sperm chromatin structure assay (SCSA) and sperm chromatin dispersion test (SCD) are indirect tools for DNA fragmentation assessment. Sperm chromatin structure assay is still the most widely studied and one of the most commonly used techniques to detect DNA damage [1531, 1532]. In SCSA, the number of cells with DNA damage is indicated by the DNA fragmentation index (DFI) [1533], whereas the proportion of immature sperm with defects in the histone-to-protamine transition is indicated by high DNA stainability [1534]. It is suggested that a threshold DFI of 25% as measured with SCSA, is associated with reduced pregnancy rates via natural conception or intra-uterine insemination (IUI) [1532]. Furthermore, DFI values > 50% on SCSA are associated with poorer outcomes from in vitro fertilisation (IVF). More recently, the mean COMET score and scores for proportions of sperm with high or low DNA damage have been shown to be of value in diagnosing male infertility and providing additional discriminatory information for the prediction of both IVF and ICSI live births [1528].

Testicular sperm is reported to have lower levels of sperm DFI when compared to ejaculated sperm [1535]. Couples with elevated DNA fragmentation may benefit from combination of testicular sperm extraction (TESE) and ICSI, an approach called TESE-ICSI, which may not overcome infertility when applied to an unselected population of infertile men with untested DFI values [1532, 1535]. However, further evidence is needed to support this practice in the routine clinical setting [1535].

### 10.3.4 Hormonal determinations

In men with testicular deficiency, hypergonadotrophic hypogonadism (also called primary hypogonadism) is usually present, with high levels of FSH and LH, with or without low levels of testosterone. Generally, the levels of FSH negatively correlate with the number of spermatogonia [1536]. When spermatogonia are absent or markedly diminished, FSH level is usually elevated; when the number of spermatogonia is normal, but maturation arrest exists at the spermatocyte or spermatid level, FSH level is usually within the normal range [1536]. However, for patients undergoing TESE, FSH levels do not accurately predict the presence of spermatogenesis, as men with maturation arrest on histology can have both normal FSH and testicular volume [1537, 1538]. Furthermore men with non-obstructive azoospermia (NOA) and high levels of FSH may still harbour focal areas of spermatogenesis at the time of TESE or microdissection TESE (mTESE) [1538, 1539].

### 10.3.5 Genetic testing

All urologists working in andrology must have an understanding of the genetic abnormalities most commonly associated with infertility, so that they can provide correct advice to couples seeking fertility treatment. Men with low sperm counts can still be offered a reasonable chance of paternity, using IVF, ICSI and sperm extraction from the testes in cases of azoospermia. However, the spermatozoa of infertile men show an increased rate of aneuploidy, structural chromosomal abnormalities, and DNA damage, carrying the risk of passing genetic abnormalities to the next generation. Current routine clinical practice is based on the screening of genomic DNA from peripheral blood samples. However, screening of chromosomal anomalies in spermatozoa (sperm aneuploidy) is also feasible and can be performed in selected cases (e.g., recurrent miscarriage) [1540-1542].

#### 10.3.5.1 Chromosomal abnormalities

Chromosomal abnormalities can be numerical (e.g., trisomy) or structural (e.g., inversions or translocations). In a survey of pooled data from 11 publications, including 9,766 infertile men, the incidence of chromosomal abnormalities was 5.8% [1543]. Of these, sex chromosome abnormalities accounted for 4.2% and autosomal abnormalities for 1.5%. In comparison, the incidence of abnormalities was 0.38% in pooled data from three series, with a total of 94,465 new-born male infants, of whom 131 (0.14%) had sex chromosomal abnormalities and 232 (0.25%) autosomal abnormalities [1543]. The frequency of chromosomal abnormalities increases as testicular deficiency becomes more severe. Patients with sperm count < 5 million/mL already show a 10-fold higher incidence (4%) of mainly autosomal structural abnormalities compared with the general population [1544, 1545]. Men with NOA are at highest risk, especially for sex chromosomal anomalies (e.g., Klinefelter syndrome) [1546, 1547].

Based on the frequencies of chromosomal aberrations in patients with different sperm concentration, karyotype analysis is currently indicated in men with azoospermia or oligozoospermia (spermatozoa < 10 million/mL) [1545]. This broad selection criterion has been recently externally validated, with the finding that the suggested threshold has a low sensitivity, specificity, and discrimination (80%, 37%, and 59%, respectively) [1548].
In this context, a novel nomogram, with a 2% probability cut-off, which allows for a more careful detection of karyotype alterations has been developed [1548]. Notwithstanding, the clinical value of spermatozoa < 10 million/mL remains a valid threshold until further studies, evaluating the cost-effectiveness, in which costs of adverse events due to chromosomal abnormalities (e.g., miscarriages and children with congenital anomalies) are performed [1549]. If there is a family history of recurrent spontaneous abortions, malformations or mental retardation, karyotype analysis should be requested, regardless of the sperm concentration.

10.3.5.1.1 Sex chromosome abnormalities (Klinefelter syndrome and variants [47,XXY; 46,XY/47,XX mosaicism])

Klinefelter syndrome is the most common sex chromosomal abnormality [1550]. Adult men with Klinefelter syndrome usually have small firm testes along with features of primary hypogonadism. The phenotype is the final result of a combination between genetic, hormonal and age-related factors [15]. The phenotype varies from that of a normally virilised male to one with the stigmata of androgen deficiency. In most cases infertility and reduced testicular volume are the only clinical features that can be detected. Leydig cell function is also commonly impaired in men with Klinefelter syndrome and thus testosterone deficiency is more frequently observed than in the general population [1551], although rarely observed during the peri-pubertal period, which usually occurs in a normal manner [15, 1552]. Rarely, more pronounced signs and symptoms of hypogonadism can be present, along with congenital abnormalities including heart and renal problems [1553].

The presence of germ cells and sperm production are variable in men with Klinefelter syndrome and are more frequently observed in mosaicism, 46,XY/47,XXY. Based on sperm fluorescence in situ hybridisation (FISH) studies showing an increased frequency of sex chromosomal abnormalities and increased incidence of autosomal aneuploidy (disomy for chromosomes 13, 18 and 21), concerns have been raised about the chromosomal normality of the embryos generated through ICSI [1554]. The production of 24,XY sperm has been reported in 0.9% and 7.0% of men with Klinefelter mosaicism [1555, 1556] and in 1.36-25% of men with somatic karyotype 47,XXY [1557-1560]. In patients with azoospermia, TESE or mTESE are therapeutic options as spermatozoa can be recovered in up to 50% of cases [1561, 1562]. Although the data are not unique [1562], there is growing evidence that TESE or mTESE yields higher sperm recovery rates when performed at a younger age [1546, 1563].

Numerous healthy children have been born using ICSI without pre-implantation genetic diagnosis (PGD) although the conception of one 47,XXY foetus has been reported [1550]. Although data published so far have not reported any difference in the prevalence of aneuploidy in children conceived using ICSI in Klinefelter syndrome compared to the general population, men with Klinefelter syndrome undergoing fertility treatments should be counselled regarding the potential genetic abnormalities in their offspring.

Regular medical follow-up of men with Klinefelter syndrome is recommended as testosterone therapy may be considered if testosterone levels are in the hypogonadal range when fertility issues have been addressed [1564]. Since this syndrome is associated with several general health problems, appropriate medical follow-up is therefore advised [16, 1565, 1566]. In particular, men with Klinefelter syndrome are at higher risk of metabolic and cardiovascular diseases (CVD), including venous thromboembolism (VTE). Therefore, men with Klinefelter syndrome should be made aware of this risk, particularly when starting testosterone therapy [1567]. In addition, a higher risk of haematological malignancies has been reported in men with Klinefelter syndrome [16].

Testicular sperm extraction in peri-pubertal or pre-pubertal boys with Klinefelter syndrome aiming at cryopreservation of testicular spermatogonial stem cells is still considered experimental and should only be performed within a research setting [1568]. The same applies to sperm retrieval in older boys who have not considered their fertility potential [1569].

10.3.5.1.2 Autosomal abnormalities

Genetic counselling should be offered to all couples seeking fertility treatment (including IVF/ICSI) when the male partner has an autosomal karyotype abnormality. The most common autosomal karyotype abnormalities are Robertsonian translocations, reciprocal translocations, paracentric inversions, and marker chromosomes. It is important to look for these structural chromosomal anomalies because there is an increased associated risk of aneuploidy or unbalanced chromosomal complements in the foetus. As with Klinefelter syndrome, sperm FISH analysis provides a more accurate risk estimation of affected offspring. However, the use of this genetic test is largely limited by the availability of laboratories able to perform this analysis [1570]. When IVF/ICSI is carried out for men with translocations, PGD or amniocentesis should be performed [1571, 1572].
10.3.5.2 Cystic fibrosis gene mutations

Cystic fibrosis (CF) is an autosomal-recessive disorder [1573]. It is the most common genetic disease of Caucasians; 4% are carriers of gene mutations involving the CF transmembrane conductance regulator (CFTR) gene located on chromosome 7p. It encodes a membrane protein that functions as an ion channel and influences the formation of the ejaculatory duct, seminal vesicle, vas deferens and distal two-thirds of the epididymis. Approximately 2,000 CFTR mutations have been identified and any CFTR alteration may lead to congenital bilateral absence of the vas deferens (CBAVD). However, only those with homozygous mutations exhibit CF disease [1574]. Congenital bilateral absence of the vas deferens is a rare reason for male factor infertility, which is found 1% of infertile men and in up to 6% of men with obstructive azoospermia [1575]. Clinical diagnosis of absent vasa is easy to miss and all men with azoospermia should be carefully examined to exclude CBAVD, particularly those with a semen volume < 1.0 mL and acidic pH < 7.0 [1576-1578]. In patients with CBAVD-only or CF, TESA, microsurgical epididymal sperm aspiration (MESA) or TESE with ICSI can be used to achieve pregnancy. However, higher sperm quality, easier sperm retrieval and better ICSI outcomes are associated with CBAVD-only patients compared with CF patients [1574].

The most frequently found mutations are F508, R117H and W1282X, but their frequency and the presence of other mutations largely depend on the ethnicity of the patient [1579, 1580]. Given the functional relevance of a DNA variant (the ST allele) in a non-coding region of CFTR [1581], it is now considered a mild CFTR mutation rather than a polymorphism and it should be analysed in each CBAVD patient. As more mutations are defined and tested for, almost all men with CBAVD will probably be found to have mutations. It is not practical to test for all known mutations, because many have a low prevalence in a particular population. Routine testing is usually restricted to the most common mutations in a particular community through the analysis of a mutation panel. Men with CBAVD often have mild clinical stigmata of CF (e.g., history of chest infections). When a man has CBAVD, it is important to test also his partner for CF mutations. If the female partner is found to be a carrier of CFTR mutations, the couple must consider carefully whether to proceed with ICSI using the man’s sperm, as the risk of having a child with CF or CBAVD will be 50%, depending on the type of mutations carried by the parents. If the female partner is negative for known mutations, the risk of being a carrier of unknown mutations is ~0.4% [1582].

10.3.5.2.1 Unilateral or bilateral absence/abnormality of the vas and renal anomalies

Congenital unilateral absence of the vas deferens (CUAVD) is usually associated with ipsilateral absence of the kidney and probably has a different genetic causation [1583]. Consequently, in these subjects CFTR mutation screening is not indicated. Men with CUAVD are usually fertile, and the condition is most commonly encountered as an incidental finding in the vasectomy clinic. Cystic fibrosis transmembrane conductance regulator gene mutation screening is indicated in men with unilateral absence of the vas deferens with normal kidneys. The prevalence of renal anomalies is rare for patients who have CBAVD and CFTR mutations [1584]. Abdominal US should be undertaken both in unilateral and bilateral absence of vas deferens without CFTR mutations. Findings may range from CUAVD with ipsilateral absence of the kidney, to bilateral vessel and renal abnormalities, such as pelvic kidney [1585].

10.3.5.3 Y microdeletions – partial and complete

Microdeletions on the Y-chromosome are termed AZFa, AZFb and AZFc deletions [1586]. Clinically relevant deletions remove partially, or in most cases completely, one or more of the AZF regions, and are the most frequent molecular genetic cause of severe oligozoospermia and azoospermia [1587]. In each AZF region, there are several spermatogenesis candidate genes [1588]. Deletions occur en bloc (i.e., removing more than one gene), it is not possible to determine the role of a single AZF gene from the AZF deletion phenotype and it is unclear if they all participate in spermatogenesis. Gene-specific deletions, which remove a single gene, have been reported only in the AZFa region and concern the USP9Y gene. These studies have suggested that USP9Y is most likely to be a “fine tuner” of sperm production, and its specific screening is not advised [1589]. It has been observed that a number of commercial laboratories can use a limited number of primer sets over the AZF a, b and c regions in their Y chromosome microdeletion assay. This can eventually miss smaller microdeletions and clinicians should be aware over the managing work-up of patients scheduled for testicular surgery [1590, 1591].

10.3.5.3.1 Clinical implications of Y microdeletions

The clinical significance of Yq microdeletions can be summarised as follows:

- They are not found in normozoospermic men, proving there is a clear cut cause-and-effect relationship between Y-deletions and spermatogenic failure [1592].
- The highest frequency of Y-deletions is found in azoospermic men (8-12%), followed by oligozoospermic (3-7%) men [1593, 1594].
• Deletions are extremely rare with a sperm concentration > 5 million/mL (~0.7%) [1595].
• AZFc deletions are most common (65-70%), followed by Y-deletions of the AZFb and AZFb+c or AZFα+b+c regions (25-30%). AZFa region deletions are rare (5%) [1596].
• Complete deletion of the AZFa region is associated with severe testicular phenotype (Sertoli cell only syndrome), while complete deletions of the AZFb region is associated with spermatogenic arrest. Complete deletions that include the AZFa and AZFb regions are of poor prognostic significance for retrieving sperm at the time of TESE and sperm is not found in these patients. Therefore, TESE should not be attempted in these patients [1597, 1598].
• Deletions of the AZFc region causes a variable phenotype ranging from azoospermia to oligozoospermia.
• Sperm can be found in 50-75% of men with AZFc microdeletions [1597-1599].
• Men with AZFc microdeletions who are oligo-zoospermic or in whom sperm is found at the time of TESE must be counselled that any male offspring will inherit the deletion.
• Classic (complete) AZF deletions do not confer a risk for cryptorchidism or testicular cancer [1595, 1600].

The specificity and genotype/phenotype correlation reported above means that Y-deletion analysis has both a diagnostic and prognostic value for testicular sperm retrieval [1600].

10.3.5.3.1.1 Testing for Y microdeletions
Historically, indications for AZF deletion screening are based on sperm count and include azoospermia and severe oligozoospermia (spermatozoa count < 5 million/mL). A recent meta-analysis assessing the prevalence of microdeletions on the Y chromosome in oligo-zoospermic men in 37 European and North American studies (n = 12,492 oligo-zoospermic men) showed that the majority of microdeletions occurred in men with sperm concentrations ≤ 1 million sperm/mL, with < 1% identified in men with > 1 million sperm/mL [1595]. In this context, while an absolute threshold for clinical testing cannot be universally given, patients may be offered testing if sperm counts are < 5 million sperm/mL, but must be tested if ≤1 million sperm/mL.

With the efforts of the European Academy of Andrology (EAA) guidelines and the European Molecular Genetics Quality Network external quality control programme (http://www.emqn.org/emqn/), Yq testing has become more reliable in different routine genetic laboratories. The EAA guidelines provide a set of primers capable of detecting > 95% of clinically relevant deletions [1601].

10.3.5.3.1.2 Genetic counselling for AZF deletions
After conception, any Y-deletions are transmitted to the male offspring, and genetic counselling is therefore mandatory. In most cases, father and son will have the same microdeletion [1601], but occasionally the son may have a more extensive deletion [1602]. The extent of spermatogenic failure (still in the range of azoos-/oligo-zoospermia) cannot be predicted entirely in the son, due to the different genetic background and the presence or absence of environmental factors with potential toxicity on reproductive function. A significant proportion of spermatozoa from men with complete AZFc deletion are nullisomic for sex chromosomes [1603, 1604], indicating a potential risk for any offspring to develop 45,X0 Turner’s syndrome and other phenotypic anomalies associated with sex chromosome mosaicism, including ambiguous genitalia [1605]. Despite this theoretical risk, babies born from fathers affected by Yq microdeletions are phenotypically normal [1600, 1601]. This could be due to the reduced implantation rate and a likely higher risk of spontaneous abortion of embryos bearing a 45,X0 karyotype.

10.3.5.3.1.3 Y-chromosome: ‘gr/gr’ deletion
A new type of Yq deletion, known as the gr/gr deletion, has been described in the AZFc region [1606]. This deletion removes half of the gene content of the AZFc region, affecting the dosage of multicy copy genes mapping inside this region. This type of deletion confers a 2.5-8 fold increased risk for oligozoospermia [1601, 1607-1609]. The frequency of gr/gr deletion in oligozoospermic patients is ~5% [1610].

According to four meta-analyses, gr/gr deletion is a significant risk factor for impaired sperm production [1608-1610]. It is worth noting that both the frequency of gr/gr deletion and its phenotypic expression vary among different ethnic groups, depending on the Y-chromosome background. For example, in some Y haplo-groups, the deletion is fixed and appears to have no negative effect on spermatogenesis. Consequently, the routine screening for gr/gr deletion is still a debated issue, especially in those laboratories serving diverse ethnic and geographic populations. A large multi-centre study has shown that gr/gr deletion is a potential risk factor for testicular germ cell tumours [1581]. However, these data need confirmation in an ethnically and geographically matched case-control study setting. For genetic counselling it is worth noting that partial AZFc deletions, gr/gr and b2/b3, may predispose to complete AZFc deletion in the next generation [1611].
10.3.5.3.1.4 Autosomal defects with severe phenotypic abnormalities and infertility

Several inherited disorders are associated with severe or considerable generalised abnormalities and infertility (e.g., Prader-Willi syndrome [1612], Bardet-Biedl syndrome [1613], Noonan’s syndrome, Myotonic dystrophy, dominant polycystic kidney disease [1614, 1615], and 5α-reductase deficiency [1616-1619], etc.) Pre-implantation genetic screening may be necessary in order to improve the ART outcomes among men with autosomal chromosomal defects [1620, 1621].

10.3.5.4 Sperm chromosomal abnormalities

Sperm can be examined for their chromosomal constitution using FISH both in men with normal karyotype and with anomalies. Aneuploidy in sperm, particularly sex chromosome aneuploidy, is associated with severe damage to spermatogenesis [1543, 1622-1624] and with translocations and may lead to recurrent pregnancy loss (RPL) or recurrent implantation failure [1625]. In a large retrospective series, couples with normal sperm FISH had similar outcomes from IVF and ICSI on pre-implantation genetic screening (PGS). However, couples with abnormal FISH had better clinical outcomes after PGS, suggesting a potential contribution of sperm to aneuploidic abnormalities in the embryo [1626]. In men with sperm aneuploidy, PGS combined with IVF and ICSI can increase chances of live births [1542].

10.3.5.5 Measurement of Oxidative Stress

Oxidative stress is considered to be central in male infertility by affecting sperm quality, function, as well as the integrity of sperm [1627]. Oxidative stress may lead to sperm DNA damage and poorer DNA integrity, which are associated with poor embryo development, miscarriage and infertility [1628, 1629]. Spermatozoa are vulnerable to oxidative stress and have limited capacity to repair damaged DNA. Oxidative stress is generally associated with poor lifestyle (e.g., smoking) and environmental exposure, and therefore antioxidant regimens and lifestyle interventions may reduce the risk of DNA fragmentation and improve sperm quality [1630]. However, these data have not been supported by RCTs. Furthermore, there are no standardised testing methods for ROS and the duration of antioxidant treatments. Although ROS can be measured by various assays (e.g., chemiluminescence), routine measurement of ROS testing should remain experimental until these tests are validated in RCTs [1631].

10.3.5.6 Outcomes from assisted reproductive technology and long-term health implications to the male and offspring

It is estimated that > 4 million babies have been born with ART since the first baby was conceived by IVF in 1978 [1632]. As the number of couples undergoing ART has increased [1633, 1634], safety concerns related to ART have been raised. Assisted reproductive technology-conceived offspring have poorer prenatal outcomes, such as lower birth weight, lower gestational age, premature delivery, and higher hospital admissions compared with naturally conceived offspring [1635, 1636]. However, the exact mechanisms resulting in these complications remain obscure. Birth defects have also been associated with children conceived via ART [1637-1639]. Meta-analyses have shown a 30-40% increase in major malformations linked with ART [1640-1642]. However, debate continues as to whether the increased risk of birth defects are related to parental age, ART or the intrinsic defects in spermatogenesis in infertile men [1643-1648].

As for the long-term outcomes, post-natal growth patterns are mostly not associated with ART [1637, 1649, 1650]. However, a number of studies have shown that ART children are taller [1651, 1652]. This may be important as there is evidence showing that rapid weight gain during early childhood is linked with higher blood pressure levels in children conceived via ART [1653]. It is also suggested that ART-conceived children have similar childhood illnesses and hospital services rates as compared with naturally conceived children [1654-1656]. Some studies have shown an increased risk of retinoblastoma [1657] and hepatoblastoma in children after ART. However, these studies have been challenged with other studies that have not supported these findings [1658]. The current evidence for cancer risk in children conceived with ART is inadequate and further studies are warranted [1659, 1660]. Finally, several epigenetic alterations seem to be caused by ART, which might be the molecular basis to some complex traits and diseases [1661].

10.3.6 Imaging in infertile men

In addition to physical examination, a scrotal US may be helpful in: (i) measuring testicular volume; (ii) assessing testicular anatomy and structure in terms of US patterns, thus detecting signs of testicular dysgenesis often related to impaired spermatogenesis (e.g., non-homogeneous testicular architecture and microcalcifications) and testicular tumours; and, (iii) finding indirect signs of obstruction (e.g., dilatation of rete testis, enlarged epididymis with cystic lesions, or absent vas deferens) [1516]. In clinical practice, Prader’s orchidometer-derived testicular volume is considered a reliable surrogate of US-measured testicular volume, easier to perform and cost-effective [1515]. Nevertheless, scrotal US has a relevant role in testicular volume
assessment when Prader’s orchidometer is unreliable (e.g., large hydrocele, inguinal testis, epididymal enlargement/fibrosis, thickened scrotal skin; small testis, where the epididymis is large in comparison to the total testicular volume [1515, 1516]). Ultrasound-patterns of testicular inhomogeneity [1662, 1663] is usually associated with ageing, although it has also been reported in association with testicular atrophy and fibrosis [1516]. At present, a diagnostic testicular biopsy is not recommended when testicular inhomogeneity is detected [1662, 1663].

10.3.6.1 Scrotal US
Scrotal US is widely used in everyday clinical practice in patients with oligo-zoospermia or azoospermia, as infertility has been found to be an additional risk factor for testicular cancer [1664, 1665]. It can be used in the diagnosis of several diseases causing infertility including testicular neoplasms and varicocele.

10.3.6.1.1 Testicular neoplasms
In one study, men with infertility had an increased risk of testicular cancer (hazard ratio [HR] 3.3). When infertility was refined according to individual semen parameters, oligo-zoospermic men had an increased risk of cancer compared with fertile control subjects (HR 11.9) [1666]. In a recent systematic review infertile men with testicular microcalcification (TM) were found to have a ~18-fold higher prevalence of testicular cancer [1667]. However, the utility of US as a routine screening tool in men with infertility to detect testicular cancer remains a matter of debate [1664, 1665].

One issue in undertaking routine screening for testicular neoplasms in this cohort of patients is the risk of overdiagnosis and the increased detection of indeterminate lesions of the testis. These testicular lesions are often detected during the diagnostic work-up of infertile men and are difficult to characterise as benign or malignant based only upon US criteria, including size, vascularity and echogenicity.

A dichotomous cut-off of certainty in terms of lesion size that may definitely distinguish benign from malignant testicular masses is currently not available. However, in a study with 81 patients with a lesion size < 10 mm, on histology showed that 56 (69%) were benign lesions, although one-third were malignant. All lesions < 5 mm in diameter were benign [1668]. Available data suggest that the smaller the lesion, the less likely that it is malignant [1669], and lesions < 5 mm could be monitored, as they have a low probability of malignancy.

Small hypoechoic/hyperechoic areas may be diagnosed as intra-testicular cysts, focal Leydig cell hyperplasia, fibrosis and focal testicular inhomogeneity after previous pathological conditions. Hence, they require careful periodic US assessment and follow-up, especially if additional risk factors for malignancy are present (i.e., infertility, bilateral TM, history of cryptorchidism, testicular atrophy, inhomogeneous parenchyma, history of testicular tumour, history of/contralateral tumour) [1516].

In the case of interval growth of a lesion and/or the presence of additional risk factors for malignancy, testicular biopsy/surgery may be considered, although the evidence for adopting such a management policy is limited. In 145 men referred for azoospermia who underwent US before testicular biopsy, 49 (34%) had a focal sonographic abnormality; a hypoechoic lesion was found in 20 patients (14%), hyperechoic lesions were seen in 10 patients (7%); and, a heterogeneous appearance of the testicular parenchyma was seen in 19 patients (13%). Of 18 evaluable patients, 11 had lesions < 5 mm; all of which were confirmed to be benign. All other patients with hyperechoic or heterogeneous areas on US with subsequent tissue diagnoses were found to have benign lesions. The authors concluded that men with severe infertility who have incidental testicular lesions, negative tumour markers and lesions < 5 mm may be observed with serial scrotal US examinations and enlarging lesions or those of greater dimension can be considered for histological biopsy [1670].

Other studies have suggested that if a testicular lesion is hyperechoic and non-vascular on colour Doppler US and associated with negative tumour markers, the likelihood of malignancy is low and consideration can be given to regular testicular surveillance, as an alternative to radical surgery. In contrast, hypoechoic and vascular lesions are more likely to be malignant [1671-1675]. However, most lesions cannot be characterised by US (indeterminate), and histology remains the only certain diagnostic tool. A multidisciplinary team discussion (MDT), including invasive diagnostic modalities, should therefore be considered in these patients.

The role of US-guided intra-operative frozen section analysis in the diagnosis of testicular cancer in indeterminate lesions remains controversial, although several authors have proposed its value in the intra-operative diagnosis of indeterminate testicular lesions [1676]. Although the default treatment after patient counselling and MDT discussion may be radical orchidectomy, an US-guided biopsy with intra-operative frozen section analysis may be offered as an alternative to radical orchidectomy and potentially obviate the
need for removal of the testis in a patient seeking fertility treatment or is hypogonadal. In men who have severe abnormalities in semen parameters (e.g., azoospermia), a concurrent mTESE can also be performed at the time of diagnostic biopsy.

In summary, if an indeterminate lesion is detected incidentally on US in an infertile man, MDT discussion is highly recommended. Based upon the current literature, lesions < 5mm in size are likely to be benign and serial US and self-examination can be performed. However, men with larger sized lesions (> 5mm), which are hypoechoic or demonstrate vascularity, may be considered for open US-guided testicular biopsy, testis sparing surgery with tumour enucleation for frozen section examination or radical orchidectomy. Therefore, in making a definitive treatment decision for surveillance vs. intervention, consideration should be given to the size of the lesion, echogenicity, vascularity and previous history (e.g., cryptorchidism, previous history of germ cell tumour [GCT]). If intervention is to be undertaken in men with severe hypospermatogenesis (e.g., azoospermia), then a simultaneous TESE can be undertaken, along with sperm banking.

10.3.6.1.2 Varicocele
At present, the clinical management of varicocele is still mainly based on physical examination; nevertheless, scrotal colour Doppler US is useful in assessing venous reflux and diameter, when palpation is unreliable and/or in detecting recurrence/persistence after surgery [1516]. Definitive evidence of reflux and venous diameter may be utilised in the decision to treat (see Section 10.4.3.1 and 10.4.3.2).

10.3.6.1.3 Other
Scrotal US is able to detect changes in the proximal part of the seminal tract due to obstruction. Especially for CBAVD patients, scrotal US is a favourable option to detect the abnormal appearance of the epididymis. Given that, three types of epididymal findings are described in CBAVD patients: tubular ectasia (honeycomb appearance), meshwork pattern, and complete or partial absence of the epididymis [1677, 1678].

10.3.6.2 Transrectal US
For patients with a low seminal volume, acidic pH and severe oligozoospermia or azoospermia, in whom obstruction is suspected, scrotal and transrectal US are of clinical value in detecting CBAVD and presence or absence of the epididymis and/or seminal vesicles (SV) (e.g., abnormalities/agenesis). Likewise, transrectal US (TRUS) has an important role in assessing obstructive azoospermia (OA) secondary to CBAVD or anomalies related to the obstruction of the ejaculatory ducts, such as ejaculatory duct cysts, seminal vesicular dilatation or hypoplasia/atrophy, although retrograde ejaculation should be excluded as a differential diagnosis [1516, 1679].

10.3.7 Recommendations for the diagnostic work-up of male infertility

<table>
<thead>
<tr>
<th>Recommendations</th>
<th>Strength rating</th>
</tr>
</thead>
<tbody>
<tr>
<td>Include a parallel assessment of the fertility status, including ovarian reserve, of the female partner during the diagnosis and management of the infertile male, since this might determine decision making in terms of timing and therapeutic strategies (e.g., assisted reproductive technology (ART) versus surgical intervention).</td>
<td>Strong</td>
</tr>
<tr>
<td>A complete medical history, physical examination and semen analysis are the essential components of male infertility evaluation.</td>
<td>Strong</td>
</tr>
<tr>
<td>Prader’s orchidometer-derived testicular volume is a reliable surrogate of ultrasound (US)-measured testicular volume in everyday clinical practice.</td>
<td>Weak</td>
</tr>
<tr>
<td>Perform semen analyses according to the most recent WHO Laboratory Manual for the Examination and Processing of Human Semen (6th edn.) indications and reference criteria or according to the previous version (5th edn.) until a formal and complete adoption of the newly-released parameters will be implemented.</td>
<td>Strong</td>
</tr>
<tr>
<td>Perform a full andrological assessment in all men with couple infertility, particularly when semen analysis is abnormal in at least two consecutive tests.</td>
<td>Strong</td>
</tr>
<tr>
<td>Include counselling for infertile men or men with abnormal semen parameters of the associated health risks.</td>
<td>Weak</td>
</tr>
<tr>
<td>In cases of oligozoospermia and azoospermia, a hormonal evaluation should be performed, including a serum total testosterone and Follicle Stimulating Hormone/Luteinising Hormone.</td>
<td>Weak</td>
</tr>
<tr>
<td>Offer standard karyotype analysis and genetic counselling to all men with azoospermia and oligozoospermia (spermatozoa &lt; 10 million/mL) for diagnostic purposes.</td>
<td>Strong</td>
</tr>
<tr>
<td>Do not test for Y-chromosome microdeletions in men with pure obstructive azoospermia as spermatogenesis will be normal.</td>
<td>Strong</td>
</tr>
</tbody>
</table>
Y-chromosome microdeletion testing may be offered in men with sperm concentrations of < 5 million sperm/mL, but must be mandatory in men with sperm concentrations of < 1 million sperm/mL.

| Strong |

Inform men with Yq microdeletion and their partners who wish to proceed with intracytoplasmic sperm injection (ICSI) that microdeletions will be passed to sons, but not to their daughters.

| Strong |

Testicular sperm extraction (any type) should not be attempted in patients with complete deletions that include the aZFa and aZFc regions, since they are a poor prognostic indicator for retrieving sperm at surgery.

| Strong |

In men with structural abnormalities of the vas deferens (unilateral or bilateral absence with no renal agenesis), test the man and his partner for cystic fibrosis transmembrane conductance regulator gene mutations, which should include common point mutations and the 5T allele.

| Strong |

Provide genetic counselling in all couples with a genetic abnormality found on clinical or genetic investigation and in patients who carry a (potential) inheritable disease.

| Strong |

For men with Klinefelter syndrome, offer long-term endocrine follow-up and appropriate medical treatment.

| Strong |

Do not routinely use reactive oxygen species testing in the diagnosis and management of the male partner of an infertile couple.

| Weak |

Sperm DNA fragmentation testing should be performed in the assessment of couples with recurrent pregnancy loss from natural conception and ART or men with unexplained infertility.

| Strong |

Perform scrotal US in patients with infertility, as there is a higher risk of testis cancer.

| Weak |

A multidisciplinary team discussion concerning invasive diagnostic modalities (e.g., US-guided testicular biopsy with frozen section versus radical orchidectomy versus surveillance) should be considered in infertile men with US-detected indeterminate testicular lesions, especially if additional risk factors for malignancy are present.

| Weak |

Perform transrectal US if a partial or complete distal obstruction is suspected.

| Strong |

Consider imaging for renal abnormalities in men with structural abnormalities of the vas deferens and no evidence of cystic fibrosis transmembrane conductance regulator abnormalities.

| Strong |

### 10.4 Special Conditions and Relevant Clinical Entities

#### 10.4.1 Cryptorchidism

Cryptorchidism is the most common congenital abnormality of the male genitalia; at 1 year of age nearly 1% of all full-term male infants have cryptorchidism [1680]. Approximately 30% of undescended testes are non-palpable and may be located within the abdominal cavity. These guidelines will only deal with management of cryptorchidism in adults.

#### 10.4.1.1 Classification

The classification of cryptorchidism is based on the duration of the condition and the anatomical position of the testes. If the undescended testis has been identified from birth then it is termed congenital while diagnosis of acquired cryptorchidism refers to men that have been previously noted to have testes situated within the scrotum. Cryptorchidism is categorised on whether it is bilateral or unilateral and the location of the testes (inguinal, intra-abdominal or ectopic).

Studies have shown that treatment of congenital and acquired cryptorchidism results in similar hormonal profiles, semen analysis and testicular volumes [1681, 1682]. However, testicular volume and hormonal function are reduced in adults treated for congenital bilateral cryptorchidism compared to unilateral cryptorchidism [1683].

#### 10.4.1.1.1 Aetiology and pathophysiology

It has been postulated that cryptorchidism may be a part of the so-called testicular dysgenesis syndrome (TDS), which is a developmental disorder of the gonads caused by environmental and/or genetic influences early in pregnancy, including exposure to endocrine disrupting chemicals. Besides cryptorchidism, TDS includes hypospadias, reduced fertility, increased risk of malignancy, and Leydig/Sertoli cell dysfunction [1684]. Cryptorchidism has also been linked with maternal gestational smoking [1685] and premature birth [1686].
10.4.1.1.2 Pathophysiological effects in maldescended testes

10.4.1.1.2.1 Degeneration of germ cells

The degeneration of germ cells in maldescended testes is apparent even after the first year of life and varies, depending on the position of the testes [1687]. During the second year, the number of germ cells declines. Early treatment is therefore recommended (surgery should be performed within the subsequent year) to conserve spermatogenesis and hormone production, as well as to decrease the risk for tumours [1688]. Surgical treatment is the most effective. Meta-analyses on the use of medical treatment with GnRH and hCG have demonstrated poor success rates [1689, 1690]. It has been reported that hCG treatment may be harmful to future spermatogenesis; therefore, the Nordic Consensus Statement on treatment of undescended testes does not recommend it use on a routine basis [1691]. See also the EAU Guidelines on Paediatric Urology [1692].

There is increasing evidence to suggest that in unilateral undescended testis, the contralateral normal descended testis may also have structural abnormalities, including smaller volume, softer consistency and reduced markers of future fertility potential (spermatogonia/tubule ratio and dark spermatogonia) [1681, 1693]. This implies that unilateral cryptorchidism may affect the contralateral testis and patients and parents should be counselled appropriately.

10.4.1.1.2.2 Relationship with fertility

Semen parameters are often impaired in men with a history of cryptorchidism [1694]. Early surgical treatment may have a positive effect on subsequent fertility [1695]. In men with a history of unilateral cryptorchidism, paternity is almost equal (89.7%) to that in men without cryptorchidism (93.7%). In men with bilateral cryptorchidism, oligozoospermia can be found in 31% and azoospermia in 42%. In cases of bilateral cryptorchidism, the rate of paternity falls to 35-53% [1696]. It is also important to screen for hypogonadism, as this is a potential long-term sequelae of cryptorchidism and could contribute to impaired fertility and potential problems such as testosterone deficiency and MetS [1697].

10.4.1.1.2.3 Germ cell tumours

As a component of TDS, cryptorchidism is a risk factor for testicular cancer and is associated with testicular microcalcifications and intratubular germ cell neoplasia in situ (GCNIS), formerly known as carcinoma in situ (CIS) of the testes. In 5-10% of testicular cancers, there is a history of cryptorchidism [1698]. The risk of a germ cell tumour is 3.6-7.4 times higher than in the general population and 2-6% of men with a history of cryptorchidism will develop a testicular tumour [1680]. Orchidopexy performed before the onset of puberty has been reported to decrease the risk of testicular cancer [1699]. However, there is evidence to suggest that even men who undergo early orchidopexy still harbour a higher risk of testicular cancer than men without cryptorchidism [1700]. Therefore all men with a history of cryptorchidism should be warned that they are at increased risk of developing testicular cancer and should perform regular testicular self-examination [1701]. There is also observational study data suggesting that cryptorchidism may be a risk factor for worsening clinical stage of seminoma but this needs to be substantiated with future prospective studies [1702].

10.4.1.2 Disease management

10.4.1.2.1 Hormonal treatment

Human chorionic gonadotropin or GnRH is not recommended for the treatment of cryptorchidism in adulthood. Although some studies have recommended the use of hormonal stimulation as an adjunct to orchidopexy to improve fertility preservation, there is a lack of long-term data and concerns regarding impairment to spermatogenesis with the use of these drugs [1703].

10.4.1.2.2 Surgical treatment

In adolescence, removal of an intra-abdominal testis (with a normal contralateral testis) can be recommended, because of the risk of malignancy [1704]. In adults, with a palpable undescended testis and a normal functioning contralateral testis (i.e., biochemically eugonadal), an orchidectomy may be offered as there is evidence that the undescended testis confers a higher risk of GCNIS and future development of GCT [1705] and regular testicular self-examination is not an option in these patients. In patients with unilateral undescended testes (UDT) and impaired testicular function on the contralateral testis as demonstrated by biochemical hypogonadism and/or impaired sperm production (infertility), an orchidectomy may be offered to preserve androgen production and fertility. However, based on Panel consensus multiple biopsies of the UDT are recommended at the time of orchidectomy to exclude intra-testicular GCNIS as a prognostic indicator of future development of GCT. As indicated above, the correction of bilateral cryptorchidism, even in adulthood, can lead to sperm production in previously azoospermic men and therefore may be considered in these patients or in patients who place a high value on fertility preservation [1706]. Vascular damage is
the most severe complication of orchidopexy and can cause testicular atrophy in 1-2% of cases. In men with non-palpable testes, the post-operative atrophy rate was 12% in cases with long vascular pedicles that enabled scrotal positioning. Post-operative atrophy in staged orchidopexy has been reported in up to 40% of patients [1707]. At the time of orchidectomy in the treatment of GCT, biopsy of the contralateral testis should be offered to patients at high risk for GCNIS (i.e., history of cryptorchidism, < 12 mL testicular volume, poor spermatogenesis [1708]).

10.4.2 Germ cell malignancy and male infertility

Testicular germ cell tumour (TGCT) is the most common malignancy in Caucasian men aged 15-40 years, and affects approximately 1% of sub-fertile men [1709]. The lifetime risk of TGCT varies among ethnic groups and countries. The highest annual incidence of TGCT occurs in Caucasians, and varies from 10/100,000 (e.g., in Denmark and Norway) to 2/100,000 (e.g., in Finland and the Baltic countries). Generally, seminomas and non-seminomas are preceded by GCNIS, and untreated GCNIS eventually progresses to invasive cancer [1710-1712]. There has been a general decline in male reproductive health and an increase in testicular cancer in western countries [1713, 1714]. In almost all countries with reliable cancer registries, the incidence of testicular cancer has increased [1600, 1715]. This has been postulated to be related to TDS, which is a developmental disorder of the testes caused by environmental and/or genetic influences in pregnancy. As detailed above, the adverse sequelae of TDS include cryptorchidism, hypospadias, infertility and an increased risk of testicular cancer [1684]. Endocrine disrupting chemicals have also been associated with sexual dysfunction [1716] and abnormal semen parameters [1717]. These cancers arise from premalignant gonocytes or GCNIS [1718]. Testicular microcalcification, seen on US, can be associated with TGCT and GCNIS of the testes [1667, 1719, 1720].

10.4.2.1 Testicular germ cell cancer and reproductive function

Sperm cryopreservation is considered standard practice in patients with cancer overall, and not only in those with testicular cancer [1721, 1722]. As such, it is important to stress that all men with cancer must be offered sperm cryopreservation prior to the therapeutic use of gonadotoxic agents or ablative surgery that may impair spermatogenesis or ejaculation (i.e., chemotherapy, radiotherapy or retroperitoneal surgery).

Men with TGCT have decreased semen quality, even before cancer treatment. Azoospermia has been observed in 5-8% of men with TGCT [1723] and oligospermia in 50% [1724]. Given that the average 10-year survival rate for testicular cancer is 98% and it is the most common cancer in men of reproductive potential, it is mandatory to include counselling regarding fertility preservation prior to any gonadotoxic treatment [1724, 1725]. Semen analysis and cryopreservation are therefore recommended prior to any gonadotoxic cancer treatment and all patients should be offered cryopreservation of ejaculated sperm or sperm extracted surgically (e.g., c/mTESE) if shown to be azoospermic or severely oligozoospermic. Given that a significant number of men with testicular cancer at the time of first presentation have severe semen abnormalities (i.e., severe...
oligozoospermia/azoospermia) even prior to any treatment [1718], it is recommended that men should undergo sperm cryopreservation prior to orchidectomy. As mentioned above, in those who are either azoospermic or severely oligo-zoospermic this will allow an opportunity to perform TESE prior to further potential gonadotoxic/ablative surgery [1724]. The use of cryopreservation has been demonstrated to be the most cost effective strategy for fertility preservation in patients undergoing potential gonadotoxic treatments [1726, 1727]. In cases of azoospermia, testicular sperm may be recovered to safeguard patient's fertility (onco-TESE) potential. The surgical principles in onco-TESE do not differ from the technique of mTESE for men with infertility (e.g., NOA) [1728, 1729]. In this context, referral to a urologist adept in microsurgery is desirable with facilities for sperm cryopreservation.

Rates of under-utilisation of semen analysis and sperm cryopreservation have been reported to be high; resulting in the failure to identify azoospermic or severely oligo-zoospermic patients at diagnosis who may eventually benefit from fertility-preserving procedures (e.g., onco-mTESE at the time of orchidectomy). Therefore, counselling about fertility preservation is a priority and needs to be broached earlier in men with testicular cancer [1724]. There are controversial arguments that performing cryopreservation prior to orchidectomy may delay subsequent treatment and have an adverse impact on survival. In this context, orchidectomy should not be unduly delayed if there are no facilities for cryopreservation or there is a potential delay in treatment.

Treatment of TGCT can result in additional impairment of semen quality [1730] and increased sperm aneuploidy up to two years following gonadotoxic therapy [1731]. Chemotherapy is also associated with DNA damage and an increased DNA fragmentation rate [1732]. However, sperm aneuploidy levels often decline to pre-treatment levels 18-24 months after treatment [1731]. Several studies reviewing the offspring of cancer survivors have not shown a significant increased risk of genetic abnormalities in the context of chemotherapy and radiotherapy [1733].

In addition to spermatogenic failure, patients with TGCT have Leydig cell dysfunction, even in the contralateral testis [1734]. The risk of hypogonadism may therefore be increased in men treated for TGCT. The measurement of pre-treatment levels of testosterone, SHBG, LH and oestradiol may help to stratify those patients at increased risk of hypogonadism and provide a baseline for post-treatment hypogonadism. Men who have had TGCT and have low normal androgen levels should be advised that they may be at increased risk of developing hypogonadism, as a result of an age-related decrease in testosterone production and could potentially develop MetS; there are no current long-term data supporting this. The risk of hypogonadism is increased in the survivors of testicular cancer and serum testosterone levels should be evaluated during the management of these patients [1735]. However, this risk is greatest at 6-12 months post-treatment and suggests that there may be some improvement in Leydig cell function after treatment. Therefore it is reasonable to delay initiation of testosterone therapy, until the patient shows continuous signs or symptoms of testosterone deficiency [1710]. The risk of low libido and ED is also increased in TGCT patients [1736]. Patients treated for TGCT are also at increased risk of CVD [1732]. Therefore, patients may require a multi-disciplinary therapy approach and, in this context, survivorship programmes incorporating a holistic view of patients considering psychological, medical and social needs could be beneficial. In patients who place a high value on fertility potential, the use of testosterone therapy in men with symptoms suggestive for TDS needs to be balanced with worsening spermatogenesis. In these patients consideration can be given to the use of selective oestrogen receptor modulators (SERMs; e.g., clomiphene) or gonadotrophin analogues (e.g., hCG), although these are off-label treatments in this particular clinical setting.

10.4.2.2 Testicular microcalcification (TM)

Microcalcification inside the testicular parenchyma can be found in 0.6-9% of men referred for testicular US [1737, 1738]. Although the true incidence of TM in the general population is unknown, it is most probably rare. Ultrasound findings of TM have been seen in men with TGCT, cryptorchidism, infertility, testicular torsion and atrophy, Klinefelter syndrome, hypogonadism, male pseudohemaphroditism and varicocele [1685]. The incidence reported seems to be with high-frequency US machines [1739]. The relationship between TM and infertility is unclear, but may relate to testicular dysgenesis, with degenerate cells being sloughed inside an obstructed seminiferous tubule and failure of the Sertoli cells to phagocytose the debris. Subsequently, calcification with hydroxyapatite occurs. Testicular microcalcification is found in testes at risk of malignant development, with a reported incidence of TM in men with TGCT of 6-46% [1740-1742]. A recent systematic review and meta-analysis of case-control studies indicated that the presence of TM is associated with a ~18-fold higher odds ratio for testicular cancer in infertile men (pooled OR: 18.11, 95% CI: 8.09, 40.55; p < 0.0001) [1667].
Testicular microcalcification should therefore be considered pre-malignant in this setting and patients counselled accordingly. Testicular biopsies from men with TM have found a higher prevalence of GCNIS, especially in those with bilateral microcalcifications [1743]. However, TM can also occur in benign testicular conditions and the microcalcification itself is not malignant. Therefore, the association of TM and TGCT is controversial and the challenge is to identify those men at risk of harbouring GCNIS and future risk of TGCT. Further investigation of the association between TM and GCNIS requires testicular biopsies in large series of men without signs of TGCT with or without risk factors for TGCT. However, clinicians and patients should be reassured that testicular cancer does not develop in most men with asymptomatic TM [1720]. Available data indicate that only men in whom TM is found by US, and who have an increased risk of TGCT, should be offered testicular biopsy to exclude GCNIS. Men potentially at high-risk of harbouring or developing GCNIS include those with infertility, atrophic testes, descended testes, history of TGCT, and contralateral TM and it has been suggested that men with these risk factors could be offered testicular biopsy [1714, 1719]. The normal mean testicular volume is estimated to be 12-30 mL and < 12 mL is considered small [1737]. Patients with a history of TGCT and TM in the contralateral testis and sub-fertile patients have been demonstrated to have an increased risk of GCNIS [1720], while there are only a few studies showing a further increase in GCNIS with TM in the context of cryptorchidism [1714, 1738, 1744]. A useful algorithm has been proposed [1714] to stratifying those patients at increased risk of GCNIS who may benefit from testicular biopsy. However, when undertaking a biopsy in this setting, the full risks and complications of adopting this strategy must be explained to the patient. With the lack of availability of large cohort studies, these recommendations must be treated with caution given the risk of overtreatment (i.e., biopsy) in these patients.

Decastro et al. [1745] suggested that testicular cancer would not develop in most men with TM (98.4%) during a 5-year follow-up. As such, an extensive screening programme would only benefit men at significant risk. In this context it would be prudent to advise patients with TM and risk factors for testicular cancer to at least undergo regular testicular examination. It has been suggested that these patients could also be offered annual physical examination by a urologist and US follow-up, although follow-up protocols may be difficult to implement in this invariably young cohort of patients [1685]. As testicular atrophy and infertility have an association with testicular cancer, some authors recommend biopsy or follow-up US if TM is seen [1714]. However, most patients who are azoospermic will be undergoing therapeutic biopsy (i.e., with the specific purpose of sperm retrieval) and therefore a definitive diagnosis can be made and there is a lack of evidence demonstrating a higher prevalence of testicular cancer in patients with both TM and testicular atrophy. In patients with incidental TM, the risk of GCNIS is low and a logical approach is to instruct patients to perform regular testicular self-examination.

### 10.4.2.3 Recommendations for germ cell malignancy and testicular microcalcification

<table>
<thead>
<tr>
<th>Recommendations</th>
<th>Strength rating</th>
</tr>
</thead>
<tbody>
<tr>
<td>Men with testicular microcalcification (TM) should learn to perform self-examination even without additional risk factors, as this may result in early detection of testicular germ cell tumour (TGCT).</td>
<td>Weak</td>
</tr>
<tr>
<td>Do not perform testicular biopsy, follow-up scrotal ultrasound (US), measure biochemical tumour markers, or abdominal or pelvic computed tomography, in men with isolated TM without associated risk factors (e.g., infertility, cryptorchidism, testicular cancer, and atrophic testis).</td>
<td>Strong</td>
</tr>
<tr>
<td>Testicular biopsy may be offered in infertile men with TM, who belong to one of the following higher risk groups: spermatogenic failure (infertility), bilateral TM, atrophic testes (&lt; 12 mL), history of descended testes and TGCT.</td>
<td>Weak</td>
</tr>
<tr>
<td>If there are suspicious findings on physical examination or US in patients with TM with associated lesions, perform inguinal surgical exploration with testicular biopsy or offer orchidectomy after multi-disciplinary meeting and discussion with the patient.</td>
<td>Strong</td>
</tr>
<tr>
<td>Men treated for TGCT are at increased risk of developing hypogonadism, sexual dysfunction and cardiovascular risk. Men should be managed in a multi-disciplinary setting with a dedicated late-effects clinic.</td>
<td>Weak</td>
</tr>
<tr>
<td>Sperm cryopreservation should be performed prior to planned orchidectomy, since men with testis cancer may have significant semen abnormalities (including azoospermia).</td>
<td>Weak</td>
</tr>
<tr>
<td>Men with testicular cancer and azoospermia or severe abnormalities in their semen parameters may be offered onco-testicular sperm extraction (onco-TESE) at the time of radical orchidectomy.</td>
<td>Weak</td>

10.4.3 **Varicocele**
Varicocele is a common congenital abnormality, that may be associated with the following andrological conditions:
- male sub-fertility;
- failure of ipsilateral testicular growth and development;
- symptoms of pain and discomfort;
- hypogonadism.

10.4.3.1 **Classification**
The following classification of varicocele [1497] is useful in clinical practice:
- Subclinical: not palpable or visible at rest or during Valsalva manoeuvre, but can be shown by special tests (Doppler US).
- Grade 1: palpable during Valsalva manoeuvre.
- Grade 2: palpable at rest.
- Grade 3: visible and palpable at rest.

Overall, the prevalence of varicocele in one study was 48%. Of 224 patients, 104 had unilateral and 120 had bilateral varicocele; 62 (13.30%) were grade 3, 99 (21.10%) were grade 2, and 63 (13.60%) were grade 1 [1746]. Worsening semen parameters are associated with a higher grade of varicocele and age [1747, 1748].

10.4.3.2 **Diagnostic evaluation**
The diagnosis of varicocele is made by physical examination and Scrotal Doppler US is indicated if physical examination is inconclusive or semen analysis remains unsatisfactory after varicocele repair to identify persistent and recurrent varicocele [1497, 1749]. A maximum venous diameter of > 3 mm in the upright position and during the Valsalva manoeuvre and venous reflux with a duration > 2 seconds correlate with the presence of a clinically significant varicocele [1750, 1751]. To calculate testicular volume Lambert's formula \((V=L \times W \times H \times 0.71)\) should be used, as it correlates well with testicular function in patients with infertility and/or varicocele [1752]. Patients with isolated, clinical right varicocele should be examined further for abdominal, retroperitoneal and congenital pathology and anomalies.

10.4.3.3 **Basic considerations**
10.4.3.3.1 Varicocele and fertility
Varicocele is present in almost 15% of the normal male population, in 25% of men with abnormal semen analysis and in 35-40% of men presenting with infertility [1497, 1747, 1753, 1754]. The incidence of varicocele among men with primary infertility is estimated at 35–44%, whereas the incidence in men with secondary infertility is 45–81% [1497, 1754].

The exact association between reduced male fertility and varicocele is unknown. Increased scrotal temperature, hypoxia and reflux of toxic metabolites can cause testicular dysfunction and infertility due to increased overall survival and DNA damage [1754].

A meta-analysis showed that improvements in semen parameters are usually observed after surgical correction in men with abnormal parameters [1755]. Varicocelectomy can also reverse sperm DNA damage and improve OS levels [1753, 1754].

10.4.3.3.2 Varicocelectomy
Varicocele repair has been a subject of debate for several decades. A meta-analysis of RCTs and observational studies in men with only clinical varicoceles has shown that surgical varicocelectomy significantly improves semen parameters in men with abnormal semen parameters, including men with NOA with hypo-spermatogenesis or late maturation (spermatid) arrest on testicular pathology [1753, 1756-1759]. Pain resolution after varicocelectomy occurs in 48-90% of patients [1760]. A recent systematic review has shown greater improvement in higher-grade varicoceles and this should be taken into account during patient counselling [1761].

In RCTs, varicocele repair in men with a subclinical varicocele was ineffective at increasing the chances of spontaneous pregnancy [1762]. Also, in randomised studies that included mainly men with normal semen parameters no benefit was found to favour treatment over observation. A Cochrane review from 2012 concluded that there is evidence to suggest that treatment of a varicocele in men from couples with otherwise unexplained subfertility may improve a couple's chance of spontaneous pregnancy [1763]. Two recent meta-analyses of RCTs comparing treatment to observation in men with a clinical varicocele, oligozoospermia and
otherwise unexplained infertility, favoured treatment, with a combined OR of 2.39-4.15 (95% CI: 1.56-3.66 and 95% CI: 2.31-7.45, respectively) [1759, 1763]. Average time to improvement in semen parameters is up to two spermatogenic cycles [1764, 1765] with spontaneous pregnancy occurring between 6 and 12 months after varicocelectomy [1766, 1767]. A further meta-analysis has reported that varicocelectomy may improve outcomes following ART in oligozoospermic men with an OR of 1.69 (95% CI: 0.95-3.02) [1768].

10.4.3.3.3 Prophylactic varicocelectomy

In adolescents with a varicocele, there is a significant risk of over-treatment because most adolescents with a varicocele have no problem achieving pregnancy later in life [1769]. Prophylactic treatment is only advised in case of documented testicular growth deterioration confirmed by serial clinical or Doppler US examinations and/or abnormal semen analysis [1770, 1771].

More novel considerations for varicocelectomy in patients with NOA, hypogonadism and DNA damage are described below:

Varicocelectomy and NOA

Several studies have suggested that varicocelectomy may lead to sperm appearing in the ejaculate in men with azoospermia. In one such study, microsurgical varicocelectomy in men with NOA led to sperm in the ejaculate post-operatively with an increase in ensuing natural or assisted pregnancies [1772]. There were further beneficial effects on sperm retrieval rates (SRRs) and ICSI outcomes. Meta-analyses have further corroborated these findings; 468 patients diagnosed with NOA and varicocele underwent surgical varicocele repair or percutaneous embolisation. In patients who underwent varicocelectomy, SRRs increased compared to those without varicocele repair (OR: 2.65; 95% CI: 1.69-4.14; p < 0.001). In 43.9% of the patients (range: 20.8%-55.0%), sperm were found in post-operative ejaculate. These findings indicate that varicocelectomy in patients with NOA and clinical varicocele is associated with improved SRR, and overall, 44% of the treated men have sperm in the ejaculate and may avoid sperm retrieval. However, the quality of evidence available is low and the risks and benefits of varicocele repair must be discussed fully with the patient with NOA and a clinically significant varicocele prior to embarking upon treatment intervention [1757]. This must necessarily take into consideration the infertile couple together, especially considering the time needed for a possible SRR and the baseline characteristics of the female partner (i.e., age, medical history, anti-Müllerian hormone (AMH) levels = good ovarian reserve, etc.).

Varicocelectomy and hypogonadism

Evidence also suggests that men with clinical varicoceles who are hypogonadal may benefit from varicocele intervention. One meta-analysis studied the efficacy of varicocele intervention by comparing the pre-operative and post-operative serum testosterone of 712 men. The combined analysis of seven studies demonstrated that the mean post-operative serum testosterone improved by 34.3 ng/dL (95% CI: 22.57-46.04, p < 0.00001, I² = 0%) compared with their pre-operative levels. An analysis of surgery vs. untreated control results showed that mean testosterone among hypogonadic patients increased by 105.65 ng/dL (95% CI: 77.99-133.32 ng/dL), favouring varicocelectomy [1773]. However, results must be treated with caution and adequate cost-benefit analysis must be undertaken to determine the risks and benefits of surgical intervention over testosterone therapy in this setting. Although, varicocelectomy may be offered to hypogonadal men with clinically significant varicoceles, patients must be advised that the full benefits of treatment in this setting must be further evaluated with prospective RCTs.

10.4.3.3.4 Varicocelectomy for assisted reproductive technology and raised DNA fragmentation

Varicocelectomy can improve sperm DNA integrity, with a mean difference of -3.37% (95% CI: -2.65% to -4.09%) [1769]. There is now increasing evidence that varicocele treatment may improve DNA fragmentation and outcomes from ART [1768, 1769]. As a consequence, more recently it has been suggested that the indications for varicocele intervention should be expanded to include men with raised DNA fragmentation. If a patient has failed ART (e.g., failure of implantation, embryogenesis or recurrent pregnancy loss) there is an argument that if DNA damage is raised, consideration could be given to varicocele intervention after extensive counselling [1774], and exclusion of other causes of raised DNA fragmentation [1769, 1775]. The dilemma is whether varicocele treatment is indicated in men with raised DNA fragmentation and normal semen parameters.

In a meta-analysis of non-azoospermic infertile men with clinical varicocele by Estevez et al., four retrospective studies were included of men undergoing ICSI, and included 870 cycles (438 subjected to ICSI with prior varicocelectomy, and 432 without prior varicocelectomy). There was a significant increase in the clinical pregnancy rates (OR = 1.59, 95% CI: 1.19-2.12, I² = 25%) and live birth rates (OR = 2.17, 95%
CI: 1.55-3.06, $I^2 = 0\%$) in the varicocelectomy group compared to the group subjected to ICSI without previous varicocelectomy. A further study evaluated the effects of varicocele repair and its impact on pregnancy and live birth rates in infertile couples undergoing ART in male partners with oligo-azoospermia or azoospermia and a varicocele [1768]. In 1,241 patients, a meta-analysis demonstrated that varicocelectomy improved live birth rates for the oligospermic (OR = 1.699) men and combined oligo-azoospermic/azoospermic groups (OR = 1.761). Pregnancy rates were higher in the azoospermic group (OR = 2.336) and combined oligo-azoospermic/azoospermic groups (OR = 1.760). Live birth rates were higher for patients undergoing IUI after intervention (OR = 8.360).

### 10.4.3.4 Disease management

Several treatments are available for varicocele (Table 42). Current evidence indicates that microsurgical varicocelectomy is the most effective among the different varicocelectomy techniques [1769, 1776]. Unfortunately, there are no large prospective RCTs comparing the efficacy of the various interventions for varicocele. However, microsurgical repair results in fewer complications and lower recurrence rates compared to the other techniques based upon case series [1777]: however, this procedure requires microsurgical training. The various other techniques are still considered viable options, although recurrences and hydrocele formation appear to be higher [1778].

Radiological techniques (sclerotherapy and embolisation) are minimally invasive widely used approaches, although higher recurrence rates compared to microscopic varicocelectomy have been reported (4-27%) [1754]. Robot-assisted varicocelectomy has a similar success rate compared to the microscopic varicocelectomy technique, although larger prospective randomised studies are needed to establish the most effective method [1779-1781].

### 10.4.4 Male accessory gland infections and infertility

#### 10.4.4.1 Introduction

Infection of the male urogenital tract is a potentially curable cause of male infertility [1794-1796]. The WHO considers urethritis, prostatitis, orchitis and epididymitis to be male accessory gland infections (MAGIs) [1794]. The effect of symptomatic or asymptomatic infections on sperm quality is contradictory [1797]. A systematic review of the relationship between sexually transmitted infections, such as those caused by Chlamydia trachomatis, genital mycoplasmas, Neisseria gonorrhoeae, Trichomonas vaginalis and viruses, and infertility was unable to draw a strong association between sexually transmitted infections and male infertility due to the limited quality of reported data [1798].
10.4.4.2 Diagnostic evaluation

10.4.4.2.1 Semen analysis

Semen analysis (see Section 10.3.2) clarifies whether the prostate is involved as part of a generalised MAGI and provides information regarding sperm quality. Leukocyte analysis allows differentiation between inflammatory and non-inflammatory chronic pelvic pain syndrome (CP/CPPS) (NIH IIa vs. NIH 3b National Institutes of Health classification for CP/CPPS).

10.4.4.2.2 Microbiological findings

After exclusion of UTI (including urethritis), > 10^6 peroxidase-positive white blood-cells (WBCs) per millilitre of ejaculate indicate an inflammatory process. In these cases, a semen culture or polymerase chain reaction (PCR) analysis should be performed for common urinary tract pathogens. A concentration of > 10^3 CFU/mL urinary tract pathogens in the ejaculate is indicative of significant bacteriospermia [1799]. The sampling should be delivered the same day to the laboratory because the sampling time can influence the rate of positive micro-organisms in semen and the frequency of isolation of different strains [1800]. The ideal diagnostic test for isolating C. trachomatis in semen has not yet been established [1801], but the most accurate method is PCR [1802-1804].

Historical data show that Ureaplasma urealyticum is pathogenic only in high concentrations (> 10^3 CFU/mL ejaculate). Fewer than 10% of samples analysed for Ureaplasma exceeded this concentration [1805]. Normal colonisation of the urethra hampers the significance of mycoplasma-associated urogenital infections, using samples such as the ejaculate [1806].

A meta-analysis indicated that Ureaplasma parvum and Mycoplasma genitalium were not associated with male infertility, but a significant relationship existed between U. urealyticum (OR: 3.03 95% CI: 1.02–8.99) and Mycoplasma hominis (OR: 2.8; 95% CI: 0.93– 3.64) [1807].

The prevalence of human papilloma virus (HPV) in the semen ranges from 2 to 31% in the general population and is higher in men with unexplained infertility (10-35.7%) [1808, 1809]. Recent systematic reviews have reported an association between male infertility, poorer pregnancy outcomes and semen HPV positivity [1810-1812]. However, data still needs to be prospectively validated to clearly define the clinical impact of HPV infection in semen. Additionally, seminal presence of Herpes Simplex virus (HSV)-2 in infertile men may be associated with lower sperm quality compared to that in HSV-negative infertile men [1797]. However, it is unclear if anti-viral therapy improves fertility rates in these men.

10.4.4.2.3 White blood cells

The clinical significance of an increased concentration of leukocytes in the ejaculate is controversial [1813]. Although leukocytospermia is a sign of inflammation, it is not necessarily associated with bacterial or viral infections, and therefore cannot be considered a reliable indicator [1814]. According to the WHO classification, leukocytospermia is defined as > 10^6 WBCs/mL. Only two studies have analysed alterations of WBCs in the ejaculate of patients with proven prostatitis [1815, 1816]. Both studies found more leukocytes in men with prostatitis compared to those without inflammation (CPPS, type NIH 3b). Furthermore, leukocytospermia should be further confirmed by performing a peroxidase test on the semen. There is currently no evidence that treatment of leukocytospermia alone without evidence of infective organisms improves conception rates [1817].

10.4.4.2.4 Sperm quality

The deleterious effects of chronic prostatitis (CP/CPPS) on sperm density, motility and morphology has been demonstrated in a recent systematic review based on case-controlled studies [1818]. Both C. trachomatis and Ureaplasma spp. can cause decreased sperm density, motility, altered morphology and increased DNA damage. Data from a recent retrospective cross-sectional study showed that U. urealyticum was the most frequent single pathogen in semen of asymptomatic infertile men; a positive semen culture was both univariably (p < 0.001) and multi-variably (p = 0.04) associated with lower sperm concentration [1819]. Human papilloma virus can also induce changes in sperm density, motility and DNA damage [1808, 1809]. Mycoplasma spp. can cause decreased motility and development of antisperm antibodies [1797].

10.4.4.2.5 Seminal plasma alterations

Seminal plasma elastase is a biochemical indicator of polymorphonuclear lymphocyte activity in the ejaculate [1796, 1820, 1821]. Various cytokines are involved in inflammation and can influence sperm function. Several studies have investigated the association between interleukin (IL) concentration, leukocytes, and sperm function through different pathways, but no correlations have been found [1822-1824].
The prostate is the main site of origin of IL-6 and IL-8 in the seminal plasma. Cytokines, especially IL-6, play an important role in the male accessory gland inflammatory process [1825]. However, elevated cytokine levels do not depend on the number of leukocytes in expressed prostatic secretion [1826].

10.4.4.2.6 Glandular secretory dysfunction
The secretory function of the prostate gland can be evaluated by measuring seminal plasma pH, citric acid, or γ-glutamine transpeptidase levels; the seminal plasma concentrations of these factors are usually altered during infection and inflammation. However, they are not recommended as diagnostic markers for MAGIs [1827].

Reactive oxygen species
Reactive oxygen species may be increased in infertile patients with asymptomatic C. trachomatis and M. hominis infection, with subsequent decrease in ROS upon antibiotic treatment. However, the levels of ROS in infertile patients with asymptomatic C. trachomatis and M. hominis in the semen are low, making it difficult to draw any firm conclusions [1828]. Chronic urogenital infections are also associated with increased leukocyte numbers [1829]. However, their biological significance in prostatitis remains unclear [1796].

10.4.4.2.7 Disease management
Treatment of CP/CPPS is usually targeted at relieving symptoms [1830, 1831]. The indications and aims of therapy are:
• reduction or eradication of micro-organisms in prostatic secretions and semen;
• normalisation of inflammatory (e.g., leukocytes) and secretory parameters;
• improvement of sperm parameters associated with fertility impairment [1832].

Only antibiotic therapy of chronic bacterial prostatitis (NIH II according to the classification) has provided symptomatic relief, eradication of micro-organisms, and a decrease in cellular and humoral inflammatory parameters in urogenital secretions. Although antibiotics might improve sperm quality [1832], there is no evidence that treatment of CP/CPPS increases the probability of natural conception [1796, 1833].

Asymptomatic presence of C. trachomatis and M. hominis in the semen can be correlated with impaired sperm quality, which recovers after antibiotic treatment. However further research is required to confirm these findings [1828].

10.4.4.3 Epididymitis
Inflammation of the epididymis causes unilateral pain and swelling, usually with acute onset. Among sexually active men aged < 35 years, epididymitis is most often caused by C. trachomatis or N. gonorrhoea [1834, 1835]. Sexually transmitted epididymitis is usually accompanied by urethritis. Non-sexually transmitted epididymitis is associated with UTIs and occurs more often in men aged > 35 years [1836].

10.4.4.3.1 Diagnostic evaluation
10.4.4.3.1.1 Ejaculate analysis
Ejaculate analysis according to WHO Laboratory Manual for the Examination and Processing of Human Semen (6th edn) criteria, may indicate persistent inflammatory activity. Transient reductions in sperm counts and progressive motility can be observed [1834, 1837, 1838]. Semen culture might help to identify pathogenic micro-organisms. Development of stenosis of the epididymal ducts, reduction of sperm count, and azoospermia are more important potential sequelae to consider in the follow-up of bilateral epididymitis (see Section 10.3.2).

10.4.4.3.1.2 Disease management
Treatment of epididymitis results in:
• microbiological cure of infection;
• improvement of clinical signs and symptoms;
• prevention of potential testicular damage;
• prevention of transmission;
• decrease of potential complications (e.g., infertility or chronic pain).

Patients with epididymitis known or suspected to be caused by N. gonorrhoeae or C. trachomatis must be told to also refer their sexual partners for evaluation and treatment [1839].

10.5 Non-Invasive Male Infertility Management

10.5.1 Idiopathic male infertility and oligo-astheno-terato-zoospermia

Oligo-astheno-teratozoospermia (OAT) is a clinical condition with a reduced number of spermatozoa in the ejaculate, which is also characterised by reduced sperm motility and morphology; often referred to as OAT syndrome (OATS). Several conditions can cause OATS, although the aetiology may be unknown in a significant number of cases [96, 1665].

10.5.2 Empirical treatments

10.5.2.1 Life-style

Studies suggest that environmental and lifestyle factors may contribute to idiopathic infertility acting additively on a susceptible genetic background [96, 1665]. Hence, lifestyle improvement can have a positive effect on sperm parameters (see below).

10.5.2.1.1 Weight loss

Few authors have investigated the role of weight loss on male fertility outcomes. Non-controlled studies have suggested that weight loss can result in improved sperm parameters [96, 1840, 1841]. However, data derived from RCTs are more conflicting. A meta-analysis of 28 cohort studies and 1,022 patients, documented that bariatric surgery did not improve sperm quality and function in morbidly obese men [1842]. Data on ART outcomes are lacking. However, it is important to recognise that weight loss can improve obesity-related secondary hypogonadism, which may result in better outcomes in couples seeking medical care for infertility, and is important for the general health of the male partner [1840, 1842].

10.5.2.1.2 Physical activity

Regular physical activity is recommended by the WHO in order to prevent and reduced the risk of several long-term chronic diseases [1843]. A recent meta-analysis has documented that moderate-intensity (20–40 metabolic equivalents [METs]/week) or even high-intensity (40–80 METs-h/week) recreational physical activity can result in better semen parameters [1844]. In addition, similar to what is observed from weight loss, improvements in hormonal profile have also been reported [1840].

10.5.2.1.3 Smoking

Epidemiological data indicates that about one in three men of reproductive age smokes, with the highest prevalence observed in Europe among all the WHO regions [1845]. Data derived from a large meta-analysis of 20 studies with 5,865 participants clearly show a negative association between smoking and sperm parameters [1845]. Experimental studies performed in rats have shown that nicotine has a dose-dependent deleterious effect on sperm, which can be improved by nicotine cessation [1846]. Data in men are lacking and only one case report has indicated an improvement of sperm parameters after 3 months of a smoking cessation programme [1847]. Similar data have been reported in a recent non-controlled study, which showed a possible benefit on ART after the male partner stopped smoking [1848].

10.5.2.1.4 Alcohol consumption

Data derived from a recent meta-analysis including 15 cross-sectional studies and 16,395 men suggested
that moderate alcohol does not adversely affect semen parameters, whereas high alcohol intake can have a detrimental effect on male fertility [1849]. Similar to what has been reported for weight loss; however, heavy chronic alcohol consumption (defined as > 2 drinks/day [1850]) can reduce testosterone levels, which can be restored by alcohol cessation [1851].

10.5.2.2 Antioxidant treatment

Inflammation is a positive reaction of the human body to overcome potential noxious stimuli. However, chronic inflammation can induce several negative biochemical and metabolic effects that contribute to the development of several medical conditions. Oxidative stress is considered to be of the most important contributing factors in the pathogenesis of idiopathic infertility. Reactive oxygen species, the final products of OS, can impair sperm function acting at several levels, including plasma membrane lipid peroxidation, which can affect sperm motility, the acrosome reaction and chromatin maturation leading to increased DNA fragmentation [1852]. Accordingly, seminal levels of ROS have been negatively associated with ART outcomes [1853]. Despite this, evidence for the role of antioxidant therapy in male infertility is still conflicting. A Cochrane systematic review and meta-analysis including 34 RCTs and 2,876 couples using various antioxidant compounds, it was concluded that antioxidant therapy had a positive impact on live-birth and pregnancy rates in sub-fertile couples undergoing ART cycles [1854]. Similar results were also reported in the most recent meta-analysis including 61 studies with 6,264 fertile men, aged 18-65 years [1855]. More recently, the Males, Antioxidants, and Infertility (MOXI) trial found that antioxidants did not improve semen parameters or DNA integrity compared to placebo among infertile men with male factor infertility. Moreover, cumulative live-birth rate did not differ at 6 months between the antioxidant and placebo groups (15% vs. 24%) [1856]. However, all the aforementioned studies also recognised important limitations: data were derived from low-quality RCTs with serious risk of bias due to poor methods of reporting randomisation; failure to report on the clinical outcomes including live-birth and clinical pregnancy rates; high attrition rates; and imprecision due to often low event rates and small overall sample sizes [1855]. No clear conclusions were possible regarding the specific antioxidants to use or and/or therapeutic regimes for improving sperm parameters and pregnancy rate [1855].

10.5.2.3 Selective oestrogen receptor modulators

Selective oestrogen receptor modulators (SERMs) have been advocated as a possible empirical treatment in male idiopathic infertility. The proposed mechanism of action is based on the activity of these compounds to block oestrogen receptors at the level of the hypothalamus, which results in stimulation of GnRH secretion leading to an increase in pituitary gonadotropin release. The latter effect, by stimulating spermatogenesis, represents the rational basis for SERM administration to patients with reduced sperm count [1857]. In an initial meta-analysis including 11 RCTs, in which only 5 were placebo-controlled, it was concluded that SERMs were not associated with an increased pregnancy rate in the 459 patients analysed [1858]. In a subsequent Cochrane review published 1 year later, these findings were confirmed in a larger number of studies (n = 10 and 738 men), although positive effects on hormonal parameters were documented. More recently, Chua et al., meta-analysed data derived from 11 RCTs and showed that SERMs were associated with a significantly increased pregnancy rate [1859]. Additionally, a significant improvement in sperm and hormonal parameters was detected. Similar results were confirmed in the latest updated meta-analysis of 16 studies [1857]. However, it should be recognised that the quality of the papers included was low and only a few studies were placebo-controlled. In conclusion, although some positive results relating to the use of SERMs in men with idiopathic infertility have been reported, no conclusive recommendations can be drawn due to poor quality of the available evidence. Furthermore, complications from the use of SERMs were under-reported.

10.5.2.4 Aromatase inhibitors

Aromatase, a cytochrome p450 enzyme, is present in the testes, prostate, brain, bone, and adipose tissue of men; it converts testosterone and androstenedione to oestradiol and oestrone, respectively. Oestradiol negatively feeds back on the hypothalamus and pituitary to reduce gonadotropic secretions, ultimately affecting spermatogenesis. In this context, aromatase inhibitors (AIs) may decrease oestrogen production by reversibly inhibiting cytochrome p450 isoenzymes 2A6 and 2C19 of the aromatase enzyme complex inhibiting the negative feedback of oestrogen on the hypothalamus resulting in stronger GnRH pulses that stimulate the pituitary to increase production of FSH [1860-1863]. Aromatase activity has been associated with male infertility characterised by testicular dysfunction due to low serum testosterone and/or testosterone to oestradiol ratio. In this context, AIs have been reported to increase endogenous testosterone production and improve spermatogenesis in the setting of infertility as an off-label option for treatment [1864]. Either steroidal (testolactone) and non-steroidal (anastrozole and letrozole) AIs significantly improve hormonal and semen parameters in infertile men, with a safe tolerability profile, although prospective RCTs are necessary to better define the efficacy of these medications in this clinical setting [1862, 1864].
In men with idiopathic oligo-astheno-teratozoospermia, life-style changes including weight loss and increased physical activity, smoking cessation and alcohol intake reduction can improve sperm quality and the chances of conception.

No clear recommendation can be made for treatment of patients with idiopathic infertility using antioxidants, although anti-oxidant use may improve semen parameters.

No conclusive recommendations on the use of selective oestrogen receptor modulators in men with idiopathic infertility can be drawn.

No conclusive recommendations on the use of either steroidal (testolactone) or nonsteroidal (anastrozole and letrozole) aromatase inhibitors in men with idiopathic infertility can be drawn, even before testis surgery.

10.5.3 Hormonal therapy
10.5.3.1 Gonadotrophins
Follicle Stimulating Hormone is primarily involved in the initiation of spermatogenesis and testicular growth during puberty. The role of FSH post puberty has not been clearly defined. Luteinising hormone stimulates testosterone production in the testes, but due to its short half-life, it is not suitable for clinical use. Human Chorionic Gonadotrophin acts in a similar manner to LH and can be used pharmacologically to stimulate testosterone release in men with failure of their hypothalamic-pituitary-gonadal axis. Human Chorionic Gonadotrophin can adequately stimulate spermatogenesis in men whom have developed hypopituitarism after normal puberty. Therefore, the treatment of men with secondary hypogonadism depends on whether or not they developed hypopituitary failure before or after puberty [5].

10.5.3.2 Secondary hypogonadism
10.5.3.2.1 Pre-Pubertal-Onset
Congenital causes resulting in low gonadotropin production are associated with testicular size < 4 mL and/or cryptorchidism. Testes size of < 4 mL occurs when they have not been exposed to any gonadotropins at all. These conditions require combination therapy with both hCG and FSH with subcutaneous administration or GnRH by pulsed delivery using a subcutaneous pump [1865]. However, GnRH treatment requires a pulsatile secretion using specific devices for either intravenous or subcutaneous administration, which may limit patient compliance. Moreover, GnRH therapy should be limited to subjects with a residual pituitary gonadotropic activity [5].

As for the type of gonadotropin treatment, it is usual to commence hCG first and titrate the dose to achieve testosterone levels within the normal physiological range. However, FSH can be given first or in combination with hCG [125]. Human Chorionic Gonadotrophin is given twice weekly and in patients with congenital secondary hypogonadism in high dose, commencing at 1,000 IU twice weekly. Testosterone levels can be assayed every 2 weeks with dose increases until ideally mid-range testosterone is achieved. Dose increases can be to 2,000, 3,000, 4,000 and 5,000 IU two or three times a week, until normal testosterone levels are achieved [1866-1869]. Failure to achieve normal testosterone status at the high dose would indicate that primary testicular failure is present; probably as a result of cryptorchidism or failure of testicular development. Human Chorionic Gonadotrophin is also used to stimulate testicular descent into the scrotum in individuals with cryptorchidism. Once the hCG dose giving a normal level testosterone is established with the implication that intra-testicular testosterone has occurred, FSH 75-150 IU three times per week subcutaneously should be commenced. Usually the higher 150 IU dose three times weekly is needed to be successful in men with testicular volume < 4mL. The trophic response of the testes to FSH is variable in these patients and it may range from no effect to achieving testicular sizes of 12-15 mL [1870]. A trophic response is usually an indication of an increase in spermatogenesis. The production of new spermatogenesis may be evident after 3 months of FSH therapy, but could occur even after 18 months of treatment [1868-1870]. A low baseline sperm concentration does not indicate a poor response to gonadotropin therapy [1871]. Semen analysis can be assessed at 3-monthly intervals. These patients can be fertile with low sperm counts < 20 million/mL as there is a high proportion of motile sperm. Follicle-stimulating hormone therapy prior to GnRH is also effective in stimulating testicular growth and fertility in men with congenital hypogonadotropic hypogonadism (HH) [1872]. A larger initial testicular volume is the best prognostic factor for induction of successful spermatogenesis [1873].

10.5.3.2.2 Post-Pubertal Onset Secondary
If secondary hypogonadism develops after puberty, hCG alone is usually required first to stimulate spermatogenesis. Doses of subcutaneous hCG required may be lower than those used in individuals with pre-pubertal onset; therefore, a starting dose of 250 IU twice weekly is suggested, and if normal testosterone
levels are reached, hCG doses may be increased up to 2,000 IU twice weekly as for pre-pubertal onset. Again, semen analysis should be performed every 3 months to assess response, unless conception has taken place. If there is a failure of stimulation of spermatogenesis, then FSH can be added (75 IU three times per week, increasing to 150 IU three times per week if indicated). Similarly, combination therapy with FSH and hCG can be administered from the beginning of treatment, promoting better outcomes in men with HH [125]. No difference in outcomes were observed when urinary-derived, highly purified FSH was compared to recombinant FSH [125].

Greater baseline testicular volume is a good prognostic indicator for response to gonadotrophin treatment [1873]. Data had suggested that previous testosterone therapy can have a negative impact on gonadotropin treatment outcomes in men with HH [1873]. However, this observation has been subsequently refuted by a meta-analysis that did not confirm a real negative role of testosterone therapy in terms of future fertility in this specific setting [125].

In the presence of hyperprolactinaemia, causing suppression of gonadotrophins resulting in sub-fertility the treatment independent of aetiology (including a pituitary adenoma) is dopamine agonist therapy or withdrawal of the drug that causes the condition. Dopamine agonists used include bromocriptine, cabergoline and quinagolide.

10.5.3.3 Primary Hypogonadism
There is no substantial evidence that gonadotrophin therapy has any beneficial effect in the presence of classical testicular failure. Likewise, there are no data to support the use of other hormonal treatments (including SERMs or AIs) in the case of primary hypogonadism to improve spermatogenesis [97, 1874].

10.5.3.4 Idiopathic Male Factor Infertility
There is some evidence that FSH treatment increases sperm parameters in idiopathic oligozoospermic men with FSH levels within the normal range (generally 1.5 – 8 mIU/mL)[1875]. It has also been reported that FSH may improve sperm DNA fragmentation rates as well as ameliorating AMH and inhibitin levels [1876-1879]. High-dose FSH therapy is more effective in achieving a testicular response than lower doses are [1880]. A Cochrane systematic review including six RCTs with 456 participants, different treatment protocols and follow-up periods concluded that FSH treatment resulted in higher live-birth and pregnancy rates compared with placebo or no treatment. However, no significant difference among groups was observed when ICSI or IUI were considered [1881]. In a more recent meta-analysis including 15 trials with > 1,200 patients, similar findings after FSH treatment were observed in terms of both spontaneous pregnancies and pregnancies after ART [1882]. A further study showed that in azoospermic men undergoing TESE-ICSI there were improved SRRs and higher pregnancy and fertilisation rates in men treated with FSH compared to untreated men [1883]. In men with NOA, combination hCG/FSH therapy was shown to increase SRR in only one study [1884]. Human chorionic gonadotrophin alone prior to TESE in NOA has not been found to have any benefit on SRRs [1885]. Overall the evidence for the use of hormone therapy prior to SSR is limited and treatment should be confined to clinical trials and not used routinely in clinical practice.

10.5.3.5 Anabolic Steroid Abuse
Oligospermia or azoospermia as a result of anabolic abuse should be treated initially by withdrawal of the anabolic steroid. There is no common indication for treating this disorder; the management is based on case reports and clinical experience. Usually, adequate sperm numbers and quality will improve over a six to twelve month period. If after this interval the condition persists, then hCG without or in combination with FSH as an alternative to clomiphene can be used to try and stimulate spermatogenesis [1886].

10.5.3.6 Recommendations for treatment of male infertility with hormonal therapy

<table>
<thead>
<tr>
<th>Recommendations</th>
<th>Strength rating</th>
</tr>
</thead>
<tbody>
<tr>
<td>Hypogonadotropic hypogonadism (secondary hypogonadism), including congenital causes, should be treated with combined human chorionic gonadotropin (hCG) and follicle-stimulating hormone (FSH) (recombinant FSH; highly purified FSH) or pulsed Gonadotropin-releasing hormone (GnRH) via pump therapy to stimulate spermatogenesis.</td>
<td>Strong</td>
</tr>
<tr>
<td>In men with hypogonadotropic hypogonadism, induce spermatogenesis by an effective drug therapy (hCG; human menopausal gonadotropins; recombinant FSH; highly purified FSH).</td>
<td>Strong</td>
</tr>
</tbody>
</table>
The use of GnRH therapy is more expensive and does not offer any advantages when compared to gonadotropins for the treatment of hypogonadotropic hypogonadism.  

In men with idiopathic oligozoospermia and FSH values within the normal range, FSH treatment may ameliorate spermatogenesis outcomes.  

No conclusive recommendations can be given on the use of high-dose FSH in men with idiopathic infertility and prior (m)TESE and therefore cannot be routinely advocated.  

Do not use testosterone therapy for the treatment of male infertility.  

Provide testosterone therapy for symptomatic patients with primary and secondary hypogonadism who are not considering parenthood.  

In the presence of hyperprolactinaemia, dopamine agonist therapy may improve spermatogenesis.  

10.6 Invasive Male Infertility Management

10.6.1 Obstructive azoospermia

Obstructive azoospermia (OA) is the absence of spermatozoa in the sediment of a centrifuged sample of ejaculate due to obstruction [1794]. Obstructive azoospermia is less common than NOA and occurs in 20-40% of men with azoospermia [1887, 1888]. Men with OA usually have normal FSH, testes of normal size and epididymal enlargement [1889]. Of clinical relevance, men with late maturation arrest may present with normal gonadotropins and testicular size and may be only distinguished from those with OA at the time of surgical exploration. The vas deferens may be absent bilaterally (CBAVD) or unilaterally (CUAVD). Obstruction in primary infertile men is more frequently present at the epididymal level.

10.6.1.1 Classification of obstructive azoospermia

10.6.1.1.1 Intratesticular obstruction

Intratesticular obstruction occurs in 15% of men with OA [1890]. Congenital forms are less common than acquired forms (post-inflammatory or post-traumatic) (Table 43).

10.6.1.1.2 Epididymal obstruction

Epididymal obstruction is the most common cause of OA, affecting 30-67% of azoospermic men [1890-1893]. Congenital epididymal obstruction usually manifests as CBAVD, which is associated with at least one mutation of the CF gene in 82% of cases [1893]. Other congenital forms of epididymal obstruction include chronic sinu-pulmonary infections (Young's syndrome) [1894]. Acquired secondary to acute (e.g., gonococcal) and subclinical forms (e.g., Chlamydial) epididymitis are most commonly due to infections [1895, 1896]. Other causes may be trauma or surgical intervention [1897, 1898] (Table 43).

10.6.1.1.3 Vas deferens obstruction

Vas deferens obstruction is the most common cause of acquired obstruction following vasectomy [1895] (Table 42). Approximately 2-6% of these men request vasectomy reversal (see 2019 EAU Guidelines on Male Infertility). Vasal obstruction may also occur after hernia repair [1899, 1900]. The most common congenital vasal obstruction is CBAVD, often accompanied by CF. Unilateral agenesis or a partial defect is associated with contralateral seminal duct anomalies or renal agenesis in 80% and 26% of cases, respectively [1584].

10.6.1.1.4 Ejaculatory duct obstruction

Ejaculatory duct obstruction is found in 1-5% of cases of OA and is classified as cystic or post-inflammatory or calculi of one or both ejaculatory ducts [1724, 1901] (Table 42). Cystic obstructions are usually congenital (i.e., Mullerian duct cyst or urogenital sinus/ejaculatory duct cysts) and are typically midline. In urogenital sinus abnormalities, one or both ejaculatory ducts empty into the cyst [1902], while in Mullerian duct anomalies, the ejaculatory ducts are laterally displaced and compressed by the cyst [1903]. Paramedian or lateral intraprostatic cysts are rare [1904]. Post-inflammatory obstructions of the ejaculatory duct are usually secondary to urethra-prostatitis [1905]. Congenital or acquired complete obstructions of the ejaculatory ducts are commonly associated with low seminal volume, decreased or absent seminal fructose, and acidic pH. The seminal vesicles (anterior-posterior diameter > 15 mm) and ejaculatory duct (> 2.3 mm in width) are usually dilated [1901, 1905-1907].

10.6.1.1.4.1 Functional obstruction of the distal seminal ducts

Functional obstruction of the distal seminal ducts might be attributed to local neurogenic dysfunction [1908]. This abnormality is often associated with urodynamic dysfunction. Impaired sperm transport can be observed as idiopathic or due to spinal cord injury, multiple sclerosis, retroperitoneal lymph node dissection, pelvic surgery, SSRIs, α-blockers and typical antipsychotic medications [1909].

10.6.1.2 Diagnostic evaluation

10.6.1.2.1 Clinical history
Clinical history-taking should follow the investigation and diagnostic evaluation of infertile men (See Section 10.3). Risk factors for obstruction include prior surgery, iatrogenic injury during inguinal herniorrhaphy, orchidopexy or hydrocelectomy.

10.6.1.2.2 Clinical examination
Clinical examination should follow the guidelines for the diagnostic evaluation of infertile men. Obstructive azoospermia is indicated by at least one testis with a volume > 15 mL, although a smaller volume may be found in some patients with:
- obstructive azoospermia and concomitant partial testicular failure;
- enlarged and dilated epididymis;
- nodules in the epididymis or vas deferens;
- absence or partial atresia of the vas deferens.

10.6.1.2.3 Semen analysis
Azoospermia means the inability to detect spermatozoa after centrifugation at ×400 magnification. At least two semen analyses must be carried out [1910, 1911] (see Section 10.3). When semen volume is low, a search must be made for spermatozoa in urine after ejaculation. Absence of spermatozoa and immature germ cells in the semen pellet suggest complete seminal duct obstruction.

10.6.1.2.4 Hormone levels
Hormones including FSH and inhibin-B should be normal, but do not exclude other causes of testicular azoospermia (e.g., NOA). Although inhibin-B concentration is a good index of Sertoli cell integrity reflecting closely the state of spermatogenesis, its diagnostic value is no better than that of FSH and its use in clinical practice has not been widely advocated [1912].

10.6.1.2.5 Genetic testing
Inability to palpate one or both sides of the vas deferens should raise concern for a CFTR mutation. Any patient with unilateral or bilateral absence of the vas deferens or seminal vesicle agenesis should be offered CFTR testing [1913].

10.6.1.2.6 Testicular biopsy
Testicular biopsy must be combined with TESE for cryopreservation. Although studies suggest that a diagnostic or isolated testicular biopsy [1914] is the most important prognostic predictor of spermatogenesis and sperm retrieval, the Panel recommends not to perform testis biopsies (including fine needle aspiration...
[FNA]) without performing simultaneously a therapeutic sperm retrieval, as this will require a further invasive procedure after biopsy. Furthermore, even patients with extremes of spermatogenic failure (e.g., Sertoli Cell Only syndrome [SCOS]) may harbour focal areas of spermatogenesis [1915, 1916].

10.6.1.3 Disease management

Sperm retrieval
10.6.1.3.1 Intratesticular obstruction
Only TESE allows sperm retrieval in these patients and is therefore recommended.

10.6.1.3.2 Epididymal obstruction
Microsurgical epididymal sperm aspiration (MESA) or percutaneous epididymal sperm aspiration (PESA) [1917] is indicated in men with CBAVD. Testicular sperm extraction and percutaneous techniques, such as testicular sperm aspiration (TESA), are also options [1918]. The source of sperm used for ICSI in cases of OA and the aetiology of the obstruction do not affect the outcome in terms of fertilisation, pregnancy, or miscarriage rates [1919]. Usually, one MESA procedure provides sufficient material for several ICSI cycles [1920] and it produces high pregnancy and fertilisation rates [1921]. In patients with OA due to acquired epididymal obstruction and with a female partner with good ovarian reserve, microsurgical epididymovasostomy (EV) is recommended [1922]. Epididymovasostomy can be performed with different techniques such as end-to-end and intussusception [1923].

Anatomical recanalisation following surgery may require 3-18 months. A recent systematic review indicated that the time to patency in EV varies between 2.8 to 6.6 months. Reports of late failure are heterogeneous and vary between 1 and 50% [1924]. Before microsurgery, and in all cases in which recanalisation is impossible, epididymal spermatozoa should be aspirated intra-operatively by MESA and cryopreserved to be used for subsequent ICSI procedures [1905]. Patency rates range between 65% and 85% and cumulative pregnancy rates between 21% and 44% [1898, 1925]. Recanalisation success rates may be adversely affected by pre-operative and intra-operative findings. Robot-assisted EV has similar success rates but larger studies are needed [1779].

10.6.1.3.3 Vas deferens obstruction after vasectomy
Vas deferens obstruction after vasectomy requires microsurgical vasectomy reversal. The mean post-procedural patency and pregnancy rates weighted by sample size were 90-97% and 52-73%, respectively [1898, 1925]. The average time to patency is 1.7-4.3 months and late failures are uncommon (0-12%) [1924]. Robot-assisted vasovasostomy has similar success rates, and larger studies, including cost-benefit analysis, are needed to establish its benefits over standard microsurgical procedures [1779].

The absence of spermatozoa in the intra-operative vas deferens fluid suggests the presence of a secondary epididymal obstruction, especially if the seminal fluid of the proximal vas deferens has a thick “toothpaste” appearance; in this case microsurgical EV may be indicated [1926-1928]. Simultaneous sperm retrieval may be performed for future cryopreservation and use for ICSI; likewise, patients should be counselled appropriately.

10.6.1.3.4 Vas deferens obstruction at the inguinal level
It is usually impossible to correct large bilateral vas deferens defects, resulting from involuntary excision of the vasa deferentia during hernia surgery in early childhood or previous orchidopexy. In these cases, TESE/MESA/PESA or proximal vas deferens sperm aspiration [1929] can be used for cryopreservation for future ICSI. Prostate cancer patients who express an interest in future fertility should be counselled for cryopreservation [1930, 1931].

10.6.1.3.5 Ejaculatory duct obstruction
The treatment of ejaculatory duct obstruction (EDO) depends on its aetiology. Transurethral resection of the ejaculatory ducts (TURED) can be used in post-inflammatory obstruction and cystic obstruction [1901, 1905]. Resection may remove part of the verumontanum. In cases of obstruction due to a midline intraprostatic cyst, incision, unroofing or aspiration of the cyst is required [1901, 1905].

Intra-operative TRUS makes this procedure safer. If distal seminal tract evaluation is carried out at the time of the procedure, installation of methylene blue dye into the seminal vesicles (chromotubation) can help to confirm intra-operative opening of the ducts. Pregnancy rates after TURED are 20-25% [1724, 1901, 1932]. Complications following TURED include epididymitis, UTI, gross haematuria, haematospermia, azospermia (in cases with partial distal ejaculatory duct obstruction) and urine reflux into the ejaculatory ducts and seminal vesicles [1901].
Alternative therapies for EDO include, seminal vesiculoscopy to remove debris or calculi and balloon dilation and laser incision for calcification on TRUS [1933]. The alternatives to TURED are MESA, PESA, TESE, proximal vas deferens sperm aspiration and seminal vesicle-ultrasonically guided aspiration.

10.6.2 Non-obstructive azoospermia

Non-obstructive azoospermia (NOA) is defined as the absence of sperm at the semen analysis after centrifugation, with usually a normal ejaculate volume. This finding should be confirmed at least at two consecutive semen analyses [1522]. The severe deficit in spermatogenesis observed in NOA patients is often a consequence of primary testicular dysfunction or may be related to a dysfunction of the hypothalamus-pituitary-gonadal (HPG) axis.

10.6.2.1 Investigation of non-obstructive azoospermia

The diagnosis of NOA is based on the evidence of two consecutive semen analyses confirming azoospermia. Causes of OA should be ruled out. Patients with NOA should undergo a comprehensive assessment to identify genetically transmissible conditions, potential treatable causes of azoospermia, and potential health-relevant co-morbidity (e.g., testicular cancer and hypogonadism [of any type]). A detailed medical history (e.g., history of cryptorchidism, previous gonadotoxic treatments for cancer, etc.) and socio-demographic characteristics [1934], along with a comprehensive physical examination should be performed in every patient to detect conditions potentially leading to azoospermia, while ruling out co-morbidity frequently associated with azoospermia. Non-obstructive azoospermia can be the first sign of pituitary or germ cell tumours of the testis [1935-1937]. Patients with NOA have been shown to be at increased risk of being diagnosed with cancer [1938]. Moreover, other systemic conditions such as MetS, T2DM, osteoporosis and CVDs have been more frequently observed in patients with NOA compared to normozoospermic men [1939-1941]. Azoospermic men are at higher risk of mortality [1942, 1943]. Therefore, investigation of infertile men provides an opportunity for long-term risk stratification for other co-morbid conditions [1944].

Genetic tests should be performed in patients with NOA to detect genetic abnormalities. As discussed (see Section 10.3), patients should undergo karyotype analysis [1544, 1545], along with a screening of Y-chromosome micro-deletions [1595, 1945] and of the gene coding for CFTR in order to exclude concomitant mutations, and to rule out CBAVD [1579, 1580]. Genetic counselling for eventual transmissible and health-relevant genetic conditions should be provided to couples.

All patients should undergo a complete hormonal investigation to exclude concomitant hypogonadism, which has been found in about 30% of patients with NOA [389, 1946, 1947]. A correct definition of the type of the associated hypogonadism (i.e., hypogonadotropic hypogonadism vs. hypergonadotropic vs. compensated hypogonadism) is relevant to differentiate diagnostic and therapeutic approaches to the patient [1948].

Scrotal US may show signs of testicular dysgenesis (e.g., non-homogeneous testicular architecture and/or microcalcifications) and testicular tumours. Testicular volume may be a predictor of spermatogenic function [1516] and is usually, but not invariably, low in patients with NOA. Some authors have advocated that testicular perfusion detected at US Doppler assessment can predict surgical sperm retrieval at TESE and guide testicular biopsies [1949]; however, to date, data are inconsistent to suggest a routine role of testicular Doppler evaluation before TESE. In a recent multicentre study including 806 men submitted to mTESE, the
size of seminiferous tubules assessed with pre-operative US was significantly associated with sperm retrieval outcomes, with a sensitivity and specificity of 76.7% and 80.7% for a cut-off point of 250 μm, respectively [1950].

10.6.2.2 Surgery for non-obstructive azoospermia
Surgical treatment for NOA is mostly aimed at retrieval of vital sperm directly from the testes (either uni- or bilaterally). This treatment is normally part of ART protocols, including IVF cycles via ICSI. Techniques and indications for surgical sperm retrieval in patients with NOA are discussed below. Any surgical approach aimed at sperm retrieval must be considered not a routine and simple biopsy; in this context, performing a diagnostic biopsy before surgery (any type) unless dedicated to ART protocols is currently considered inappropriate.

10.6.2.3 Indications and techniques of sperm retrieval
Spermatogenesis within the testes may be focal, which means that spermatozoa can usually be found in small and isolated foci. With a wide variability among cohorts and techniques, positive SRRs have been reported in up to 50% of patients with NOA [1951, 1952]. Numerous predictive factors for positive sperm retrieval have been investigated, although no definitive factors have been demonstrated to predict sperm retrieval [1952].

Historically, there is a good correlation between the histology found at testicular biopsy and the likelihood of finding mature sperm cells during testicular sperm retrieval [1914, 1953, 1954]. The presence of hypospermatogenesis at testicular biopsy showed good accuracy in predicting positive sperm retrieval after either single or multiple conventional TESE or mTESE compared with maturation arrest pattern or SCOS [1914, 1953, 1954]. However, formal diagnostic biopsy is not recommended in this clinical setting for the reasons outlined above.

Hormonal levels, including FSH, LH, inhibin B and AMH have been variably correlated with sperm retrieval outcomes at surgery, and data from retrospective series are still controversial [1883, 1955-1960]. Similarly, conflicting results have been published regarding testicular volume as a predictor of positive sperm retrieval [1883, 1914, 1958]. Therefore, no clinical variable may be currently considered as a reliable predictor for positive sperm retrieval throughout ART patient work-up [1952].

In case of complete AZFa and AZFb microdeletions, the likelihood of sperm retrieval is zero and therefore TESE procedures are contraindicated [1600]. Conversely, patients with Klinefelter syndrome [1562] and a history of undescended testes have been shown to have higher chance of finding sperm at surgery [1958].

Historically, surgical techniques for retrieving sperm in men with NOA include testicular sperm aspiration (TESA), single or multiple conventional TESE (cTESE) and mTESE.

• Fine needle aspiration mapping
Fine needle aspiration (FNA) mapping technique has been proposed as a prognostic procedure aimed to select patients with NOA for TESE and ICSI [1961]. The procedure is performed under local anaesthesia in the office and percutaneous aspiration is performed with 23G needle in multiple sites, ranging from 4 to 18 [1961]. The retrieved tissue is sent for cytological and histological evaluation to provide information on the presence of mature sperm and on testicular histological pattern. Given that focal spermatogenesis may occur within the testes of patients with NOA, FNA mapping may provide information on the sites with the higher probability of retrieving sperm, thus serving as a guide for further sperm retrieval surgery in the context of ART procedures (e.g., ICSI). Turek et al. have shown that a higher number of aspiration sites may increase the chance of finding sperm [1962, 1963]. The extent and type of subsequent sperm retrieval procedure can be tailored according to the FNA mapping results: TESA or TESE could be suggested in case of multiple positive sites for sperm, while a more precise and potentially more-invasive technique, such as mTESE, could be considered for patients with few positive sites at FNA [1961]. However, no RCTs have compared the diagnostic yield from FNA and mTESE. A positive FNA requires a secondary therapeutic surgical approach, which may increase the risk of testicular damage, and without appropriate cost-benefit analysis, is not justifiable. No studies have evaluated the salvage rate of mTESE in men who have undergone FNA mapping. Therefore, FNA mapping cannot be recommended as a primary therapeutic intervention in men with NOA until further RCTs are undertaken.

• Testicular sperm aspiration
Testicular sperm aspiration (TESA) is a minimally invasive, office-based, procedure in which testicular tissue is retrieved with a biopsy needle under local anaesthesia. Reported SRRs with TESA range from 11 to 60% according to patient profile and surgical techniques [1964-1967]. Data have shown that using larger needles (18-21G) with multiple passes could yield a higher chance of positive sperm retrieval [1967]. Complications
after TESA are uncommon and mainly include minor bleeding with scrotal haematoma and post-operative pain [1967].

As a less-invasive and less-costly procedure TESA has been proposed as a possible first-line approach before sending patients for a more-invasive procedure [1967]. To date no RCTs have compared SRRs from TESA, cTESE and mTESE. A meta-analysis including data from case-control studies, reported that TESE was two times (95% CI: 1.8-2.2) more likely to result in successful sperm retrieval as compared with TESA [1952]. Given the low success rates compared with TESE, TESA is no longer recommended in men with NOA.

- **Conventional and microTESE**

  In patients with NOA, a testicular sperm extraction procedure is required to retrieve sperm that can be utilised in ARTs. Testicular sperm extraction was first performed through a single or multiple open biopsy of the testicle (conventional TESE [cTESE]). Conventional TESE requires a scrotal incision and open biopsy of the testes [1968]. Reported SRRs in single-arm studies are about 50% [1951]. Observational studies have demonstrated that multiple biopsies yield a higher chance of sperm retrieval [1951, 1969].

  In 1999, Schlegel pioneered the use of a micro testicular extraction of sperm (mTESE) approach, which utilised an operative optical microscope to inspect seminiferous tubules at a magnification of 20-25x and extract those tubules which were larger, dilated and opaque as these were more likely to harbor sperm [1968]. The rationale of this technique is to increase the probability of retrieving sperm with a lower amount of tissue sampled and a subsequent lower risk of complications. A meta-analysis that pooled data analysis of case-control studies comparing cTESE with mTESE showed a lower unadjusted SRR of 35% (95% CI: 30-40) for cTESE and 52% for mTESE [1952]. A more recent meta-analysis comparing cTESE and mTESE in patients with NOA showed a mean SRR of 47% (95% CI: 45;49%). No differences were observed when mTESE was compared with cTESE (46 [range 43-49] % for cTESE vs. 46 [range 42-49] % for mTESE, respectively) [1970].

  Meta-regression analysis demonstrated that the SRR per cycle was independent of age and hormonal parameters at enrolment. However, the SRR increased as a function of testicular volume. Retrieved sperms resulted in a live-birth rate of up to 28% per ICSI cycle [1912]. The difference in surgical sperm retrieval outcomes between the two meta-analyses may be explained by the data studied [1952] only one analysed case control studies whilst Corona et al. [1912] also included the single randomised controlled trial), but it is important to note that all the studies comparing cTESE and mTESE have shown that the latter is superior in retrieving sperm.

  The probability of finding vital sperm at TESE varies also according to testicular histology: data from non-randomised studies comparing cTESE with mTESE have shown a higher chance of sperm retrieval with mTESE only for patients with a histological diagnosis of SCOS [1971]. In such cases, results ranged from 22.5 to 41% and from 6.3 to 29% for mTESE vs. cTESE, respectively [1971]. Conversely, no difference between the two techniques has been found when comparing patients with a histology suggestive of maturation arrest [1971]. A single study showed a small advantage of mTESE when hypospermatogenesis was found [1972]. In light of these findings, some authors have advocated that cTESE could be the technique of choice in patients with a histological finding of maturation arrest or hypo-spermatogenesis [1952, 1971].

  In a study assessing the role of salvage mTESE after a previously failed cTESE or TESA, sperm were successfully retrieved in 46.5% of cases [1857]. In studies reporting sperm retrieval by micro-TESE for men who had failed percutaneous testicular sperm aspiration or non-microsurgical testicular sperm extraction, the SRR was 39.1% (range 18.4-57.1%) [1973, 1974]. Similarly, a variable SRR has been reported for salvage mTESE after a previously failed mTESE (ranging from 18.4% to 42.8%) [1975, 1976].

  Conventional TESE has been associated with a higher rate of complications compared with other techniques [1951]. A total of 51.7% of patients have been found with intratesticular haematoma at scrotal US 3 months after surgery, with testicular fibrosis observed in up to 30% of patients at 6-months’ assessment [1977].

  A recent meta-analysis investigated the risk of hypogonadism after TESE due to testicular atrophy [1978]; patients with NOA experienced a mean 2.7 nmol/L decrease in total testosterone 6 months after cTESE, which recovered to baseline within 18-26 months. Lower rates of complications have been observed with mTESE compared to cTESE, both in terms of haematoma and fibrosis [1971]. Both procedures have shown a recovery of baseline testosterone levels after long-term follow-up [1972, 1979].
Follow-up after TESE

When compared with cTESE, mTESE has been reported to have fewer post-operative complications and negative effects on testicular function. In a recent meta-analysis analysing the complications of TESE, men with Klinefelter syndrome and NOA had the largest decrease in total testosterone levels 6 months after TESE (mean decrease of 4.1 and 2.7 nmol/L, respectively), which recovered to baseline levels 26 and 18 months after TESE, respectively [1978, 1979]. Therefore, it would be reasonable to provide long-term endocrinological follow-up after TESE (any type) to detect hypogonadism, particularly for patients with Klinefelter syndrome. Testosterone measurement could be offered in asymptomatic men at 18 months post-TESE or in those men who become symptomatic for hypogonadism after surgery [1980]. Temporary discontinuation of treatment may reveal the expected recovery of testosterone secretion and revise the decision for testosterone therapy [1981]. Human chorionic gonadotropin or selective oestrogen receptors modulators (SERMs) administration could be considered in highly selected, hypogonadal patients who have not completed their fertility attempts to increase intratesticular testosterone concentration and manage the hypogonadal symptoms [1979].

The main limitation to contemporary literature is the paucity of randomised controlled studies comparing cTESE and mTESE. Although no difference in SSR was observed between cTESE/mTESE techniques in patients with NOA in the latest and most comprehensive meta-analysis [1970], it is important to note that in all the individual trials comparing cTESE and mTESE the latter was superior in retrieving sperm. Furthermore, the current data suggests that mTESE has less complications than cTESE and therefore the consensus opinion of the guidelines panel is that mTESE is the optimum approach for surgical sperm retrieval procedures. However, this is based on low-quality evidence and larger RCTs comparing SSR, risks and costs between the two techniques are urgently needed.

Hormonal therapy prior to surgical sperm retrieval approaches

Stimulating spermatogenesis by optimising intratesticular testosterone (ITT) has been proposed to increase the chance of sperm retrieval at the time of surgery in men with NOA. Similarly, increasing FSH serum levels could stimulate spermatogenesis. There is evidence that treatment with hCG can lead to an increase in ITT [1878] and Leydig cells within the testes [1982]. It has been shown in azoospermic patients with elevated gonadotropins levels that administration of hCG and/or FSH can lead to a so-called “gonadotropins reset”, with a reduction in FSH plasma concentrations and improvement in Sertoli cells function [1983]. Similarly, clomiphene citrate may increase pituitary secretion by blocking feedback inhibition of oestradiol, thus inducing an increase in FSH and LH in patients with NOA [1984]. While azoospermic patients with secondary hypogonadism should be treated accordingly to stimulate sperm production [389], no RCT has shown a benefit of hormonal treatment to enhance the chances of sperm retrieval among patients with idiopathic NOA [1985]. In a large multicentre case-control study, 496 patients with idiopathic NOA treated with a combination of clomiphene, hCG and human menopausal gonadotropin according to hormonal profile, were compared with 116 controls subjected to mTESE without receiving any pre-operative treatment [1884]. A total of 11% of treated patients had sperm in the ejaculate at the end of treatment; of the remaining patients, 57% had positive sperm retrieval at mTESE as compared with 33% in the control group. Likewise, in a small case-control study including 50 men with idiopathic NOA, of whom 25 were treated with recombinant FSH before mTESE, there was observed a 24% SRR compared with 12% in the control group [1883]. Conversely, Gul et al. [1885] failed to find any advantage of pre-operative treatment with hCG compared with no treatment, in 34 idiopathic NOA patients candidates for mTESE.

Hormonal therapy has been proposed to increase the chance of sperm retrieval at salvage surgery after previously failed cTESE or mTESE. Retrospective data have shown that treatment with hCG and recombinant FSH could lead to a 10-15% SRR at salvage mTESE [1878, 1986]. In a small case-control study 28 NOA patients were treated with hCG with or without FSH for 4-5 months before salvage mTESE and compared with 20 controls subjected to salvage surgery [1987]. Sperm retrieval rate was 21% in the treated group compared with 0% in the control group. The histological finding of hypo-spermatogenesis emerged as a predictor of sperm retrieval after hormonal treatment [1987]. Further prospective trials are needed to elucidate the effect of hormonal treatment before salvage surgery in NOA patients, with a previously failed cTESE or mTESE. However, patients should be counselled that the evidence for the role of hormone stimulation prior to sperm retrieval surgery in men with idiopathic NOA is limited [1988]. Currently, it is not recommended in routine practice.

### 10.7 Assisted Reproductive Technologies

#### 10.7.1 Types of assisted reproductive technology

Assisted reproductive technology consists of procedures that involve the in vitro handling of both human oocytes and sperm, or of embryos, with the objective of establishing pregnancy [1989, 1990].

Once couples have been prepared for treatment, the following are the steps that make up an ART cycle:

1. Pharmacological stimulation of growth of multiple ovarian follicles, while at the same time other medications is given to suppress the natural menstrual cycle and down-regulate the pituitary gland.
2. Careful monitoring at intervals to assess the growth of the follicles.
3. Ovulation triggering: when the follicles have reached an appropriate size, a drug is administered to bring about final maturation of the eggs.
4. Egg collection (usually with a trans-vaginal US probe to guide the pickup) and, in some cases of male infertility, sperm retrieval.
5. Fertilisation process, which is usually completed by IVF or ICSI.
6. Laboratory procedures follow for embryo culture: culture media, oxygen concentration, co-culture, assisted hatching etc.
7. The embryos are placed into the uterus. Issues of importance here include endometrial preparation, the best timing for embryo transfer, how many embryos to transfer, what type of catheter to use, the use of US guidance, need for bed rest etc.
8. Luteal phase support, for which several hormonal options are available.

Fertility treatments are complex and each cycle consists of several steps. If one of the steps is incorrectly applied, conception may not occur [1989].

Several ART techniques are available:

#### 10.7.1.1 Intra-uterine insemination (IUI)

Intra-uterine insemination is an infertility treatment that involves the placement of the prepared sperm into the uterine cavity timed around ovulation. This can be done in combination with ovarian stimulation or in a natural cycle. The aim of the stimulation cycle is to increase the number of follicles available for fertilisation and to enhance the accurate timing of insemination in comparison to the natural cycle IUI [1991–1993].
Intra-uterine insemination is generally, though not exclusively, used when there is at least one patent fallopian tube with normal sperm parameters and regular ovulatory cycles (unstimulated cycles) and when the female partner is aged < 40 years.

The global pregnancy rate (PR) and delivery rate (DR) for each IUI cycle with the partner's sperm are 12.0% and 8.0%, respectively. Using donor sperm, the resultant PR and DR per cycle are 17.0% and 12.3%, respectively [1994]. The rates of successful treatment cycles for patients decrease with increase in age, and the birth rates across all age groups have remained broadly stable over time. The highest birth rates have been reported in patients younger than 38 years (14% in patients aged < 35 years and 12% in those aged 35-37 years). The rates of successful treatment are low for patients older than 42 years. The multiple pregnancy rate (MPR) for IUI is ~8% [1992]. Intra-uterine insemination is not recommended in couples with unexplained infertility, male factor infertility and mild endometriosis, unless the couples have religious, cultural or social objections to proceed with IVF [1995].

Intra-uterine insemination with ovarian stimulation is a safer, cheaper, more patient-friendly and non-inferior alternative to IVF in the management of couples with unexplained and mild male factor infertility [1991, 1992]. A recent RCT showed lower multiple pregnancy rates and comparable live-birth rates in patients treated with IUI with hormonal stimulation when compared to women undergoing IVF with single embryo transfer [1996]. Additionally, IUI is a more cost-effective treatment than IVF for couples with unexplained or mild male subfertility [1997].

10.7.1.2 In vitro fertilisation (IVF)

Involves using controlled ovarian hyperstimulation to recruit multiple oocytes during each cycle from the female partner. Follicular development is monitored ultrasonically, and ova are harvested before ovulation with the use of US-guided needle aspiration. The recovered oocytes are mixed with processed semen to perform IVF. The developing embryos are incubated for 2-3 days in culture and then placed trans-cervically into the uterus.

The rapid refinement of embryo cryopreservation methods has resulted in better perinatal outcomes of frozen-thawed embryo transfer (FET) and makes it a viable alternative to fresh embryo transfer (ET) [1998, 1999]. Frozen-thawed embryo transfer seems to be associated with lower risk of gestational complications than fresh ET. Individual approaches remain appropriate to balance the options of FET or fresh ET at present [2000].

Generally, only 20%-30% of transferred embryos result in clinical pregnancies. The global PR and DR per aspiration for non-donor IVF is 24.0% and 17.6%, respectively [1994].

According to the NICE guidelines, IVF treatment is appropriate in cases of unexplained infertility for women who have not conceived after 2 years of regular unprotected sexual intercourse [2001].

10.7.1.3 Intracytoplasmic sperm injection

Intracytoplasmic sperm injection is a procedure through which a single sperm is injected directly into an egg using a glass micropipette.

The difference between ICSI and IVF is the method used to achieve fertilisation. In conventional IVF, oocytes are incubated with sperm in a Petri dish, and the male gamete fertilises the oocyte naturally. In ICSI, the cumulus-oocyte complexes go through a denudation process in which the cumulus oophorus and corona radiata cells are removed mechanically or by an enzymatic process. This step is essential to enable microscopic evaluation of the oocyte regarding its maturity stage, as ICSI is performed only in metaphase II oocytes [2002]. A thin and delicate glass micropipette (injection needle) is used to immobilise and pick up morphologically normal sperm selected for injection. A single spermatozoon is aspirated by its tail into the injection needle, which is inserted through the zona pellucida into the oocyte cytoplasm. The spermatozoon is released at a cytoplasmic site sufficiently distant from the first polar body. During this process, the oocyte is held still by a glass micropipette [2002].

With this technique the oocyte can be fertilised independently of the morphology and/or motility of the spermatozoon injected.

Intracytoplasmic sperm injection is currently the most commonly used ART, accounting for 70–80% of the cycles performed [2003].

The procedure was first used in cases of fertilisation failure after standard IVF or when an inadequate number of sperm cells was available. The consistency of fertilisation independent of the functional quality of the
spermatozoa has extended the application of ICSI to immature spermatozoa retrieved surgically from the epididymis and testis [2004]. Intracytoplasmic sperm injection is the natural treatment for couples with severe male factor infertility and is also used for a number of non-male factor indications (Table 44) [2005].

The need to denude the oocyte allows assessment of the nuclear maturity of the oocyte. Intracytoplasmic sperm injection is also preferred in conjunction with pre-implantation genetic diagnosis and has recently been used to treat HIV discordant couples, in whom there is a pressing need to minimise exposure of the oocyte to a large number of spermatozoa [2004].

The global PR and DR per aspiration for ICSI is 26.2% and 19.0%, respectively [1994]. For all ages and with all the different sperm types used, fertilisation after ICSI is at approximately 70%-80% and it ensures a clinical pregnancy rate of up to 45% [2003, 2004].

Existing evidence does not support ICSI in preference over IVF in the general non-male factor ART population; however, in couples with unexplained infertility, ICSI is associated with lower fertilisation failure rates than IVF [2005].

Overall, pregnancy outcomes from ICSI are comparable between epididymal and testicular sperm and also between fresh and frozen–thawed epididymal sperm in men with OA [2006]. However, these results are from studies of low evidence [2005].

Sperm injection outcomes with fresh or frozen–thawed testicular sperm have been compared in men with NOA. In a meta-analysis of 11 studies and 574 ICSI cycles, no significant difference was observed between fresh and frozen–thawed testicular sperm with regards to fertilisation rate (RR: 0.97, 95% CI: 0.92–1.02) and clinical pregnancy rates (RR: 1.00, 95% CI: 0.75–1.33) [2007]. However, no meta-analysis was performed on data regarding implantation, miscarriage, and low-birth rates.

10.7.1.4 Testicular sperm in men with raised DNA fragmentation in ejaculated sperm
The use of testicular sperm for ICSI is associated with possibly improved outcomes compared with ejaculated sperm in men with high sperm DNA fragmentation [1535, 2005]. Men with unexplained infertility with raised DNA fragmentation may be considered for TESE after failure of ART, although they should be counselled that live-birth rates are under reported in the literature and patients must weigh up the risks of performing an invasive procedure in a potentially normozoospermic or unexplained condition. The advantages of the use of testicular sperm in men with cryptozoospermia have not yet been confirmed in large scale randomised studies [2008].

In terms of a practical approach, urologists may offer the use of testicular sperm in patients with high DNA fragmentation. However, patients should be counselled regarding the low levels of evidence for this (i.e., non-randomised studies). Furthermore, testicular sperm should only be used in this setting once the common causes of oxidative stress have been excluded including varicoceles, modifications of dietary/lifestyle factors and treatment of accessory gland infections.

ICSI = intracytoplasmic sperm injection; IVF = in vitro fertilisation; OAT = oligo-asthenoteratozoospermia

Intracytoplasmic sperm injection is carried out using viable sperm populations. Several semen processing techniques have been developed to select the optimal sperm fraction for ICSI. Density gradient centrifugation (DGC) and the swim-up procedures have been used as standards for semen preparation for ICSI for more than two decades [2010]. However, these traditional sperm selection techniques are unable to select sperm fractions with optimal DNA integrity and functional characteristics. Advanced sperm selection techniques have been introduced to optimise the selection of high-quality sperm for ICSI [2011]. These selection methods are based on sperm surface charge (electrophoresis and zeta potential), apoptosis (magnetic-activated sperm cell sorting (MACS) and glass wool), membrane maturity (hyaluronic acid binding), or ultra-morphological sperm assessment [2012].

10.7.1.4 Intra-cytoplasmic morphologically selected sperm injection

Intra-cytoplasmic morphologically selected sperm injection (IMSI) was first introduced in 2002 as a modification of the ICSI technique [2013]. This technique increases the magnification of sperm to > 6,000 times; the purpose of which is to perform the motile sperm organelle morphology examination (MSOME), a method used to select spermatozoa that have the choicest morphology in couples with the most severe male factor. Bartoov et al. showed that, for patients with a history of ICSI failure, addition of IMSI resulted in a 60% pregnancy rate, compared with a 30% rate for patients not using IMSI [2014]. The pregnancy rate following IVF-IMSI was significantly higher and the miscarriage rate significantly lower, than for the routine IVF-ICSI procedure (60.0% vs. 25.0%, and 14% vs. 40%, respectively) [2015]. However, the most recently updated Cochrane review neither supported nor refuted the clinical use of IMSI [2016].

10.7.1.5 Physiological ICSI (PICSI) technique: a selection based on membrane maturity of sperm

The Human oocytes are surrounded by hyaluronic acid (HA), which acts as a natural selector. Only mature sperm that express receptors specific to HA can reach the oocytes and fertilise them. Those sperm have normal shapes, low DNA fragmentation rates, and low frequency of chromosomal aneuploidy [2017]. Several studies have attempted to verify whether sperm selection based on HA binding affects IVF outcomes. A meta-analysis included six prospective randomised studies and one retrospective study, all of which used a PICSI sperm-selection dish (a plastic culture dish with microdots of HA hydro gel on its inner surface) or the Sperm Slow method (a viscous medium containing HA). No improvements in fertilisation and pregnancy rates were recorded, although embryo quality was superior in PICSI compared with conventional ICSI [2017]. A recent large-sample multicentre randomised trial provided conclusive evidence against the use of PICSI in ART (PICSI live-birth rate vs. ICSI: OR: 1.12, 95% CI: 0.95–1.34) [2018]. A time-lapse study found no difference in embryo development dynamics in oocytes fertilised via HA-ICSI vs. conventional ICSI [2019].

10.7.1.6 Magnetic-activated cell sorting

Magnetic-activated cell sorting (MACS) is an advanced sperm-selection technique used to isolate sperm that do not show signs of apoptosis and, therefore, are presumed to have a lower rate of DNA damage [2011]. Use of MACS after density gradient centrifugation (DGC) has been found to improve sperm morphology and decrease DNA fragmentation and apoptotic markers, but it reduces motility of the selected sperm [2011, 2012]. Magnetic-activated cell sorting failed to improve ICSI outcomes compared with DGC or swim-up, although a slightly higher pregnancy rate (RR: 1.5, 95% CI: 1.14–1.98) was observed in MACS patients relative to the control group [2020]. No difference in implantation or miscarriage rate was noted (RR: 1.03, 95% CI: 0.8–1.31 and RR: 2, 95% CI: 0.19–20.9, respectively).
Finally, another RCT performed on infants conceived via ovum-donation IVF cycles did not report any differences in terms of obstetrical and perinatal outcomes between pregnancies or babies conceived with sperm selected via MACS or swim-up [2021].

10.7.2 Safety
The most significant risk of pre-implantation ART treatment is the ovarian hyperstimulation syndrome, a potentially life-threatening condition resulting from excessive ovarian stimulation during ART techniques, ranging from 0.6% to 5% in ART cycles [2022].

Other problems include the risk of multiple pregnancies due to the transfer of more than one embryo and the associated risks to mother and baby, including multiple and preterm birth. The most prevalent maternal complications include pre-eclampsia, gestational diabetes, placenta previa, placental abruption, postpartum haemorrhage, and preterm labour and delivery [1956, 2023, 2024]. The risks of foetal demise during the third trimester, perinatal mortality, preterm birth, and low birth weight increase with the number of foetuses in the pregnancy. The foetal consequences of preterm birth (cerebral palsy, retinopathy, and broncho-pulmonary dysplasia) and foetal growth restriction (polycythaemia, hypoglycaemia, and necrotising enterocolitis) are significant [2025].

The average number of embryos transferred in fresh non-donor IVF and ICSI cycles in 2011 was 1.91, compared with 2.09 in 2008, 2.00 in 2009, and 1.95 in 2010, reflecting a continuing decrease from previous years. The average number of embryos transferred in frozen ET cycles decreased from 1.72 in 2008 to 1.65 in 2009 to 1.60 in 2010 and to 1.59 in 2011 [2026].

The global multiple birth rate for fresh cycle transfer has decreased from 21.5% in 2010 to 20.5% in 2011 and for frozen ET cycles from 12.0% to 11.5% [1994].

In 2011, the rate of early pregnancy loss was 20.1% after fresh ET, compared with 25.4% after frozen ET. Both rates showed wide regional variation [1994]. The multiple birth rates after fresh non-donor ET was 19.6% (twins) and 0.9% (triplets and higher-order births); for frozen ET non-donor cycles, twin and triplet and higher-order birth rates were 11.1% and 0.4%, respectively [1994].

Rates of premature delivery and perinatal mortality were lower for frozen ETs than for fresh ETs. The global perinatal mortality rate per 1,000 births after non-donor fresh ET was 19.1%, and after frozen ET was 13.1%. The perinatal mortality rate per 1,000 births after non-donor fresh ET was 16.3 and after frozen ET was 8.6.

In terms of potential adverse effect, ICSI-conceived offspring has a greater neonatal morbidity, obstetric complications and congenital malformations, compared with spontaneous conception [2027-2029]. Additionally, epigenetic disorders and impaired neurodevelopment have been observed in infants born using ICSI compared with naturally conceived children [2005]. Among singleton infants born at 37 weeks of gestation or later, those following IVF had a risk of low birth weight that was 2.6 times (95% CI: 2.4–2.7) greater than in the general population (absolute risk of low birth weight with spontaneous vs. resulting from IVF was 2.5% vs. 6.5%) [1636]. Singleton infants after IVF were 39% more likely (adjusted RR: 1.39, 95% CI: 1.21–1.59) to have a non-chromosomal birth defect (particularly gastrointestinal and musculoskeletal) compared with all other singleton births. No single ART procedure (e.g., ICSI, fresh, or frozen ETs) was found to substantially increase the risk of birth defects.

Analyses from the Massachusetts Outcome Study of ART reported a 50% increase (adjusted prevalence ratio of 1.5, 95% CI: 1.3–1.6) in birth defects in infants after IVF vs. spontaneous pregnancy, and a 30% increase (adjusted prevalence ratio of 1.3, 95% CI: 1.1–1.5) in birth defects in infants after subfertility vs. spontaneous pregnancy [2030-2032]. No difference in risk of cancer was found between ART-conceived children and those spontaneously conceived [2033].

Analyses from the Massachusetts Outcome Study of ART reported a 50% increase (adjusted prevalence ratio of 1.5, 95% CI: 1.3–1.6) in birth defects in infants after IVF vs. spontaneous pregnancy, and a 30% increase (adjusted prevalence ratio of 1.3, 95% CI: 1.1–1.5) in birth defects in infants after subfertility vs. spontaneous pregnancy [2030-2032]. No difference in risk of cancer was found between ART-conceived children and those spontaneously conceived [2033].

Health differences between ICSI and IVF conceptions have not been comprehensively assessed and results are contradictory. Some authors found a significantly reduced risk of birth defects in IVF compared to ICSI conceived infants [1639], while two meta-analyses demonstrated no difference in risk of congenital malformations between IVF and ICSI conception [1642, 2034]. Data about ICSI- and IVF-conceived adolescents or young adults are scarce but it seems that there is no difference in outcomes between the two techniques. Further research into health outcomes in adolescence and adulthood is required before conclusions can be drawn about the long-term safety of ICSI compared to IVF [2035].
10.8 Psychosocial aspects in men's infertility

Male infertility impacts men's psychological well-being in different ways. It results in emotional distress and challenges men's sense of identity. Factors such as personality style, sociocultural background, and treatment specificities (e.g., repeated cycles, treatment side-effects), may determine men's adjustment to infertility [2036]. The effects may be particularly worst in socially isolated men, with an avoidant coping style [2037]. Infertility-associated distress and psychiatric morbidity in men are further related to the male and mixed factor and increases after the clinical diagnosis [2038]. Within this regard, special attention has been given to men's psychological adaptation after the failure of medically assisted reproduction treatments. While the risk factors for emotional maladjustment encompass difficulties in couples’ communication or avoidance/religious coping style from the female partner, the protective factors include seeking information, reframe infertility by assigning it a positive meaning, having social and spouse support, and talk openly about the infertility issue [2039].

It is worth noting that a failed treatment often results in a prolonged grief response, requiring post-treatment psychological support [2040]. Indeed, the literature supports the relevance of addressing men's psychological needs, as a means to reduce the impact of infertility treatments across all of its stages. The mental health expert is thus regarded as part of the infertility intervention team, acting in all intervention stages, using strategies that may range from psycho-education techniques to more comprehensive psycho-therapeutic approaches [2041]. Furthermore, there should be a deeper focus on preventive policies; It has been recognised that men, such as women, want to become parents. Yet, they have very limited knowledge on infertility related risk factors, including a lack of awareness on the age-related decline in fertility, and tend to overestimate the chance of spontaneous conception [2042, 2043].

11. LATE EFFECTS, SURVIVORSHIP AND MEN’S HEALTH

The EAU Guidelines Panel of Sexual and Reproductive Health have extensively reviewed the literature to provide guidance on: (i) late effects of urological diseases (both occurring during childhood and adulthood) on male sexual and reproductive health; (ii) late and long-term effects of cancers on male sexual and reproductive health; and, (iii) future directions to support personalised medicine strategies for promotion and raising the awareness of male sexual and reproductive health overall.

A systematic literature search for original English-language publications and review articles published up to December 2019 and a further search up to December 2020 were performed using both Pubmed and Google, yielding only a limited number of papers addressing the role of health care professionals in supporting male patients who have suffered from cancers in terms of sexual and reproductive health, or the concept of Men’s Health programmes.

Despite considerable public health initiatives over the past few decades, the Panel has observed that there is still a significant gender gap between male and female in life expectancy [2044]. The main contributors to male mortality in Europe are non-communicable diseases (namely CVDs, cancer, diabetes and respiratory disease) and injuries [1679], as highlighted in a recent WHO report disproving the prevailing misconception that the higher rate of premature mortality among men is a natural phenomenon [2044, 2045]. The recent pandemic situation linked with SARS-CoV-2 infection associated diseases (COVID-19) further demonstrates how the development of strategies dedicated to male health is of fundamental importance [61].

The WHO report also addresses male sexual and reproductive health which is considered under-reported, linking in particular male infertility, as a proxy for overall health, to serious diseases in men [1934, 1939, 1940, 2046-2048]. These data suggest that health care policies should redirect their focus to preventive strategies and in particular pay attention to follow-up of men with sexual and reproductive complaints [1942, 2049].

Considering that infertile men seem to be at greater risk of death, simply because of their inability to become fathers, is unacceptable [1943]. The Panel aims to develop a concept of a more streamlined and holistic approach to men’s health.

For these guidelines, the Panel aimed to challenge clinicians to look beyond the pathology of disorders alone and consider the potential associations with other health disorders. Men with varicoceles have a higher incidence of heart disease and higher risk of diabetes and hyperlipidaemia following diagnosis [2049]. A diagnosis of infertility may have a profound psychological impact on men (and their partners), potentially...
resulting in anxiety, enduring sadness, anger, and a sense of personal inadequacy and “unmet masculinity” [2038]. A combination of factors, personality, sociocultural background, and specific treatments/professional support, will determine how men cope with this diagnosis [2041].

The most common cancer among European men (excluding non-melanoma skin cancer) is PCa [399]. Due to new therapeutic approaches, survival rates have improved significantly [2050] and as men live longer, health-related quality of life and related sexual well-being will become increasingly important [389]. Regardless of the type of treatment used [1692], sexual dysfunction and distress are common post-treatment complications [390, 2051-2053].

Furthermore, little is known about the relevance of fertility and fertility-preservation strategies in cancer survivors [1931, 2054-2057]. In PCa, it has been documented that the psychological consequences persist, even after complete remission or cure and erectile function is restored [2058]. In addition, special attention must be given to gay and bisexual men with PCa; these men present specific sexual concerns steaming from heteronormativity standards that have a negative impact in health care quality [2059]. Therefore urologists dealing with sexual and reproductive health are primed to act as a vanguard for cancer survivorship programmes.

Finally, the relationship between ED and heart disease has been firmly established for well over two decades [315, 316, 318, 2060-2063]. Cardiovascular disease is the leading cause of both male mortality and premature mortality [2064-2067]. Studies indicate that all major risk factors for CVD, including hypertension, smoking and elevated cholesterol are more prevalent in men than women [2068-2074]. Given that ED is an established early sign of atherosclerotic disease and predicts cardiovascular events as an independent factor [318], it provides urologists with the unique opportunity for CVD screening and health modification and optimise CVD risk factors, while treating men's primary complaint (e.g., ED). Currently, both the EAU and AUA guidelines recommend screening for CVD risk factors in men with ED and late onset hypogonadism [2075-2077] (see Sections 3.7.3 and 5.2).

There is clearly a need to prospectively collect data addressing all aspects of male health, including CVD screening protocols and assess the impact of primary and secondary preventive strategies. The EAU Sexual and Reproductive Health Guidelines Panel aims to promote and develop a long-term strategy to raise men's health at a global level.

6. CITATION INFORMATION
1. INTRODUCTION

1.1 Aim and objectives
The European Association of Urology (EAU) Urological Infections Guidelines Panel has compiled these clinical guidelines to provide medical professionals with evidence-based information and recommendations for the prevention and treatment of urinary tract infections (UTIs) and male accessory gland infections. These guidelines also aim to address the important public health aspects of infection control and antimicrobial stewardship. Separate EAU guidelines documents are available addressing paediatric urological infections [1] and infections in patients with neurological urinary tract dysfunction [2].

It must be emphasised that clinical guidelines present the best evidence available to the experts. However, following guideline recommendations will not necessarily result in the best outcome. Guidelines can never replace clinical expertise when making treatment decisions for individual patients, but rather help to focus decisions - also taking personal values and preferences/individual circumstances of patients into account. Guidelines are not mandates and do not purport to be a legal standard of care.

1.2 Panel composition
The EAU Urological Infections Guidelines Panel consists of a multi-disciplinary group of urologists, with particular expertise in this area, an infectious disease specialist and a clinical microbiologist. All experts involved in the production of this document have submitted potential conflict of interest statements, which can be viewed on the EAU website Uroweb: http://uroweb.org/guideline/urological-infections/.

1.3 Available publications
A quick reference document, the Pocket Guidelines, is available in print and as an app for iOS and Android devices. These are abridged versions, which may require consultation together with the full text version. All documents are accessible through the EAU website Uroweb: http://uroweb.org/guideline/urological-infections/.

1.4 Publication history
The Urological Infections Guidelines were first published in 2001. This 2022 document presents a limited update of the 2021 publication.

2. METHODS

2.1 Introduction
For the 2022 Urological Infections Guidelines, new and relevant evidence was identified, collated and appraised through a structured assessment of the literature for sections 3.5 Recurrent UTI, 3.12 Acute Infective Epididymitis and 3.15 Peri-Procedural Antibiotic Prophylaxis. Broad and comprehensive literature searches, covering these sections were performed. Databases searched included Medline, EMBASE, and the Cochrane Libraries. The time frames covered and the number of unique records identified, retrieved and screened for relevance for each section were:

<table>
<thead>
<tr>
<th>Section</th>
<th>No. of unique records</th>
<th>Search time frame</th>
</tr>
</thead>
<tbody>
<tr>
<td>3.5 Recurrent UTI</td>

</table>

Detailed search strategies are available online: http://uroweb.org/guideline/urological-infections/?type=appendices-publications.
The 2022 edition of the EAU Guidelines uses a modified GRADE methodology [3]. For each recommendation within the guidelines there is an accompanying online strength rating form which addresses a number of key elements namely:

1. the overall quality of the evidence which exists for the recommendation, references used in this text are graded according to a classification system modified from the Oxford Centre for Evidence-Based Medicine Levels of Evidence [4];
2. the magnitude of the effect (individual or combined effects);
3. the certainty of the results (precision, consistency, heterogeneity and other statistical or study related factors);
4. the balance between desirable and undesirable outcomes;
5. the impact of patient values and preferences on the intervention;
6. the certainty of those patient values and preferences.

These key elements are the basis which panels use to define the strength rating of each recommendation. The strength of each recommendation is represented by the words ‘strong’ or ‘weak’ [5]. The strength of each recommendation is determined by the balance between desirable and undesirable consequences of alternative management strategies, the quality of the evidence (including certainty of estimates), and nature and variability of patient values and preferences.

Additional information can be found in the general Methodology section of this print, and on the EAU website; http://www.uroweb.org/guideline/. A list of associations endorsing the EAU Guidelines can also be viewed online at the above address.

2.2 Review
This document was subject to independent peer review prior to publication in 2019.

3. THE GUIDELINE

3.1 Classification
Different classification systems of UTI exist. Most widely used are those developed by the Centres for Disease Control and Prevention (CDC) [6], Infectious Diseases Society of America (IDSA) [7], European Society of Clinical Microbiology and Infectious Diseases (ESCMID) [8] as well as the U.S. Food and Drug Administration (FDA) [9, 10]. Current UTI guidelines frequently use the concept of uncomplicated and complicated UTI with a number of modifications (Figure 1). In 2011 the EAU Section of Infections in Urology proposed the ORENUC classification system based on the clinical presentation of the UTI, the anatomical level of the UTI, the grade of severity of the infection, the categorisation of risk factors and availability of appropriate antimicrobial therapy [11].

Figure 1: Concept of uncomplicated and complicated UTI
The following classification of UTIs is adopted in the EAU Urological Infections Guidelines:

<table>
<thead>
<tr>
<th>Classification of UTI</th>
<th>Definition</th>
</tr>
</thead>
<tbody>
<tr>
<td>Uncomplicated UTIs</td>
<td>Acute, sporadic or recurrent lower (uncomplicated cystitis) and/or upper (uncomplicated pyelonephritis) UTI, limited to non-pregnant women with no known relevant anatomical and functional abnormalities within the urinary tract or comorbidities.</td>
</tr>
<tr>
<td>Complicated UTIs</td>
<td>All UTIs which are not defined as uncomplicated. Meaning in a narrower sense UTIs in a patient with an increased chance of a complicated course: i.e. all men, pregnant women, patients with relevant anatomical or functional abnormalities of the urinary tract, indwelling urinary catheters, renal diseases, and/or with other concomitant immunocompromising diseases for example, diabetes.</td>
</tr>
<tr>
<td>Recurrent UTIs</td>
<td>Recurrences of uncomplicated and/or complicated UTIs, with a frequency of at least three UTIs/year or two UTIs in the last six months.</td>
</tr>
<tr>
<td>Catheter-associated UTIs</td>
<td>Catheter-associated urinary tract infection (CA-UTI) refers to UTIs occurring in a person whose urinary tract is currently catheterised or has had a catheter in place within the past 48 hours.</td>
</tr>
<tr>
<td>Urosepsis</td>
<td>Urosepsis is defined as life threatening organ dysfunction caused by a dysregulated host response to infection originating from the urinary tract and/or male genital organs [12].</td>
</tr>
</tbody>
</table>

3.2 Antimicrobial Stewardship

Although the benefits to patients of antibiotic use are clear, overuse and misuse have contributed to the growing problem of resistance amongst uropathogenic bacteria, which is a serious threat to public health [13, 14]. In acute care hospitals, 20-50% of prescribed antibiotics are either unnecessary or inappropriate [15]. In response, a worldwide initiative seeks to incorporate Antimicrobial Stewardship programs in healthcare [16]. Antimicrobial Stewardship aims to optimise clinical outcomes and ensure cost-effective therapy whilst minimising unintended consequences of antimicrobial use such as healthcare associated infections including *Clostridium difficile*, toxicity, selection of virulent organisms and emergence of resistant bacterial strains [17].

Stewardship programs have two main sets of actions. The first set mandates use of recommended care at the patient level conforming to guidelines. The second set describes strategies to achieve adherence to the mandated guidance. These include persuasive actions such as education and feedback together with restricting availability linked to local formularies. A Cochrane review of effectiveness of interventions to improve antibiotic prescribing practices for hospital inpatients, updated in 2017, found high-certainty evidence that such interventions are effective in increasing adherence with antibiotic policy leading to reduced antibiotic treatment duration and that it may also reduce hospital stay. The review found no evidence that reduced antibiotic usage increased mortality [18].

The important components of antimicrobial stewardship programs are [19]:

- regular training of staff in best use of antimicrobial agents;
- adherence to local, national or international guidelines;
- regular ward visits and consultation with infectious diseases physicians and clinical microbiologists;
- audit of adherence and treatment outcomes;
- regular monitoring and feedback to prescribers of their performance and local pathogen resistance profiles.

A 2016 systematic review of evidence for effectiveness of various Antimicrobial Stewardship interventions in healthcare institutions identified 145 studies of nine Stewardship objectives. Guideline-driven empirical therapy using a restricted choice of antibiotics and including de-escalation, intravenous to oral switch, therapeutic drug monitoring, and bedside consultation resulted in a 35% (95% CI 20–46%) relative risk reduction (RRR) in mortality. Use of de-escalation (tailoring to a more narrow spectrum agent), showed a RRR of 56% (95% CI 34 – 70%) for mortality [20].

To facilitate local initiatives and audit, a set of valid, reliable, and applicable indicators of the quality of antibiotic use in the treatment of hospitalised patients with complicated UTI was developed [21]. Its use in the Netherlands appeared to result in shortened hospital stay [22]. A literature search of Pubmed from April 2014 [20], to February 2017 identified no further randomised controlled trials (RCTs) relating to stewardship...
programmes for UTIs. Studies to provide high-quality evidence of effectiveness of Stewardship programmes in urology patients are urgently needed.

3.3  **Asymptomatic bacteriuria in adults**

3.3.1  **Background**

Urinary growth of bacteria in an asymptomatic individual (asymptomatic bacteriuria - ABU) is common, and corresponds to a commensal colonisation [23]. Clinical studies have shown that ABU may protect against superinfecting symptomatic UTI, thus treatment of ABU should be performed only in cases of proven benefit for the patient to avoid the risk of selecting antimicrobial resistance and eradicating a potentially protective ABU strain [24, 25]. The aim of this section is to support the clinician in deciding when ABU should or should not be treated.

3.3.2  **Epidemiology, aetiology and pathophysiology**

Asymptomatic bacteriuria occurs in an estimated 1-5% of healthy pre-menopausal females. Increasing to 4-19% in otherwise healthy elderly females and men, 0.7-27% in patients with diabetes, 2-10% in pregnant women, 15-50% in institutionalised elderly populations, and in 23-89% in patients with spinal cord injuries [26]. Asymptomatic bacteriuria in younger men is uncommon, but when detected, chronic bacterial prostatitis must be considered. The spectrum of bacteria in ABU is similar to species found in uncomplicated or complicated UTIs, depending on the presence of risk factors (see sections 3.4 and 3.7).

3.3.3  **Diagnostic evaluation**

Asymptomatic bacteriuria in an individual without urinary tract symptoms is defined by a mid-stream sample of urine showing bacterial growth > 10^5 cfu/mL in two consecutive samples in women [27] and in one single sample in men [28]. In a single catheterised sample, bacterial growth may be as low as 10^2 cfu/mL to be considered representing true bacteriuria in both men and women [26, 29]. Cystoscopy and/or imaging of the upper urinary tract is not mandatory if the medical history is otherwise without remark. If persistent growth of urease producing bacteria, i.e. *Proteus mirabilis* is detected, stone formation in the urinary tract must be excluded [30]. In men, a digital rectal examination (DRE) has to be performed to investigate the possibility of prostate diseases (see section 3.11).

3.3.4  **Evidence summary**

A systematic search of the literature from January 2000 to November 2016 identified 3,582 titles of which 224 were selected for full text review and 50 were included [31]. For the subgroups of pregnancy, prior to urologic surgeries, post-menopausal women and institutionalised elderly patients only data from RCTs were included, on which a meta-analysis was performed [31]. For the other subgroups non-RCTs were also included in the narrative analysis [31]. The following patient populations were not covered by the systematic review: immuno-compromised patients; patients with candiduria; patients with dysfunctional and/or reconstructed lower urinary tracts; and patients with indwelling catheters. For these groups the guideline was updated using a structured literature search. The evidence question addressed was: What is the most effective management for people with asymptomatic bacteriuria?

3.3.5  **Disease management**

3.3.5.1  **Patients without identified risk factors**

Asymptomatic bacteriuria does not cause renal disease or damage [32]. Only one prospective, non-randomised study investigated the effect of treatment of ABU in adult, non-diabetic, non-pregnant women [33], and found no difference in the rate of symptomatic UTIs. Furthermore, as the treatment of ABU has been proven to be unnecessary in most high-risk patient subgroups, there is panel consensus that the results of these subgroups can also be applied to patients without identified risk factors. Therefore, screening and treatment of ABU is not recommended in patients without risk factors.

3.3.5.2  **Patients with ABU and recurrent UTI, otherwise healthy**

One RCT investigated the effect of ABU treatment in female patients with recurrent symptomatic UTI without identified risk factors [25] and demonstrated that treatment of ABU increases the risk for a subsequent symptomatic UTI episode, compared to non-treated patients (RR 0.28, 95% CI 0.21 to 0.38; n=673). This protective effect of spontaneously developed ABU can be used as part of prevention in female patients with recurrent symptomatic UTI; therefore, treatment of ABU is not recommended.
3.3.5.3 Pregnant women

3.3.5.3.1 Is treatment of ABU beneficial in pregnant women?

Twelve RCTs comparing antibiotic treatments of ABU with placebo controls or no treatment [34-45], with different antibiotic doses and regimens were identified, ten published before 1988 and one in 2015. Eleven RCTs (n=2,002) reported on the rate of symptomatic UTIs [34, 36-44, 46]. Antibiotic treatment significantly reduced the number of symptomatic UTIs compared to placebo or no treatment (average RR 0.22, 95% CI 0.12 to 0.40).

Six RCTs reported on the resolution of bacteriuria [34-36, 38, 41, 43]. Antibiotic treatment was effective in the resolution of bacteriuria compared to placebo (average RR 2.99, 95% CI 1.65 to 5.39; n=716). Eight RCTs reported on the rate of low birthweights [34, 36-39, 42, 45, 46]. Antibiotic treatment was associated with lower rates of low birthweight compared to placebo or no treatment (average RR 0.58, 95% CI 0.36 to 0.94; n=1,689). Four RCTs reported on the rate of preterm deliveries [42, 43, 45, 46]. Antibiotic treatment was associated with lower rates of preterm delivery compared to placebo or no treatment (average RR 0.34, 95% CI 0.18 to 0.66; n=854).

Based on the beneficial maternal and foetal effects of antibiotic treatment pregnant women should be screened and treated for ABU. However, the panel would like to emphasise that most available studies have low methodological quality and are from the 60s to 80s. Diagnostic and treatment protocols and accessibility to medical services have dramatically changed since then; therefore, the quality of evidence for this recommendation is low. In a newer study of higher methodological quality the beneficial effects of antibiotic treatment are not as evident [46]. Therefore, it is advisable to consult national recommendations for pregnant women.

3.3.5.3.2 Which treatment duration should be applied to treat ABU in pregnancy?

Sixteen RCTs comparing the efficacy of different antibiotic treatments in pregnant women with ABU were identified [47-62]. There was significant heterogeneity amongst the studies. Studies compared different antibiotic regimens or the same antibiotic regimens with different durations. The duration of treatment ranged from single dose to continuous treatment (until delivery). For practical purposes the grouping strategy used by the previously published Cochrane review by Widmer et al., was adopted with some modifications [63]. The following treatment groups were used for comparison:

1. single dose (single day);
2. short course (2-7 days);
3. long course (8-14 days);
4. continuous (until delivery).

Nine studies compared single dose to short course treatment [48, 52, 53, 57-62], one study compared single dose to long course treatment [56] and one study compared long course to continuous treatment [49]. As long term and continuous antibiotic treatment is not used in current practice, only studies comparing single dose to standard short course treatment are presented.

3.3.5.3.2.1 Single dose vs. short course treatment

Three RCTs reported on the rate of symptomatic UTIs [52, 61, 62], with no significant difference between the two durations (average RR 1.07, 95% CI 0.47 to 2.47; n=891). Nine RCTs reported on the rate of ABU resolution [48, 52, 53, 57-62], with no significant difference between the two durations (average RR 0.97, 95% CI 0.89 to 1.07; n=1,268). Six RCTs reported on the rate of side effects [48, 52, 57, 58, 60, 61]. Single dose treatment was associated with significantly less side effects compared to short course treatment (average RR 0.40, 95% CI 0.22 to 0.72; n=458). Three RCTs reported on the rate of preterm deliveries [52, 54, 62], with no significant difference between the two durations (average RR 1.16, 95% CI 0.75 to 1.78; n=814). One RCT reported on the rate of low birthweights [62]. There were significantly more babies with low birthweight in the single dose duration compared to short course treatment (average RR 1.65, 95% CI 1.06 to 2.57; n=714).

According to the data analysis, single dose treatment was associated with a significantly lower rate of side effects but a significantly higher rate of low birthweight. Therefore, standard short course treatment should be applied to treat ABU in pregnancy; however, it should be emphasised that the overall quality of the scientific evidence underpinning this recommendation is low.

3.3.5.4 Patients with identified risk-factors

3.3.5.4.1 Diabetes mellitus

Diabetes mellitus, even when well regulated, is reported to correlate to a higher frequency of ABU [64]. One RCT demonstrated that eradicating ABU did not reduce the risk of symptomatic UTI and infectious complications in patients with diabetes mellitus. The time to first symptomatic episode was also similar in both
groups. Furthermore, untreated ABU did not correlate to diabetic nephropathy [65]. Screening and treatment of ABU in well-controlled diabetes mellitus is therefore not recommended. However, poorly regulated diabetes is a risk factor for symptomatic UTI and infectious complications.

3.3.5.4.2 ABU in post-menopausal women
Elderly women have an increased incidence of ABU [66]. Four RCTs compared antibiotic treatment of ABU with placebo controls or no treatment, in a post-menopausal female population, with different antibiotic doses and regimens [67-70]. Women in these studies were mostly nursing home residents, which may bias the results of this analysis. Three RCTs reported on the rate of symptomatic UTIs (average RR 0.71, 95% CI 0.49 to 1.05; n=208) and the resolution of bacteriuria (average RR 1.28, 95% CI 0.50 to 3.24; n=203) [52, 61, 62], with no significant benefit of antibiotic treatment. Therefore, ABU in post-menopausal women does not require treatment, and should be managed as for pre-menopausal women.

3.3.5.4.3 Elderly institutionalised patients
The rate of ABU is 15-50% in elderly institutionalised patients [71]. Differential diagnosis of ABU from symptomatic UTI is difficult in the multi-diseased and mentally deteriorated patient, and is probably a cause of unnecessary antibiotic treatment [72, 73]. Seven RCTs compared antibiotic treatment of ABU with placebo controls or no treatment in elderly patients, with different antibiotic doses and regimens [67-70, 74-76].

Three RCTs reported on the rate of symptomatic UTIs [67, 69, 74]. Antibiotic treatment was not significantly beneficial in reducing the rate of symptomatic UTIs compared to placebo or no treatment (average RR 0.68, 95% CI 0.46 to 1.00; n=210). Six RCTs reported on the resolution of bacteriuria [67, 69, 70, 74-76]. There was no benefit of antibiotic treatment compared to placebo in the resolution of ABU (average RR 1.33, 95% CI 0.63 to 2.79; n=328). One RCT compared the rates of incontinence in this patient group before and after the eradication of ABU, and found no effect of antibiotic treatment [77]. Therefore, screening and treatment of ABU is not recommended in this patient group.

3.3.5.4.4 Patients with renal transplants
Two RCTs and two retrospective studies compared the effect of antibiotic treatment to no treatment in renal transplant patients [78-81]. Meta-analysis of the two RCTs did not find antibiotic treatment beneficial in terms of reducing symptomatic UTIs (RR 0.86, 95% CI 0.51 to 1.45; n=200). The two retrospective studies reached the same conclusion. Furthermore, there were no significant differences in the rate of ABU clearance, graft loss or change in renal function during long-term follow-up up to 24 months [78-81]. Therefore, treatment of ABU is not recommended in renal transplant recipients.

3.3.5.4.5 Patients with dysfunctional and/or reconstructed lower urinary tracts
Patients with lower urinary tract dysfunction (LUTD) (e.g. neurogenic bladder patients secondary to multiple sclerosis, spinal cord injury patients, patients with incomplete bladder emptying, patients with neo-bladder and ileo-cystoplasty, patients using clean intermittent catheterisation (CIC), and patients with ileal conduits, orthotopic bladder replacement and continent reservoirs) frequently become colonised [82, 83]. Studies have shown no benefit in ABU treatment in these patient groups [84, 85]. Furthermore, in LUTD patients who do not spontaneously develop ABU, deliberate colonisation with an ABU strain (Escherichia coli 83972) has shown a protective effect against symptomatic recurrences [84, 85]. Screening and treatment of ABU in these patient groups is therefore, not recommended. If these patient groups develop recurrent symptomatic UTI (see section 3.5) the potential protective effect of a spontaneously developed ABU against lower UTI must be considered before any treatment.

3.3.5.4.6 Patients with catheters in the urinary tract
Patients with indwelling or suprapubic catheters and nephrostomy tubes invariably become carriers of ABU, with antibiotic treatment showing no benefit [86]. This is also applicable for patients with ABU and indwelling ureteral stents [87]. Routine treatment of catheter-associated bacteriuria is not recommended. For detailed recommendations see section 3.8.

3.3.5.4.7 Patients with ABU subjected to catheter placements/exchanges
In patients subjected to uncomplicated placement/exchanges of indwelling urethral catheters ABU is not considered a risk factor and should not be screened or treated [88]. In patients subjected to placement/exchanges of nephrostomy tubes and indwelling ureteral stents, ABU is considered a risk factor for infectious complications [89]; therefore, screening and treatment prior to the procedure is recommended.
3.3.5.4.8 Immuno-compromised and severely diseased patients, patients with candiduria
These patient groups have to be considered individually and the benefit of screening and treatment of ABU
should be reviewed in each case. Patients with asymptomatic candiduria may, although not necessarily, have
an underlying disorder or defect. Treatment of asymptomatic candiduria is not recommended [90].

3.3.5.5 Prior to urological surgery
In diagnostic and therapeutic procedures not entering the urinary tract, ABU is generally not considered as
a risk factor, and screening and treatment are not considered necessary. On the other hand, in procedures
entering the urinary tract and breaching the mucosa, particularly in endoscopic urological surgery, bacteriuria is
a definite risk factor.

Two RCTs [91, 92] and two prospective non-randomised studies [93, 94] compared the effect of
antibiotic treatment to no treatment before transurethral prostate or bladder tumour resections. Antibiotic
treatment significantly reduced the number of post-operative symptomatic UTIs compared to no treatment in
the meta-analysis of the two RCTs (average RR 0.20, 95% CI 0.05 to 0.86; n=167). The rates of post-operative
fever and septicemia were also significantly lower in case of antibiotic treatment compared to no treatment
in the two RCTs. One RCT including patients with spinal cord injury undergoing elective endoscopic urological
surgeries found no significant difference in the rate of post-operative UTIs between single-dose or three to five
days short term pre-operative antibiotic treatment of ABU [95].

A urine culture must therefore be taken prior to such interventions and in case of ABU, pre-operative
treatment is recommended.

3.3.5.6 Prior to orthopaedic surgery
One RCT (n=471) and one multicentre cohort study (n=303) comparing the treatment of ABU with no treatment
prior to orthopaedic surgery (hip arthroplasty/hemiarthroplasty or total knee arthroplasty) were identified
[96, 97]. Neither of the studies showed a beneficial effect of antibiotic treatment in terms of prosthetic joint
infection (3.8% vs. 0% and 3.9% vs. 4.7%, respectively). The cohort study reported no significant difference
in the rate of post-operative symptomatic UTI (0.65% vs. 2.7%) [97]. Therefore, treatment of bacteriuria is not
recommended prior to arthroplasty surgery.

3.3.5.7 Pharmacological management
If the decision is taken to eradicate ABU, the same choice of antibiotics and treatment duration as in
symptomatic uncomplicated (section 3.4.4.4) or complicated (section 3.7.5) UTI can be given, depending
on gender, medical background and presence of complicating factors. Treatment should be tailored and not
empirical.

3.3.6 Follow-up
There are no studies focusing on follow-up after treatment of ABU.

3.3.7 Summary of evidence and recommendations for the management of ABU

### 3.4 Uncomplicated cystitis

#### 3.4.1 Introduction

Uncomplicated cystitis is defined as acute, sporadic or recurrent cystitis limited to non-pregnant women with no known relevant anatomical and functional abnormalities within the urinary tract or comorbidities.

#### 3.4.2 Epidemiology, aetiology and pathophysiology

Almost half of all women will experience at least one episode of cystitis during their lifetime. Nearly one in three women will have had at least one episode of cystitis by the age of 24 years [98]. Risk factors include sexual intercourse, use of spermicides, a new sexual partner, a mother with a history of UTI and a history of UTI during childhood. The majority of cases of uncomplicated cystitis are caused by *E. coli*.

#### 3.4.3 Diagnostic evaluation

**3.4.3.1 Clinical diagnosis**

The diagnosis of uncomplicated cystitis can be made with a high probability based on a focused history of lower urinary tract symptoms (dysuria, frequency and urgency) and the absence of vaginal discharge [99, 100]. In elderly women genitourinary symptoms are not necessarily related to cystitis [101, 102].

**3.4.3.2 Differential diagnosis**

Uncomplicated cystitis should be differentiated from ABU, which is considered not to be infection but rather a commensal colonisation, which should not be treated and therefore not screened for, except if it is considered a risk factor in clearly defined situations (see section 3.3).

**3.4.3.3 Laboratory diagnosis**

In patients presenting with typical symptoms of an uncomplicated cystitis urine analysis (i.e. urine culture, dip stick testing, etc.) leads only to a minimal increase in diagnostic accuracy [103]. However, if the diagnosis is unclear dipstick analysis can increase the likelihood of an uncomplicated cystitis diagnosis [104, 105]. Taking a urine culture is recommended in patients with atypical symptoms, as well as those who fail to respond to appropriate antimicrobial therapy [106, 107].

**3.4.3.4 Summary of evidence and recommendations for the diagnostic evaluation of uncomplicated cystitis**

Recommendations | Strength rating
--- | ---
Diagnose uncomplicated cystitis in women who have no other risk factors for complicated urinary tract infections based on:  
• a focused history of lower urinary tract symptoms (dysuria, frequency and urgency);  
• the absence of vaginal discharge. | Strong
Use urine dipstick testing for diagnosis of acute uncomplicated cystitis. | Weak
Urine cultures should be done in the following situations:
• suspected acute pyelonephritis;
• symptoms that do not resolve or recur within four weeks after completion of treatment;
• women who present with atypical symptoms;
• pregnant women. | Strong

3.4.4 Disease management
Antimicrobial therapy is recommended because clinical success is significantly more likely in women treated with antimicrobials compared with placebo [108]. In female patients with mild-to-moderate symptoms, symptomatic therapy (e.g. Ibuprofen), as an alternative to antimicrobial treatment, may be considered in consultation with individual patients [109-112]. The choice of antimicrobial therapy should be guided by [99]:
• spectrum and susceptibility patterns of the aetiological pathogens;
• efficacy for the particular indication in clinical studies;
• tolerability and adverse reactions;
• adverse ecological effects;
• costs;
• availability.
According to these principles and the available susceptibility patterns in Europe, oral treatment with fosfomycin trometamol 3 g single dose, pivmecillinam 400 mg three times a day for three to five days, and nitrofurantoin (e.g. nitrofurantoin monohydrate/macrocrystals 100 mg twice daily for five days), should be considered for first-line treatment, when available [113-116].

Alternative antimicrobials include trimethoprim alone or combined with a sulphonamide. Co-trimoxazole (160/800 mg twice daily for three days) or trimethoprim (200 mg twice daily for five days) should only be considered as drugs of first choice in areas with known resistance rates for *E. coli* of < 20% [117, 118].

Aminopenicillins are no longer suitable for empirical therapy because of worldwide high *E. coli* resistance. Aminopenicillins in combination with a beta-lactamase inhibitor such as ampicillin/sulbactam or amoxicillin/clavulanic acid and oral cephalosporins are not recommended for empirical therapy due to ecological collateral damage, but may be used in selected cases [119, 120].

Important notice:
On March 11, 2019 the European Commission implemented stringent regulatory conditions regarding the use of fluoroquinolones due to their disabling and potentially long-lasting side effects [121]. This legally binding decision is applicable in all EU countries. National authorities have been urged to enforce this ruling and to take all appropriate measures to promote the correct use of this class of antibiotics. In uncomplicated cystitis a fluoroquinolone should only be used when it is considered inappropriate to use other antibacterial agents that are commonly recommended for the treatment of these infections [121].

3.4.4.1 Cystitis in pregnancy
Short courses of antimicrobial therapy can also be considered for treatment of cystitis in pregnancy [122], but not all antimicrobials are suitable during pregnancy. In general, penicillins, cephalosporins, fosfomycin, nitrofurantoin (not in case of glucose-6-phosphate dehydrogenase deficiency and during the end of pregnancy), trimethoprim (not in the first trimenon) and sulphonamides (not in the last trimenon), can be considered.

3.4.4.2 Cystitis in men
Cystitis in men without involvement of the prostate is uncommon and should be classed as a complicated infection. Therefore, treatment with antimicrobials penetrating into the prostate tissue is needed in males with symptoms of UTI. A treatment duration of at least seven days is recommended, preferably with trimethoprim sulframethoxazole or a fluoroquinolone if in accordance with susceptibility testing (see section 3.4.4.4) [123].
3.4.4.3 Renal insufficiency
In patients with renal insufficiency the choice of antimicrobials may be influenced by decreased renal excretion; however, most antimicrobials, have a wide therapeutic index. No adjustment of dose is necessary until glomerular filtration rate (GFR) is < 20 mL/min, with the exception of antimicrobials with nephrotoxic potential, e.g. aminoglycosides. The combination of loop diuretics (e.g. furosemide) and a cephalosporin is nephrotoxic. Nitrofurantoin is contraindicated in patients with an estimated glomerular filtration rate (eGFR) of less than 30 ml/min/1.73m² as accumulation of the drug leads to increased side effects as well as reduced urinary tract recovery, with the risk of treatment failure [124].

3.4.4.4 Summary of evidence and recommendations for antimicrobial therapy for uncomplicated cystitis

<table>

3.4.5 Follow-up
Routine post-treatment urinalysis or urine cultures in asymptomatic patients are not indicated [26]. In women whose symptoms do not resolve by end of treatment, and in those whose symptoms resolve but recur within two weeks, urine culture and antimicrobial susceptibility testing should be performed [125]. For therapy in this situation, one should assume that the infecting organism is not susceptible to the agent originally used. Retreatment with a seven-day regimen using another agent should be considered [125].
3.5 Recurrent UTIs

3.5.1 Introduction
Recurrent UTIs (rUTIs) are recurrences of uncomplicated and/or complicated UTIs, with a frequency of at least three UTIs/year or two UTIs in the last six months. Although rUTIs include both lower tract infection (cystitis) and upper tract infection (pyelonephritis), repeated pyelonephritis should prompt consideration of a complicated aetiology.

3.5.2 Diagnostic evaluation
Recurrent UTIs are common. Risk factors are outlined in Table 2. Diagnosis of rUTI should be confirmed by urine culture. An extensive routine workup including cystoscopy, imaging, etc., is not routinely recommended as the diagnostic yield is low [126]. However, it should be performed without delay in atypical cases, for example, if renal calculi, outflow obstruction, interstitial cystitis or urothelial cancer is suspected.

3.5.3 Disease management and follow-up
Prevention of rUTIs includes counselling regarding avoidance of risk factors, non-antimicrobial measures and antimicrobial prophylaxis [125]. These interventions should be attempted in this order. Any urological risk factor must be identified and treated. Significant residual urine should be treated optimally, including by clean intermittent catheterisation (CIC) when judged to be appropriate.

3.5.3.1 Evidence Summary
A broad literature search with cut-off of May 31st, 2021 identified 3,604 abstracts of which 361 were selected for full text review. In total 114 systematic reviews or guidelines based on systematic literature searches and 131 original publications were selected for further analysis. A further eighteen relevant publications were identified from the references of the reviewed studies. Selected studies were assigned to one of nine subgroups based on the method of prevention. The evidence question addressed was: In women with recurrent symptomatic lower UTI what interventions reduce the rate of recurrence?

3.5.3.2 Behavioural modifications
Women with rUTI should be counselled on avoidance of risks (eg, insufficient hydration, habitual and post-coital delayed urination, wiping from back to front after defecation, douching and wearing occlusive underwear) before initiation of long-term prophylactic drug treatment, although there is limited evidence available regarding these approaches [128, 129]. A open-label RCT found that additional fluid intake of 1.5 L in pre-menopausal women with rUTI who were low-volume drinkers (< 1.5 L a day) reduced the number of cystitis episodes and antibiotic usage over a twelve-month period [130]

3.5.3.3 Non-antimicrobial prophylaxis
3.5.3.3.1 Hormonal replacement
Based on the results of four meta-analyses topical oestrogen admission (either as a creme or a pessary) shows a trend towards rUTI prevention [131-134]. All studies reported that application was superior compared to placebo but was inferior compared to antibiotics. Due to its pharmacokinetics vaginal admission has no systematic side effects, however local irritation and minor bleeding can occur. The use of oral oestrogens was not effective for rUTI prophylaxis compared to placebo, furthermore it was associated with an unfavourable systematic side effect profile. A single prospective, non-comparative study of 30 pre-menopausal women with rUTI on oral contraceptives reported a beneficial effect of topical oestrogen admission [135].

3.5.3.3.2 Immunoactive prophylaxis
Several meta-analyses and systematic reviews based on nine RCTs showed that oral immunotherapy with
OM-89 is an effective and safe method for the prevention of rUTIs compared to placebo at short-term follow-up (< six months) [132, 136, 137]. A vaginal suppository containing ten strains of heat-killed uropathogenic bacteria significantly reduced the risk of rUTI compared to placebo in a meta-analysis of three small RCTs [136-138]. The preventive effect was more pronounced with booster treatment.

3.5.3.3.3 Prophylaxis with probiotics (Lactobacillus spp.)
Four meta-analyses with differing results and ten relevant systematic reviews were identified [132, 139-151]. Two meta-analyses reported significant positive effects for rUTI prevention with effective probiotics compared to placebo [143, 145]. The contradictory results of the four meta-analyses are a result of the analysis of different Lactobacillus strains and different administration regimes, treatment durations, and patient populations. Most studies concluded that not all Lactobacillus strains are effective for vaginal flora restoration and rUTI prevention. The highest efficacy was shown with L. rhamnosus GR-1, L. reuteri B-54, L. reuteri RC-14, L. casei shirota, and L. crispatus CTV-05 [132, 141, 143, 145]. Although meta-analyses including all known Lactobacilli strains did not show a significant treatment benefit [132, 141, 143, 145], sensitivity analysis excluding studies using ineffective strains resulted in a positive treatment effect [143].

Of the ten systematic reviews seven concluded that prophylaxis with vaginal probiotics has a beneficial clinical impact for the prevention of rUI [133, 134, 139, 142, 144, 146-149, 151]. The available data was of too low-quality to allow the panel to make recommendations on the route of admission, optimal dosage, and treatment duration for probiotic prophylaxis.

3.5.3.3.4 Prophylaxis with cranberry
Six meta-analyses and several systematic reviews including 82 clinical trials were identified [132, 152-156]. A Cochrane review and meta-analysis found that when compared with placebo, water or no treatment, cranberry products did not significantly reduce the occurrence of symptomatic UTI overall or in women with recurrent UTIs [152]. However, five subsequent meta-analyses concluded that consumption of cranberry-containing products may protect against UTIs in certain patient populations [132, 153-156]. The differing outcomes across the meta-analyses can be contributed to the clinical and methodological heterogeneity of the included studies [157]. Although the efficacy of cranberry products is unclear, the panel consensus is that clinicians may recommend them for rUTI prevention in women who are informed of the weak evidence base due to their favourable benefit to harm ratio. However, there is no clear clinical evidence regarding the appropriate dose and treatment duration.

3.5.3.3.5 Prophylaxis with D-mannose
A meta-analysis including one RCT, one randomised cross-over trial and one prospective cohort study analysed data on 390 patients and found that D-mannose was effective for rUTI prevention compared to placebo with comparable efficacy to antibiotic prophylaxis [158]. Another systematic review, concluded that D-mannose had a significant effect on UTI, but that further studies were needed to confirm these findings [139].

3.5.3.3.6 Endovesical instillation
Endovesical instillations of hyaluronic acid (HA) and chondroitin sulphate (CS) have been used for glycosaminoglycan (GAG) layer replenishment in the treatment of interstitial cystitis, overactive bladder, radiation cystitis, and for prevention of rUTI [159]. A meta-analysis (n=143) based on two RCTs and two non-RCTs found significantly decreased UTI rates per patient/year and significantly longer mean UTI recurrence times for HA and HA-CS therapy compared to control treatment [160]. In addition, subgroup analysis of the two RCTs using HA-CS reported a significantly decreased UTI rate per patient/year, significantly longer mean UTI recurrence time and a significantly better pelvic pain and urgency/frequency (PUF) total score. However, 24 hour urinary frequency was not significantly improved after therapy [160].

Another meta-analysis (n=800) including two RCTs and six non-RCTs found that when compared to control treatment HA, with or without CS, was associated with a significantly lower mean UTI rate per patient/year and a significantly longer time to UTI recurrence [161]. Furthermore, HA-CS therapy was associated with significantly greater mean reductions in PUF total and symptom scores and the percentage of patients with UTI recurrence during follow-up was also lower [161].

As randomised controlled studies are available only for HA plus CS, the quality of evidence is higher for the combination than for HA alone.

3.5.3.3.7 Methenamine hippurate
A Cochrane review from 2012 based on thirteen studies, with high levels of heterogeneity, concluded that methenamine hippurate may be effective for preventing UTI in patients without renal tract abnormalities, particularly when used for short-term prophylaxis [162]. However, a meta-analysis from 2021 based on six studies found that although studies showed a trend towards a benefit for methenamine hippurate in prevention
of rUTIs there was no statistically significant difference between the efficacy of methenamine hippurate and any comparators [163]. Due to these contradictory results, no recommendation on the use of methenamine can be made.

3.5.3.4 Antimicrobials for preventing rUTI
3.5.3.4.1 Continuous low-dose antimicrobial prophylaxis and post-coital prophylaxis
Four meta-analyses and numerous systematic reviews and guidelines were identified [134, 164-174]. All available meta-analyses conclude that antibiotic prophylaxis is the most effective approach against UTI recurrences compared with placebo or no treatment [164-166]. Antimicrobials may be given as continuous low-dose prophylaxis for longer periods, or as post-coital prophylaxis. There is no significant difference in the efficacy of the two approaches. There is no consensus about the optimal duration of continuous antimicrobial prophylaxis, with studies reporting treatment duration of three to twelve months. After discontinuation of the drug, UTIs tend to re-occur, especially among those who have had three or more infections annually. It is mandatory to offer both continuous low-dose antimicrobial and post-coital prophylaxis after counselling, and when behavioural modifications and non-antimicrobial measures have been unsuccessful.

Differences in outcomes between antibiotics did not reach statistical significance. The choice of agent should be based on the local resistance patterns. Regimens include nitrofurantoin 50 mg or 100 mg once daily, fosfomycin trometamol 3 g every ten days, trimethoprim 100 mg once daily and during pregnancy cephalaxin 125 mg or 250 mg or cefaclor 250 mg once daily [125, 175]. Post-coital prophylaxis should be considered in pregnant women with a history of frequent UTIs before onset of pregnancy, to reduce their risk of UTI [176].

3.5.3.4.2 Self-diagnosis and self-treatment
In patients with good compliance, self-diagnosis and self-treatment with a short course regimen of an antimicrobial agent should be considered [177]. The choice of antimicrobials is the same as for sporadic acute uncomplicated UTI (section 3.4.4.4).

### 3.6 Uncomplicated pyelonephritis

Uncomplicated pyelonephritis is defined as pyelonephritis limited to non-pregnant, pre-menopausal women with no known relevant urological abnormalities or comorbidities.

#### 3.6.1 Diagnostic evaluation

##### Clinical diagnosis

Pyelonephritis is suggested by fever (> 38°C), chills, flank pain, nausea, vomiting, or costovertebral angle tenderness, with or without the typical symptoms of cystitis [178]. Pregnant women with acute pyelonephritis need special attention, as this kind of infection may not only have an adverse effect on the mother with anaemia, renal and respiratory insufficiency, but also on the unborn child with more frequent pre-term labour and birth [179].

##### Differential diagnosis

It is vital to differentiate as soon as possible between uncomplicated and complicated mostly obstructive pyelonephritis, as the latter can rapidly lead to urosepsis. This differential diagnosis should be made by the appropriate imaging technique (see section 3.6.1.4).

##### Laboratory diagnosis

Urinalysis including the assessment of white and red blood cells and nitrite, is recommended for routine diagnosis [180]. In addition, urine culture and antimicrobial susceptibility testing should be performed in all cases of pyelonephritis.

##### Imaging diagnosis

Evaluation of the upper urinary tract with ultrasound (US) should be performed to rule out urinary tract obstruction or renal stone disease in patients with a history of urolithiasis, renal function disturbances or a high urine pH [181]. Additional investigations, such as a contrast enhanced computed tomography (CT) scan, or excretory urography should be considered if the patient remains febrile after 72 hours of treatment, or immediately if there is deterioration in clinical status [181]. For diagnosis of complicating factors in pregnant women, US or magnetic resonance imaging (MRI) should be used preferentially to avoid radiation risk to the foetus [181].

</tr>
</tbody>
</table>
Perform urinalysis (e.g. using the dipstick method), including the assessment of white and red blood cells and nitrite, for routine diagnosis.

Perform urine culture and antimicrobial susceptibility testing in patients with pyelonephritis.

Perform imaging of the urinary tract to exclude urgent urological disorders.

### Disease management

#### 3.6.3.1 Outpatient treatment

Fluoroquinolones and cephalosporines are the only antimicrobial agents that can be recommended for oral empirical treatment of uncomplicated pyelonephritis [182]. However, oral cephalosporines achieve significantly lower blood and urinary concentrations than intravenous cephalosporines. Other agents such as nitrofurantoin, oral fosfomycin, and pivmecillinam should be avoided as there is insufficient data regarding their efficacy [183]. In the setting of fluoroquinolone hypersensitivity or known resistance, other acceptable choices include trimethoprim-sulfamethoxazole (160/800 mg) or an oral beta-lactam, if the uropathogen is known to be susceptible. If such agents are used in the absence of antimicrobial susceptibility results, an initial intravenous dose of a long-acting parenteral antimicrobial (e.g. ceftriaxone) should be administered. A short outpatient antibiotic course of treatment, for acute pyelonephritis, has been shown to be equivalent to longer durations of therapy in terms of clinical and microbiological success. However, this is associated with a higher recurrence rate of infection within four to six weeks and needs to be tailored to local policies and resistance patterns [184].

#### 3.6.3.2 Inpatient treatment

Patients with uncomplicated pyelonephritis requiring hospitalisation should be treated initially with an intravenous antimicrobial regimen e.g. a fluoroquinolone, an aminoglycoside (with or without ampicillin), or an extended-spectrum cephalosporin or penicillin [185]. Ceftolozane/tazobactam achieved a clinical response rate of over 90% in patients with uncomplicated pyelonephritis [186, 187]. It also demonstrated significantly higher composite cure rates than levofloxacin among levofloxacin-resistant pathogens [188]. Ceftazidime-avibactam combination has been shown to be effective for treating ceftazidime-resistant *Enterobacterales* and *Pseudomonas aeruginosa* UTIs [189].

Novel antimicrobial agents include imipenem/cilastatin, cefiderocol, meropenem-vaborbactam and plazomicin. Imipenem/cilastatin has been investigated in a phase 2 randomised trial and showed good clinical response rates [190]. Cefatazidime-avibactam and doripenem showed similar efficacy against ceftazidime non-susceptible pathogens and may offer an alternative to carbapenems in this setting [191]. Meropenem-vaborbactam has been shown to be non-inferior to piperacillin-tazobactam in a phase 3 RCT [192]. It was also effective for treating carbapenem-resistant *Enterobacterales* with cure rates of 65% compared to best available treatment [193]. Once daily plazomicin was non-inferior to meropenem for the treatment of cUTIs and acute pyelonephritis caused by *Enterobacterales*, including multidrug-resistant strains [194]. Cefiderocol was non-inferior to imipenem/cilastatin for the treatment of complicated UTI in people with multidrug-resistant Gram-negative infections in a phase 2 RCT [195].

Carbapenems and novel broad spectrum antimicrobial agents should only be considered in patients with early culture results indicating the presence of multi-drug resistant organisms. The choice between these agents should be based on local resistance patterns and optimised on the basis of drug susceptibility results. In patients presenting with signs of urosepsis empiric antimicrobial coverage for ESBL-producing organisms is warranted [196]. Patients initially treated with parental therapy who improve clinically and can tolerate oral fluids may transition to oral antimicrobial therapy [197].

In pregnant women with pyelonephritis, outpatient management with appropriate parenteral antimicrobials may also be considered, provided symptoms are mild and close follow-up is feasible [198, 199]. In more severe cases of pyelonephritis, hospitalisation and supportive care are usually required. After clinical improvement parenteral therapy can also be switched to oral therapy for a total treatment duration of seven to ten days. In men with febrile UTI, pyelonephritis, or recurrent infection, or whenever a complicating factor is suspected a minimum treatment duration of two weeks is recommended, preferably with a fluoroquinolone since prostatic involvement is frequent [200].

3.6.4 *Follow-up*

Post-treatment urinalysis or urine cultures in asymptomatic patients post-therapy are not indicated.
3.7 Complicated UTIs

3.7.1 Introduction
A complicated UTI (cUTI) occurs in an individual in whom factors related to the host (e.g. underlying diabetes or immunosuppression) or specific anatomical or functional abnormalities related to the urinary tract (e.g. obstruction, incomplete voiding due to detrusor muscle dysfunction) are believed to result in an infection that will be more difficult to eradicate than an uncomplicated infection [201-203]. New insights into the management of cUTIs also suggest to consider infections caused by multi-drug resistant uropathogens [204]. The underlying factors that are generally accepted to result in a cUTI are outlined in Table 5. The designation of cUTI encompasses a wide variety of underlying conditions that result in a remarkably heterogeneous patient population. Therefore, it is readily apparent that a universal approach to the evaluation and treatment of cUTIs is not sufficient, although there are general principles of management that can be applied to the majority of patients with cUTIs. The following recommendations are based on the Stichting Werkgroep Antibioticabeleid (SWAB) Guidelines from the Dutch Working Party on Antibiotic Policy [205].

3.7.2 Diagnostic evaluation
3.7.2.1 Clinical presentation
A cUTI is associated with clinical symptoms (e.g. dysuria, urgency, frequency, flank pain, costovertebral angle tenderness, suprapubic pain and fever), although in some clinical situations the symptoms may be atypical for example, in neuropathic bladder disturbances, CA-UTI or patients who have undergone radical cystectomy with urinary diversion. In addition, all patients with nephrostomy may have an atypical clinical presentation. Clinical presentation can vary from severe obstructive acute pyelonephritis with imminent urosepsis to a post-operative CA-UTI, which might disappear spontaneously as soon as the catheter is removed. Clinicians must also recognise that symptoms, especially lower urinary tract symptoms (LUTS), are not only caused by UTIs but also by other urological disorders, such as, for example, benign prostatic hyperplasia and autonomic dysfunction in patients with spinal lesions and neurogenic bladders. Concomitant medical conditions, such as diabetes mellitus and renal failure, which can be related to urological abnormalities, are often also present in a cUTI.

3.7.2.2 Urine culture
Laboratory urine culture is the recommended method to determine the presence or absence of clinically significant bacteriuria in patients suspected of having a cUTI.

3.7.3 Microbiology (spectrum and antimicrobial resistance)
A broad range of micro-organisms cause cUTIs. The spectrum is much larger than in uncomplicated UTIs and the bacteria are more likely to be resistant (especially in treatment-related cUTI) than those isolated in uncomplicated UTIs [206, 207]. E. coli, Proteus spp., Klebsiella spp., Pseudomonas spp., Serratia spp. and Enterococcus spp. are the most common species found in cultures. Enterobacterales predominate (60-75%), with E. coli as the most common pathogen; particularly if the UTI is a first infection. Otherwise, the bacterial spectrum may vary over time and from one hospital to another [208].

3.7.4 General principles of cUTI treatment
Appropriate management of the urological abnormality or the underlying complicating factor is mandatory. Optimal antimicrobial therapy for cUTI depends on the severity of illness at presentation, as well as local resistance patterns and specific host factors (such as allergies). In addition, urine culture and susceptibility testing should be performed, and initial empirical therapy should be tailored and followed by (oral) administration of an appropriate antimicrobial agent on the basis of the isolated uropathogen.

3.7.4.1 Choice of antimicrobials
Considering the current resistance percentages of amoxicillin, co-amoxiclav, trimethoprim and trimethoprim-sulphamethoxazole, it can be concluded that these agents are not suitable for the empirical treatment of
pyelonephritis in a normal host and, therefore, also not for treatment of all cUTIs [209]. The same applies to ciprofloxacin and other fluoroquinolones in urological patients [209].

Patients with a UTI with systemic symptoms requiring hospitalisation should be initially treated with an intravenous antimicrobial regimen, such as an aminoglycoside with or without amoxicillin, or a second or third generation cephalosporin, or an extended-spectrum penicillin with or without an aminoglycoside [205]. The choice between these agents should be based on local resistance data, and the regimen should be tailored on the basis of susceptibility results [183]. These recommendations are not only suitable for pyelonephritis, but for all other cUTIs.

Alternative regimens for the treatment of cUTIs, particularly those caused by multidrug-resistant pathogens have been studied. Ceftolozane/tazobactam 1.5 g every eight hours demonstrated high clinical cure rates for cUTIs caused by ESBL-producing Enterobacterales in a pooled analysis of phase 3 clinical trials [210]. Cefiderocol (2 g) three times daily was non-inferior to imipenem-cilastatin (1 g) three times daily for the treatment of cUTI in patients with multidrug-resistant Gram-negative infections [195]. Imipenem/cilastatin plus relebactam (250 or 125 mg) was as effective as imipenem/cilastatin alone for treatment of cUTI in a phase 2 RCT [190]. Ceftazidime/avibactam has been shown to be as effective as carbapenems for the treatment of cUTI in a systematic review reporting a baseline of 25% for ESBL-producing Enterobacterales, but more severe adverse events were reported in the ceftazidime/avibactam group [211]. Once-daily plazomicin was shown to be non-inferior to meropenem for the treatment of cUTIs caused by Enterobacterales, including multidrug-resistant strains [194].

In view of the high degree of resistance, particularly among patients admitted to the department of urology, fluoroquinolones are not automatically suitable as empirical antimicrobial therapy, especially when the patient has used ciprofloxacin in the last six months [212]. Fluoroquinolones can only be recommended as empirical treatment when the patient is not seriously ill and it is considered safe to start initial oral treatment or if the patient has had an anaphylactic reaction to beta-lactam antimicrobials. Intravenous levofloxacin 750 mg once daily for five days has been shown to be non-inferior to meropenem for the treatment of cUTIs caused by Enterobacterales, including multidrug-resistant strains [213].

### 3.7.4.2 Duration of antimicrobial therapy

Treatment for seven [214] to fourteen days (for men fourteen days when prostatitis cannot be excluded) [215], is generally recommended, but the duration should be closely related to the treatment of the underlying abnormality. When the patient is hemodynamically stable and afebrile for at least 48 hours, a shorter treatment duration (e.g. seven days) may be considered in patients where a short-course treatment is desired due to relative-contraindications to the administered antibiotic [213].

Recommendations | Strength rating
--- | ---
Use the combination of:
- amoxicillin plus an aminoglycoside;
- a second generation cephalosporin plus an aminoglycoside;
- a third generation cephalosporin intravenously as empirical treatment of complicated UTI with systemic symptoms. | Strong

Only use ciprofloxacin provided that the local resistance percentages are < 10% when:
- the entire treatment is given orally;
- patients do not require hospitalisation;
- patient has an anaphylaxis for beta-lactam antimicrobials. | Strong

Do not use ciprofloxacin and other fluoroquinolones for the empirical treatment of complicated UTI in patients from urology departments or when patients have used fluoroquinolones in the last six months. | Strong

Manage any urological abnormality and/or underlying complicating factors. | Strong

3.8 Catheter-associated UTIs

3.8.1 Introduction
Catheter-associated UTI refers to UTIs occurring in a person whose urinary tract is currently catheterised or has been catheterised within the past 48 hours. The urinary catheter literature is problematic as many published studies use the term CA-bacteriuria without providing information on what proportion are CA-ABU and CA-UTI, and some studies use the term CA-UTI when referring to CA-ABU or CA-bacteriuria [206].

3.8.2 Epidemiology, aetiology and pathophysiology
Catheter-associated UTIs are the leading cause of secondary healthcare-associated bacteraemia. Approximately 20% of hospital-acquired bacteremiaias arise from the urinary tract, and the mortality associated with this condition is approximately 10% [216]. A multistate point-prevalence survey of 11,282 patients across 183 hospitals reported that UTI accounted for 12.9% of healthcare acquired infections [217]. The incidence of bacteriuria associated with indwelling catheterisation is 3-8% per day [218-222]. The duration of catheterisation is the most important risk factor for the development of a CA-UTI [223, 224]. A systematic review and meta-analysis reported an average CA-UTI incidence of 13.79/1000 hospitalised patients with a prevalence of 9.33% [225]. This study also demonstrated that patients at high risk for CA-UTI were female, had a prolonged duration of catheterisation, had diabetes and had longer hospital and intensive care unit (ICU) stays [225].

Urinary catheterisation perturbs host defence mechanisms and provides easier access of uropathogens to the bladder. Indwelling urinary catheters facilitate colonisation with uropathogens by providing a surface for the attachment of host cell binding receptors recognised by bacterial adhesins, thus enhancing microbial adhesion. In addition, the uroepithelial mucosa is damaged, exposing new binding sites for bacterial adhesins, and residual urine in the bladder is increased through pooling below the catheter bulb [226]. Catheter-associated UTIs are often polymicrobial and caused by multiple-drug resistant uropathogens.

3.8.3 Diagnostic evaluation

3.8.3.1 Clinical diagnosis
Signs and systemic symptoms compatible with CA-UTI include new onset or worsening of fever, rigors, altered mental status, malaise, or lethargy with no other identified cause, flank pain, costovertebral angle tenderness, acute haematuria, pelvic discomfort and in those whose catheters have been removed dysuria, urgent or frequent urination and suprapubic pain or tenderness [205]. In the catheterised patient, the presence or absence of odorous or cloudy urine alone should not be used to differentiate CA-ABU from CA-UTI [205, 206].

3.8.3.2 Laboratory diagnosis
Microbiologically, CA-UTI is defined by microbial growth of \( \geq 10^3 \) cfu/mL of one or more bacterial species in a single catheter urine specimen or in a mid-stream voided urine specimen from a patient whose urethral, suprapubic, or condom catheter has been removed within the previous 48 hours [206]. In catheterised patients, pyuria is not diagnostic for CA-UTI. The presence, absence, or degree of pyuria should not be used to differentiate CA-ABU from CA-UTI. Pyuria accompanying CA-ABU should not be interpreted as an indication for antimicrobial treatment. The absence of pyuria in a symptomatic patient suggests a diagnosis other than CA-UTI [206].

3.8.4 Disease management

3.8.4.1 Limiting catheterisation and appropriate catheter discontinuation

Indwelling catheters should be placed only when they are clinically indicated; for example, for management of urinary retention or where strict monitoring of fluid balance is required. Catheter restriction protocols are an important part of multi-modal interventions to reduce CA-UTI rates. Nurse-driven protocols in hospitals as well as community based multi-modal targeted infection programs have been proven to reduce CA-UTI rates [227, 228]. Adjunctive devices such as electronic reminder systems have also been shown to assist in prompt catheter removal in hospital settings (including non-ICU). A systematic review of nineteen different interventions to reduce UTI (including catheter discontinuation and limiting catheterisation), in nursing home patients reported successful CA-UTI reduction and reduced catheter usage [229]. Another report of over 2,800 patients on a surgical oncology unit found that increasing catheter bundle compliance resulted in a significant reduction in CA-UTI rates [230].

3.8.4.2 Urethral cleaning and chlorhexidine bathing

A network meta-analysis of 33 studies (6,490 patients) found no difference in the incidence of CA-UTI comparing the different urethral cleaning methods vs. disinfection [231]. The efficacy of chlorhexidine baths (either using 2% chlorhexidine-impregnated cloths or 4% chlorhexidine-based soap) in reducing CA-UTI is debatable. In a RCT of 10,783 ICU patients, no difference in CA-UTI rates were reported between chlorhexidine and control bathing groups [232]. However, a systematic review of fifteen studies involving only ICU patients reported that daily chlorhexidine bathing was associated with a significant reduction in CA-UTI (RR 0.68) [233].

3.8.4.3 Alternatives to indwelling urethral catheterisation

Alternatives include intermittent urethral catheterisation (IC) or suprapubic catheterisation. In a systematic review of patients undergoing gynaecological surgery, indwelling catheters were associated with higher rates of symptomatic UTIs compared to IC [234]. A further meta-analysis of postpartum women reported no difference in the incidence of UTI after labour between continuous catheterisation and IC [234]. A prospective cohort study of nursing home residents found that residents with a suprapubic catheter had fewer CA-UTIs and where hospitalised less, but were more likely to be colonised with multidrug-resistant organisms [235].

A Cochrane review found insufficient evidence to assess the value of different policies for replacing long-term urinary catheters on patient outcomes [88]. Another Cochrane review investigating the role of urethral (indwelling or intermittent) vs. suprapubic catheterisation in the short-term found inconclusive evidence of an effect on UTI rates [236]. For patients with neurogenic bladders, a further systematic review found no randomised or quasi-randomised controlled trials and therefore no conclusions regarding the use of the different types of catheter could be made [237]. Therefore, based on the available literature, while there are some limited studies showing a benefit of IC or suprapubic catheterisation over urethral catheterisation for CA-UTI rates, there is insufficient evidence to recommend those approaches routinely [238].

3.8.4.4 Impregnated or coated catheters

Hydrophilic coated catheters have been found to be beneficial for reducing CA-UTI rates. A meta-analysis of seven studies investigating RCTs comparing hydrophilic coated to PVC (standard) catheters for IC found a statistically lower risk ratio (0.84) for the frequency of UTI in the hydrophilic catheter group [239]. A systematic
review and practice policy statements on UTI prevention in patients with spina bifida recommended the use of single-use and hydrophilic catheters for IC [240].

Silver-alloy-impregnated catheters have not been associated with reduced CA-UTI rates. A small RCT of 54 ICU patients showed no significant difference in UTI rates between the silver-alloy impregnated group and the standard silicone foley catheter group [241]. In a cohort study of patients undergoing suprapubic catheter placement at the time of pelvic organ prolapsed surgery, a 5% difference in UTI rate at six weeks was noted, although this was not significant [242]. A systematic review of 26 trials (12,422 patients) reported that silver alloy-coated catheters were not associated with a statistically significant reduction in CA-UTI and were considerably more expensive [243]. However, the same study found that nitrofurazone-impregnated catheters reduce the risk of symptomatic CA-UTI; however, this was borderline significant (RR 0.84, 95% CI 0.71 to 0.99) [243]. A more recent RCT (214 patients) evaluating the use of nitrofurazone-infused catheters post-renal transplant found no benefit for their use [244]. Additionally, another RCT showed no benefit for the use of silver-alloy-coated indwelling catheters for reduction of UTI in 489 patients with spinal cord injury [245].

From a microbiological perspective, there may be a difference in organisms causing CA-UTI from urethral and suprapubic catheters and therefore urine culture results are important to guide therapy [238].

3.8.4.5 Antibiotic prophylaxis for catheter removal or insertion
The question of whether antibiotic prophylaxis reduces the rate of symptomatic UTI in adults following indwelling bladder catheter removal has been the subject of multiple RCTs. A review and meta-analysis identified seven RCTs with 1,520 participants. Meta-analysis showed overall benefit for use of prophylaxis RR (95%CI) = 0.45 (0.28-0.72); ARR 5.8% (from 10.5% to 4.7%) with a number needed to treat (NNT) of 17 [214]. Results for individual trials were inconsistent with five trials including the possibility of no benefit [214]. In an affectional RCT with 172 participants undergoing laparoscopic radical prostatectomy randomised to seven days of ciprofloxacin (n=80) or no treatment (n=80) at the time of catheter removal, which occurred at a mean of nine days post-operatively, there was no difference in infective complications recorded at up to four weeks after catheter removal. More isolates obtained from the prophylaxis group (11) were resistant to ciprofloxacin compared to the no treatment group (3) [215]. With regards to catheter insertion, a systematic review and meta-analysis showed that prophylactic antibiotics reduced the rate of bacteriuria and other signs of infection, such as pyuria, fever and gram-negative isolates in patients’ urine, in surgical patients who undergo bladder drainage for at least 24 hours post-operatively [246].

3.8.4.6 Antibiotic prophylaxis for intermittent self-catheterisation (ISC)
An RCT investigating the effect of antibiotic prophylaxis in patients performing ISC showed that the frequency of symptomatic antibiotic-treated UTI was reduced by 48% using prophylaxis in a cohort of 404 patients performing ISC [247]. However, resistance against the antibiotics used for UTI treatment was more frequent in urinary isolates from the prophylaxis group than in those from the control group at nine to twelve months.

While the literature shows some benefit for reduction of CA-UTI by utilising antibiotics, the routine use of antibiotics for such a common procedure in the healthcare setting would result in an increased usage of antimicrobials. As highlighted in some of the RCTs this strategy is associated with increased antimicrobial resistance. Antibiotic use is the main driving force in the development of antimicrobial resistance. Current antimicrobial stewardship principles would not favour the routine use of antibiotic prophylaxis for either catheter changes or ISC even when UTIs could be prevented [238].

3.8.4.7 Antimicrobial treatment for suspected CA-UTI
A urine specimen for culture should be obtained prior to initiating antimicrobial therapy for presumed CA-UTI due to the wide spectrum of potential infecting organisms and the increased likelihood of antimicrobial resistance. The urine culture should be obtained from the freshly placed catheter prior to the initiation of antimicrobial therapy [206]. Based on the global prevalence on infections in urology (GPIU) study, the causative micro-organisms in CA-UTI are comparable with the causative micro-organisms in other cUTIs; therefore, symptomatic CA-UTIs should be treated according to the recommendations for cUTI (see section 3.7.5) [248].

Seven days is the recommended duration of antimicrobial treatment for patients with CA-UTI who have prompt resolution of symptoms, and fourteen days of treatment is recommended for those with a delayed response, regardless of whether the patient remains catheterised or not [206]. A five-day regimen of levofloxacin may be considered in patients with CA-UTI who are not severely ill. Data are insufficient to make such a recommendation about other fluoroquinolones. With the rise in fluoroquinolone resistance, alternative antimicrobial agents should be selected where possible to start empirical therapy based on local microbiological information. A five-day antibiotic regimen with catheter exchange has been shown in one study to be non-inferior to a ten-day regimen with catheter retention on the basis of clinical cure [249].

A three-day antimicrobial regimen may be considered for women aged ≤ 65 years who develop CA-UTI without upper urinary tract symptoms after an indwelling catheter has been removed. If an indwelling
catheter has been in place for two weeks at the onset of CA-UTI and is still indicated, the catheter should be replaced to hasten resolution of symptoms and to reduce the risk of subsequent CA-bacteriuria and CA-UTI. If use of the catheter can be discontinued, a culture of a voided mid-stream urine specimen should be obtained prior to the initiation of antimicrobial therapy to help guide treatment [206]. Long-term indwelling catheters should not be changed routinely. Follow appropriate practices for catheter insertion and care [250].

3.9 Urosepsis

3.9.1 Introduction

Patients with urosepsis should be diagnosed at an early stage, especially in the case of a cUTI. Systemic inflammatory response syndrome (SIRS), characterised by fever or hypothermia, leukocytosis or leukopenia, tachycardia and tachypnoea, has been recognised as a set of alerting symptoms [251, 252]; however, SIRS is no longer included in the recent terminology of sepsis (Table 6) [12]. Mortality is considerably increased the more severe the sepsis is.

The treatment of urosepsis involves adequate life-supporting care, appropriate and prompt antimicrobial therapy, adjunctive measures and the optimal management of urinary tract disorders [253]. Source control by decompression of any obstruction and drainage of larger abscesses in the urinary tract is essential [253]. Urologists are recommended to treat patients in collaboration with intensive care and infectious diseases specialists.

Urosepsis is seen in both community-acquired and healthcare associated infections. Nosocomial urosepsis may be reduced by measures used to prevent nosocomial infection, e.g. reduction of hospital stay, early removal of indwelling urinary catheters, avoidance of unnecessary urethral catheterisation, correct use of closed catheter systems, and attention to simple daily aseptic techniques to avoid cross-infection.

Sepsis is diagnosed when clinical evidence of infection is accompanied by signs of systemic inflammation, presence of symptoms of organ dysfunction and persistent hypotension associated with tissue anoxia (Table 6).
3.9.2 **Epidemiology, aetiology and pathophysiology**

Urinary tract infections can manifest from bacteriuria with limited clinical symptoms to sepsis or severe sepsis, depending on localised and potential systemic extension. It is important to note that a patient can move from an almost harmless state to severe sepsis in a very short time.

Mortality rates associated with sepsis vary depending on the organ source [254] with urinary tract sepsis generally having a lower mortality than that from other sources [255]. Sepsis is more common in men than in women [256]. In recent years, the overall incidence of sepsis arising from all sources has increased by 8.7% per year [254], but the associated mortality has decreased, which suggests improved management of patients (total in-hospital mortality rate fell from 27.8% to 17.9% from 1995 to 2000) [257]. Although the rate of sepsis due to Gram-positive and fungal organisms has increased, Gram-negative bacteria remain predominant in urosepsis [248, 258].

In urosepsis, as in other types of sepsis, the severity depends mostly upon the host response. Patients who are more likely to develop urosepsis include elderly patients, diabetics, immunosuppressed patients, such as transplant recipients and patients receiving cancer chemotherapy or corticosteroids. Urosepsis also depends on local factors, such as urinary tract calculi, obstruction at any level in the urinary tract, congenital uropathy, neurogenic bladder disorders, or endoscopic manoeuvres. However, all patients can be affected by bacterial species that are capable of inducing inflammation within the urinary tract.

3.9.3 **Diagnostic evaluation**

For diagnosis of systemic symptoms in sepsis either the full Sequential [Sepsis-related] Organ Failure Assessment (SOFA) score, or the quickSOFA score should be applied (Table 6). Microbiology sampling should be applied to urine, two sets of blood cultures [259], and if appropriate drainage fluids. Imaging investigations, such as sonography and CT-scan should be performed early [260].

**Table 6. Definition and criteria of sepsis and septic shock** [12, 251, 252]

<table>
<thead>
<tr>
<th>Disorder</th>
<th>Definition</th>
</tr>
</thead>
<tbody>
<tr>
<td>Sepsis</td>
<td>Life-threatening organ dysfunction caused by a dysregulated host response to infection. For clinical application, organ dysfunction can be represented by an increase in the Sequential [Sepsis-related] Organ Failure Assessment (SOFA) score of 2 points or more. For rapid identification a quickSOFA (qSOFA) score was developed: respiratory rate of 22/min or greater, altered mentation, or systolic blood pressure of 100 mmHg or less.</td>
</tr>
<tr>
<td>Septic shock</td>
<td>Septic shock should be defined as a subset of sepsis in which particularly profound circulatory, cellular, and metabolic abnormalities are associated with a greater risk of mortality than with sepsis alone. Patients with septic shock can be clinically identified by a vasopressor requirement to maintain a mean arterial pressure of 65 mmHg or greater and serum lactate level greater than 2 mmol/L (&gt;18 mg/dL) in the absence of hypovolemia.</td>
</tr>
</tbody>
</table>

3.9.4 **Physiology and biochemical markers**

*E. coli* remains the most prevalent micro-organism. In several countries, bacterial strains can be resistant or multi-resistant and therefore difficult to treat [258]. Most commonly, the condition develops in compromised patients (e.g. those with diabetes or immunosuppression), with typical signs of generalised sepsis associated with local signs of infection.

3.9.4.1 **Cytokines as markers of the septic response**

Cytokines are involved in the pathogenesis of sepsis [255]. They are molecules that regulate the amplitude and duration of the host inflammatory response. They are released from various cells including monocytes, macrophages and endothelial cells, in response to various infectious stimuli. The complex balance between pro- and anti-inflammatory responses is modified in severe sepsis. An immunosuppressive phase follows the initial pro-inflammatory mechanism. Sepsis may indicate an immune system that is severely compromised and unable to eradicate pathogens or a non-regulated and excessive activation of inflammation, or both. Genetic predisposition is a probable explanation of sepsis in several patients. Mechanisms of organ failure and death in patients with sepsis remain only partially understood [255].

3.9.4.2 **Biochemical markers**

Procalcitonin is the inactive pro-peptide of calcitonin. Normally, levels are undetectable in healthy humans. During severe generalised infections (bacterial, parasitic and fungal) with systemic manifestations, procalcitonin levels rise [261]. In contrast, during severe viral infections or inflammatory reactions of non-infectious origin,
Procalcitonin levels show only a moderate or no increase. Mid-regional proadrenomedulline is another sepsis marker. Mid-regional proadrenomedulline has been shown to play a decisive role in the induction of hyperdynamic circulation during the early stages of sepsis and progression to septic shock [262]. Procalcitonin monitoring may be useful in patients likely to develop sepsis and to differentiate from a severe inflammatory status not due to bacterial infection [261, 263]. In addition, serum lactate is a marker of organ dysfunction and is associated with mortality in sepsis [264]. Serum lactate should therefore also be monitored in patients with severe infections.

3.9.5 Disease management
3.9.5.1 Prevention
Sepsis shock is the most frequent cause of death for patients hospitalised for community-acquired and nosocomial infection (20-40%). Urosepsis treatment requires a combination of treatment including source control (obstruction of the urinary tract), adequate life-support care, and appropriate antimicrobial therapy [255, 260]. In such a situation, it is recommended that urologists collaborate with intensive care and infectious disease specialists for the best management of the patient.

3.9.5.1.1 Preventive measures of proven or probable efficacy
The most effective methods to prevent nosocomial urosepsis are the same as those used to prevent other nosocomial infections [265, 266]; they include:

- Isolation of patients with multi-resistant organisms following local and national recommendations.
- Prudent use of antimicrobial agents for prophylaxis and treatment of established infections, to avoid selection of resistant strains. Antibiotic agents should be chosen according to the predominant pathogens at a given site of infection in the hospital environment.
- Reduction in hospital stay. Long inpatient periods before surgery lead to a greater incidence of nosocomial infections.
- Early removal of indwelling urethral catheters, as soon as allowed by the patient’s condition. Nosocomial UTIs are promoted by bladder catheterisation as well as by ureteral stenting [267]. Antibiotic prophylaxis does not prevent stent colonisation, which appears in 100% of patients with a permanent ureteral stent and in 70% of those temporarily stented.
- Use of closed catheter drainage and minimisation of breaks in the integrity of the system, e.g. for urine sampling or bladder wash-out.
- Use of least-invasive methods to release urinary tract obstruction until the patient is stabilised.
- Attention to simple everyday techniques to assure asepsis, including the routine use of protective disposable gloves, frequent hand disinfection, and using infectious disease control measures to prevent cross-infections.

3.9.5.1.2 Appropriate peri-operative antimicrobial prophylaxis
For appropriate peri-operative antimicrobial prophylaxis see section 3.15. The potential side effects of antibiotics must be considered before their administration in a prophylactic regimen.

3.9.5.2 Treatment
Early goal-directed resuscitation was initially shown to improve survival for emergency department patients presenting with septic shock in a randomised, controlled, single-centre study [268]. However, follow-up studies in an improved emergency medicine background have not achieved positive effects with this strategy [269-271]. An individual patient data meta-analysis of the later three multicentre trials concluded that early goal-directed therapy did not result in better outcomes than usual care and was associated with higher hospitalisation costs [272].

3.9.5.2.1 Antimicrobial therapy
Initial empiric antimicrobial therapy should provide broad antimicrobial coverage against all likely causative pathogens and should be adapted on the basis of culture results, once available [253, 260]. The dosage of the antimicrobial substances is of paramount importance in patients with sepsis syndrome and should generally be high, with appropriate adjustment for renal function [253]. Antimicrobials must be administered no later than one hour after clinical assumption of sepsis [253].

3.9.5.2.2 Source control
Obstruction in the urinary tract is the most frequent urological source of urosepsis. Drainage of obstruction and abscesses, and removal of foreign bodies, such as urinary catheters or stones is therefore the most important source control strategy. These are key components of the strategy. This condition is an absolute emergency.
3.9.5.2.3 Adjunctive measures

The most important adjunctive measures in the management of sepsis are the following [253, 260]:

- fluid therapy with crystalloids, or albumin, if crystalloids are not adequately increasing blood pressure: passive leg raising-induced changes in cardiac output and in arterial pulse pressure are predictors of fluid responsiveness in adults [273];
- as vasopressors norepinephrine should be used primarily, dobutamine in myocardial dysfunction;
- hydrocortisone should be given only if fluid and vasopressors do not achieve a mean arterial pressure of ≥ 65 mmHg;
- blood products should be given to target a haemoglobin level of 7-9 g/dL;
- mechanical ventilation should be applied with a tidal volume 6 mL/kg and plateau pressure ≤ 30 cm H₂O and a high positive end-expiratory pressure;
- sedation should be given minimally, neuromuscular blocking agents should be avoided;
- glucose levels should be target at ≤ 180 mg/dL;
- deep vein thrombosis prevention should be given with low-molecular weight heparin subcutaneously;
- stress ulcer prophylaxis should be applied in patients at risk, using proton pump inhibitors;
- enteral nutrition should be started early (< 48 hours).

In conclusion, sepsis in urology remains a severe situation with a considerable mortality rate. A recent campaign, ‘Surviving Sepsis Guidelines’, aims to reduce mortality by 25% in the next years [253, 260, 274]. Early recognition of the symptoms may decrease the mortality by timely treatment of urinary tract disorders, e.g. obstruction, or urolithiasis. Adequate life-support measures and appropriate antimicrobial treatment provide the best conditions for improving patient survival. The prevention of sepsis is dependent on good practice to avoid nosocomial infections and using antimicrobial prophylaxis and therapy in a prudent and well-accepted manner.

3.10 Urethritis

3.10.1 Introduction

Urethritis can be of either infectious or non-infectious origin. Inflammation of the urethra presents usually with LUTS and must be distinguished from other infections of the lower urinary tract. Urethral infection is typically spread by sexual contact.

3.10.2 Epidemiology, aetiology and pathogenesis

From a therapeutic and clinical point of view, gonorrhoeal urethritis (GU) caused by Neisseria gonorrhoeae must be differentiated from non-gonococcal urethritis (NGU). Non-gonococcal urethritis is a non-specific diagnosis that can have many infectious aetiologies. Causative pathogens include Chlamydia trachomatis, Mycoplasma genitalium, Ureaplasma urealyticum and Trichomonas vaginalis. The role of Ureaplasma spp. as urethritis causative pathogens is controversial. Recent data suggests that U. urealyticum, but not U. parvum is an aetiological agent in NGU [275]. The prevalence of isolated causative pathogens are: C. trachomatis 11-50%; M. genitalium 6-50%; Ureaplasmas 5-26%; T. vaginalis 1-20%; and adenoviruses 2-4% [276].

Causative agents either remain extracellularly on the epithelial layer or penetrate into the epithelium (N. gonorrhoeae and C. trachomatis) and cause pyogenic infection. Although arising from urethritis, chlamydiae and gonococci can spread further through the urogenital tract to cause epididymitis in men or cervicitis, endometritis and salpingitis in women [277].

Mucopurulent or purulent discharge, dysuria and urethral pruritus are symptoms of urethritis. However, many infections of the urethra are asymptomatic.

3.10.3 Evidence Summary

A systematic search of the literature form January 2014 until February 2019 identified 488 titles of which 71 were selected for full text review. Thirteen systematic reviews or guidelines based on systematic literature searches [275-287], and seventeen original publications [288-304] were selected for further analysis. In addition, a further eleven relevant publications were identified from the references of the reviewed literature [305-315]. The evidence questions addressed were:

1. In patients with urethritis what is the best method of detecting the causative pathogen?
2. In patients with urethritis what are the best treatment strategies for clinical or microbiological cure?

3.10.4 Diagnostic evaluation

In symptomatic patients the diagnosis of urethritis can be made based on the presence of any of the following criteria [276, 277]:

- Mucoid, mucopurulent, or purulent urethral discharge.
- Gram or methylene-blue stain of urethral secretions demonstrating inflammation. Five or more polymorphonuclear leucocytes (PMNL) per high power field (HPF) is the historical cut-off for the diagnosis of urethritis. A threshold of ≥ 2 PMNL/HPF was proposed recently based on better diagnostic accuracy [292, 305-307], but this was not supported by other studies [291]. Therefore, in line with the 2016 European Guideline on the management of NGU [276] the use of ≥ 5 PMNL/HPF cut-off level is recommended until the benefit of alternative cut-off levels is confirmed.
Evidence of urethral inflammation in the Gram stain of urethral secretions with gonococci located intracellularly as Gram-negative diplococci indicates GU. Non-gonococcal urethritis is confirmed when staining of urethral secretions indicates inflammation in the absence of intracellular diplococci. Clinicians should always perform point-of-care diagnostics (e.g., Gram staining, first-void urine with microscopy, leukocyte esterase testing) if available to obtain objective evidence of urethral inflammation and to guide treatment [276, 277, 290]. Recent studies showed that processing time of point-of-care diagnostics is highly relevant in terms of patient compliance and real-life applicability [288, 289].

Men who meet the criteria for urethritis should be tested for C. trachomatis, M. genitalium and N. gonorrhoea with nucleic acid amplification tests (NAAT), even if point-of-care tests are negative for gonorrhea [276, 279]. The sensitivity and specificity of NAATs is better than that of any of the other tests available for the diagnosis of chlamydial and gonococcal infections [280, 308]. The performance of first-catch urine is non-inferior to urethral swabs [308]. In case of delayed treatment, if a NAAT is positive for gonorrhea, a culture using urethral swabs should be performed before treatment to assess the antimicrobial resistance profile of the infective strain [277]. N. gonorrhoeae and C. trachomatis cultures are mainly used to evaluate treatment failures and monitor developing resistance to current treatment. Trichomonas spp. can usually be identified microscopically [277] or by NAATs [282].

Non-gonococcal urethritis is classified as persistent when symptoms do not resolve within three to four weeks following treatment. When this occurs NAATs should be performed for urethritis pathogens including T. vaginalis four weeks after completion of therapy [276, 293].

3.10.5 Disease management
For severe urethritis empirical treatment should be started following diagnosis. If the patients symptoms are mild, delayed treatment guided by the results of NAATs is recommended. All sexual partners at risk should be assessed and treated whilst maintaining patient confidentiality [276, 296].

3.10.5.1 Gonococcal urethritis
For GU, a combination treatment using two antimicrobials with different mechanisms of action is recommended to improve treatment efficacy and to hinder increasing resistance to cephalosporins [277]. Ceftriaxone 1 g intramuscularly or intravenously with azithromycin 1 g single oral dose should be used as first-line treatment. Azithromycin is recommended because of its favourable susceptibility rates compared to other antimicrobials, good compliance with the single-dose regimen and the possibility of a C. trachomatis co-infection [277]. In case of azithromycin allergy, doxycycline can be used instead in combination with ceftriaxone or cefixime [277]. A 400 mg oral dose of cefixime is recommended as an alternative regimen to ceftriaxone; however, it has less favourable pharmacodynamics and may lead to the emergence of resistance [278, 314].

A number of alternative regimens for the treatment of GU have been studied. In a randomised, open label, non-comparative clinical study dual treatment with a combination of intramuscular gentamicin 240 mg plus oral azithromycin 2 g (n=202) single doses and a combination of oral gemifloxacin 320 mg plus oral azithromycin 2 g (n=199) single doses were associated with microbiological cure rates of 100% and 99.5%, respectively [310]. A 2014 systematic review focusing on the use of single-dose intramuscular gentamicin concluded that there is insufficient data to support or refute the efficacy and safety of this regimen in the treatment of uncomplicated gonorrhea [284]. In three prospective single arm studies enrolling men with GU the use of extended-release azithromycin 2 g single oral dose resulted in microbiological cure rates of 83% (n=36), 93.8% (n=122) and 90.9% (n=33), respectively [300, 301, 303]. However, azithromycin monotherapy is generally not recommended because of its effect on increasing macrolide resistance rates [277]. Intramuscular spectinomycin 2 g single dose shows microbiological cure rates above 96% [311, 314] in urogenital gonorrhoeal infections; therefore, where available, it can be a valid treatment alternative. An open label, randomised trial compared oral fosfomycin trometamol 3 g on days one, three and five (n=60) with intramuscular ceftriaxone 250 mg plus oral azithromycin 1 g single dose (n=61) in men with uncomplicated GU. In the per-protocol analysis clinical and microbiologic cure rates were 96.8% and 95.3% respectively [304].

The worldwide increase in gonorrhoeal antimicrobial resistance and the emergence of multidrug-resistant gonorrhoeal strains is a globally recognised healthcare crisis which emphasises the importance of guideline adherence [283, 295, 315].

3.10.5.2 Non-gonococcal urethritis
For NGU without an identified pathogen oral doxycycline 100 mg twice daily for seven days should be used as first-line treatment. Alternatively, single dose oral azithromycin 500 mg day one and 250 mg days two
to four can be used. This regimen provides better efficacy compared to azithromycin 1 g single dose for *M. genitalium* infections, in which azithromycin 1 g single dose treatment is associated with the development of increasing macrolide resistance significantly decreasing the overall cure rate [276, 279, 285, 299]. However, a retrospective cohort study did not find significant difference between the extended and 1 g single dose azithromycin regimen regarding cure rates and the selection of macrolide resistance in *M. genitalium* urethritis [297]. If macrolide resistant *M. genitalium* is detected moxifloxacin 400 mg can be used for seven to fourteen days [276, 277, 286]. In case of failure after both azithromycin and moxifloxacin treatment, pristinamycin (registered in France) is the only antimicrobial agent with documented activity against *M. genitalium* [279, 298, 309]. Josamycin 500 mg three times a day for ten days is used in Russia, but will not eradicate macrolide-resistant strains [279].

For chlamydial urethritis azithromycin 1 g single dose and doxycycline 100 mg twice daily for seven days are both effective options [313]. A Cochrane review found that in men with urogenital *C. trachomatis* infection regimens with azithromycin are probably less effective than doxycycline for microbiological failure, however, there might be little or no difference for clinical failure [287]. Fluoroquinolones, such as ofloxacin or levofloxacin, may be used as second-line treatment only in selected cases where the use of other agents is not possible [312].

For *U. urealyticum* infections the efficacy of doxycycline 100 mg twice daily for seven days is similar to azithromycin 1 g single dose treatment [276, 294]. For urethritis caused by *T. vaginalis* oral metronidazole or tinidazole 2 g single dose is recommended as first-line treatment. For treatment options for persistent or recurrent *T. vaginalis* infection refer to the review of Sena et al., [282].

In case of persistent NGU treatment should cover *M. genitalium* and *T. vaginalis* [276, 277].

### 3.10.6 Follow-up

Patients should be followed up for control of pathogen eradication after completion of therapy only if therapeutic adherence is in question, symptoms persist or reoccurrence is suspected. Patients should be instructed to abstain from sexual intercourse for seven days after therapy is initiated, provided their symptoms have resolved and their sexual partners have been adequately treated. Reporting and source tracing should be done in accordance with national guidelines and in cooperation with specialists in venereology, whenever required. Persons who have been diagnosed with a new STD should receive testing for other STDs, including syphilis and HIV [281].

SD = single dose; b.i.d = twice daily; q.d = everyday; p.o. = orally; i.m. = intramuscular; i.v. = intravenous.

* Despite the lack of RCTs there is increasing evidence that intravenous treatment with ceftriaxone is safe and effective for the treatment of gonorrhoeal infections and avoids the discomfort of an intramuscular injection for patients [316].

### 3.11 Bacterial Prostatitis

#### 3.11.1 Introduction

Bacterial prostatitis is a clinical condition caused by bacterial pathogens. It is recommended that urologists use the classification suggested by the National Institute of Diabetes, Digestive and Kidney Diseases (NIDDK) of the National Institutes of Health (NIH), in which bacterial prostatitis, with confirmed or suspected infection, is distinguished from chronic pelvic pain syndrome (CPPS) (Table 9) [317-319].
### Table 9: Classification of prostatitis and CPPS according to NIDDK/NIH [317-319]

</table>

CPPS = chronic pelvic pain syndrome; EPS = expressed prostatic secretion; VB3 = voided bladder urine specimen 3 (urine following prostatic massage).

### 3.11.2 Evidence Summary

A systematic literature search from 1980 until June 2017 was performed. One systematic review [320], six RCTs [321-326], two narrative reviews [327, 328], one prospective cohort study [329], two prospective cross-sectional studies [330, 331], and one retrospective cohort study [323], were selected from 856 references.

A retrospective study [332] investigated the potential role of unusual pathogens in prostatitis syndrome in 1,442 patients over a four year period. An infectious aetiology was determined in 74.2% of patients; *C. trachomatis*, *T. vaginalis* and *U. urealyticum* infections were found in 37.2%, 10.5% and 5% of patients, respectively whilst *E. coli* infection was found in only 6.6% of cases. Cross sectional studies confirmed the validity of the Meares and Stamey test to determine the bacterial strain and targeted antibiotic therapies [330, 331]. The evidence levels were good, in particular those regarding information on atypical strains, epidemiology and antibiotic treatments.

A systematic review on antimicrobial therapy for CBP [320] compared multiple antibiotic regimens from eighteen selected studies enrolling a total of 2,196 patients. The role of fluoroquinolones as first-line agents was confirmed with no significant differences between levofloxacin, ciprofloxacin and prulifloxacin in terms of microbiological eradication, clinical efficacy and adverse events. The efficacy of macrolides and tetracyclines on atypical pathogens was confirmed.

Randomised controlled trials on combined treatments [325, 326] indicated that the combination of plants/herbal extracts or PDE5Is with antibiotics may improve quality of life and symptoms in patients with CBP; however, the number of enrolled patients was inadequate to obtain definitive conclusions.

A review of treatment of bacterial prostatitis [327] indicated that the treatment of CBP is hampered by the lack of an active antibiotic transport mechanism into infected prostate tissue and fluids. The review underlined the potential effect of different compounds in the treatment of ABP and CBP on the basis of over 40 studies on the topic.

One RCT compared the effects of two different metronidazole regimens for the treatment of CBP caused by *T. vaginalis* [324]. Metronidazole 500 mg three times daily for fourteen days was found to be efficient for micro-organism eradication in 93.3% of patients with clinical failure in 3.33% of cases. The evidence question addressed was: In men with NIDDK/NIH Category I or II prostatitis what is the best antimicrobial treatment strategy for clinical resolution and eradication of the causative pathogen?

### 3.11.3 Epidemiology, aetiology and pathogenesis

Prostatitis is a common diagnosis, but less than 10% of cases have proven bacterial infection [228]. *Enterobacterales*, especially *E. coli*, are the predominant pathogens in ABP [333]. In CBP, the spectrum of species are wider and may include atypical micro-organisms [327]. In patients with immune deficiency or HIV infection, prostatitis may be caused by fastidious pathogens, such as *M. tuberculosis*, *Candida spp* and other rare pathogens, such as *Coccidioides immitis*, *Blastomyces dermatitidis*, and *Histoplasma capsulatum* [334]. The significance of identified intracellular bacteria, such as *C. trachomatis*, is uncertain [335]; however, two studies have highlighted its possible role as a causative pathogen in CBP [336, 337].

### 3.11.4 Diagnostic evaluation

#### 3.11.4.1 History and symptoms

Acute bacterial prostatitis usually presents abruptly with voiding symptoms and distressing but poorly localised pain. It is often associated with malaise and fever. Transrectal prostate biopsy increases the risk of ABP despite antibiotic prophylaxis and antiseptic prevention procedures [321]. Chronic bacterial prostatitis is defined by symptoms that persist for at least three months [338-340]. The predominant symptoms are pain at various locations including the perineum, scrotum, penis and inner part of the leg as well as LUTS [317-319].
3.11.4.2 **Symptom questionnaires**
In CBP symptoms appear to have a strong basis for use as a classification parameter [341]. Prostatitis symptom questionnaires have therefore been developed to assess severity and response to therapy [341, 342]. They include the validated Chronic Prostatitis Symptom Index (CPSI); however, its usefulness in clinical practice is uncertain [329].

3.11.4.3 **Clinical findings**
In ABP, the prostate may be swollen and tender on DRE. Prostatic massage should be avoided as it can induce bacteraemia and sepsis. Urine dipstick testing for nitrite and leukocytes has a positive predictive value of 95% and a negative predictive value of 70% [343]. Blood culture and complete blood count are useful in ABP. Imaging studies can detect a suspected prostatic abscess [327].

In case of longer lasting symptoms CPPS as well as other urogenital and anorectal disorders must be taken into consideration. Symptoms of CBP or CPPS can mask prostate tuberculosis. Pyospermia and hematospermia in men in endemic regions or with a history of tuberculosis should trigger investigation for urogenital tuberculosis.

3.11.4.4 **Urine cultures and expressed prostatic secretion**
The most important investigation in the evaluation of a patient with ABP is mid-stream urine culture [327]. In CBP, quantitative bacteriological localisation cultures and microscopy of the segmented urine and expressed prostatic secretion (EPS), as described by Meares and Stamey [344], are still important investigations to categorise clinical prostatitis [330, 331]. Accurate microbiological analysis of samples from the Meares and Stamey test may also provide useful information on the presence of atypical pathogens such as *C. trachomatis*, *T. vaginalis* and *U. urealiticum* [332]. The two-glass test has been shown to offer similar diagnostic sensitivity to the four-glass test [345].

3.11.4.5 **Prostate biopsy**
Prostate biopsies cannot be recommended as routine work-up and are not advisable in patients with untreated bacterial prostatitis due to the increased risk of sepsis.

3.11.4.6 **Other tests**
Transrectal US may reveal endoprostatic abscesses, calcification in the prostate, and dilatation of the seminal vesicles; however, it is unreliable as a diagnostic tool for prostatitis [346].

3.11.4.7 **Additional investigations**

3.11.4.7.1 Ejaculate analysis
Performing an ejaculated semen culture improves the diagnostic utility of the four-glass test [330]; however, semen cultures are more often positive than EPS cultures in men with non-bacterial prostatitis [331]. Bladder outflow and urethral obstruction should always be considered and ruled out by uroflowmetry, retrograde urethrography, or endoscopy.

3.11.4.7.2 First-void urine sample
First-void urine is the preferred specimen for the diagnosis of urogenital *C. trachomatis* infection in men by NAATs, since it is non-invasive and yet allows the detection of infected epithelial cells and associated *C. trachomatis* particles [347].

3.11.4.7.3 Prostate specific antigen (PSA)
Prostate specific antigen is increased in about 60% and 20% of men with ABP and CBP, respectively [328]. The PSA level decreases after antibiotic therapy (which occurs in approximately 40% of patients) and correlates with clinical and microbiological improvement [322]. Measurement of free and total PSA adds no practical diagnostic information in prostatitis [348].

3.11.4.8 **Summary of evidence and recommendations for the diagnosis of bacterial prostatitis**

</table>
Transrectal ultrasound is unreliable and cannot be used as a diagnostic tool in prostatitis.  

Semen culture sensitivity is reported to be approximately 50%; therefore, it is not routinely part of the diagnostic assessment of CBP.  

Prostate specific antigen levels may be elevated during active prostatitis; therefore, PSA testing should be avoided as it offers no practical diagnostic information for prostatitis.

#### 3.11.5 Disease management

##### 3.11.5.1 Antimicrobials

Antimicrobials are life-saving in ABP and recommended in CBP. Culture-guided antibiotic treatments are the optimum standard; however, empirical therapies should be considered in all patients with ABP.

In ABP parenteral administration of high doses of bactericidal antimicrobials, such as broad-spectrum penicillins, a third-generation cephalosporin or fluoroquinolones, is recommended [349]. For initial therapy, any of these antimicrobials may be combined with an aminoglycoside [333-342, 349-353]. Ancillary measures include adequate fluid intake and urine drainage [228]. After normalisation of infection parameters, oral therapy can be substituted and continued for a total of two to four weeks [354].

Fluoroquinolones, despite the high resistance rates of uropathogens, are recommended as first-line agents in the empirical treatment of CBP because of their favourable pharmacokinetic properties [355], their generally good safety profile and antibacterial activity against Gram-negative pathogens including *P. aeruginosa* and *C. trachomatis* [320, 356]. However, increasing bacterial resistance is a concern. Azithromycin and doxycycline are active against atypical pathogens such as *C. trachomatis* and genital mycoplasmas [323, 332]. Levofloxacin did not demonstrate significant clearance of *C. trachomatis* in patients with CBP [357]. Metronidazole treatment is indicated in patients with *T. vaginalis* infections [324].

Duration of fluoroquinolone treatment must be at least fourteen days while azithromycin and doxycycline treatments should be extended to at least three to four weeks [323, 332]. In CBP antimicrobials should be given for four to six weeks after initial diagnosis [327]. If intracellular bacteria have been detected macrolides or tetracyclines should be given [320, 355, 358].

##### 3.11.5.2 Intraprostatic injection of antimicrobials

This treatment has not been evaluated in controlled trials and should not be considered [359, 360].

##### 3.11.5.3 Combined treatments

A combination of fluoroquinolones with various herbal extracts may attenuate clinical symptoms without increasing the rate of adverse events [325]. However, a combination of fluoroquinolones with vardenafil did not improved microbiological eradication rates or attenuated pain or voiding symptoms in comparison with fluoroquinolone treatment alone [326].

##### 3.11.5.4 Drainage and surgery

Approximately 10% of men with ABP will experience urinary retention [361] which can be managed by urethral or suprapubic catheterisation. However, recent evidence suggests that suprapubic catheterisation can reduce the risk of development of CBP [362].

In case of prostatic abscess, both drainage and conservative treatment strategies appear feasible [363]; however, the abscess size may matter. In one study, conservative treatment was successful if the abscess cavities were < 1 cm in diameter, while larger abscesses were better treated by single aspiration or continuous drainage [364].
3.11.5.5 Summary of evidence and recommendations for the disease management of bacterial prostatitis

### Summary of evidence

The treatment regimen for ABP is based on clinical experience and a number of uncontrolled clinical studies. For systemically ill patients with ABP, parenteral antibiotic therapy is preferable. After normalisation of infection parameters, oral therapy can be substituted and continued for a total of two to four weeks.

The role of fluoroquinolones as first-line agents for antimicrobial therapy for CBP was confirmed in a systematic review, with no significant differences between levofloxacin, ciprofloxacin and prulifloxacin in terms of microbiological eradication, clinical efficacy and adverse events.

Metronidazole 500 mg three times daily for fourteen days was found to be efficient for eradication in 93.3% of patients with *T. vaginalis* CBP.

In patients with CBP caused by obligate intracellular pathogens, macrolides showed higher microbiological and clinical cure rates compared to fluoroquinolones.

Clinicians should consider local drug-resistance patterns when choosing antibiotics.

### Recommendations

**Acute bacterial prostatitis**

Treat acute bacterial prostatitis according to the recommendations for complicated UTIs (see section 3.7.5).

**Strong**

**Chronic bacterial prostatitis (CBP)**

Prescribe a fluoroquinolone (e.g. ciprofloxacin, levofloxacin) as first-line treatment for CBP.

**Strong**

Prescribe a macrolide (e.g. azithromycin) or a tetracycline (e.g. doxycycline) if intracellular bacteria have been identified as the causative agent of CBP.

**Strong**

Prescribe metronidazole in patients with *Trichomonas vaginalis* CBP.

**Strong**

</table>

*b.i.d = twice daily; t.i.d = three times daily.*

3.11.6 **Follow-up**

In asymptomatic post-treatment patients routine urinalysis and/or urine culture is not mandatory as there are no validated tests of cure for bacterial prostatitis except for cessation of symptoms [327]. In patients with persistent symptoms and repeated positive microbiological results for sexually transmitted infectious pathogens, microbiological screening of the patient’s partner/s is recommended. Antibiotic treatments may be repeated with a more prolonged course, higher dosage and/or different compounds [327].

3.12 **Acute Infective Epididymitis**

3.12.1 **Epidemiology, Aetiology and Pathophysiology**

Epididymitis is a common condition with incidence ranging from 25 to 65 cases per 10,000 adult males per year and can be acute, chronic or recurrent [365]. Acute epididymitis is clinically characterised by pain, swelling and increased temperature of the epididymis, which may involve the testis and scrotal skin. It is generally caused by migration of pathogens from the urethra or bladder that can be identified by appropriate diagnostics in up to 90% of patients [366]. Torsion of the spermatic cord (testicular torsion) is the most important differential diagnosis in boys and young men.

The predominant pathogens isolated are *Enterobacterales* (typically *E. coli*), *C. trachomatis* and *N. gonorrhoeae* [367]. Men who have anal intercourse and those with abnormalities of the urinary tract resulting in bacteriuria are at higher risk of epididymitis caused by *Enterobacterales* [368]. The mumps virus should be
considered if there are viral prodromal symptoms and salivary gland enlargement. Tuberculous epididymitis may occur, typically as chronic epididymitis, in high-risk groups such as men with immunodeficiency and those from high prevalence countries, it frequently results in a discharging scrotal sinus. *Brucella* or *Candida* spp. are rare possible pathogens.

3.12.2 **Diagnostic Evaluation**

Culture of a mid-stream specimen of urine should be performed and any previous urine culture results should be checked. Sexually transmitted infections including *C. trachomatis* or *N. gonorrhoeae* should be detected by NAAT on first-voided urine or urethral swab. A urethral swab or smear should be performed for Gram staining and culture of *N. gonorrhoeae*, when available [365, 369, 370]. Detection of these pathogens should be reported according to local procedures. All patients with probable sexually transmitted infections (STIs) should be advised to attend an appropriate clinic to be screened for other STIs. Men with *Enterobacterales* may require investigation for lower urinary tract abnormalities. If tuberculous epididymitis is suspected, three sequential early morning urine samples should be cultured for acid-fast bacilli (AFB) and sent for screening by NAAT for *M. tuberculosis* DNA [371]. If appropriate, prostate secretion, ejaculate, discharge from a draining scrotal fistula, as well as fine needle aspiration and biopsy specimens should be investigated using microscopy, AFB culture and NAAT. Scrotal US is more accurate for the diagnose of acute epididymitis than urinalysis alone [372] and may also be beneficial for the exclusion of other pathologies [373].

3.12.3 **Disease Management**

Men with suspected STI should be informed of the risks to others and advised not to have sex until free of infection. Empirical antimicrobial therapy has to be chosen with consideration of the most probable pathogen and degree of penetration into the inflamed epididymis and may need to be varied according to local pathogen sensitivities and guidance. Generally, both *C. trachomatis* and *Enterobacterales* should be covered initially and the regimen modified according to pathogen identification. Doxycycline and some specific fluoroquinolones have good clinical and microbiological cure rates in patients with suspected *C. trachomatis* or *M. genitalium* and both achieve adequate levels in inflamed male genital tissues with oral dosing. Macrolide antibiotics such as azithromycin are effective against *C. trachomatis* but have not been tested in epididymitis; however, initial pharmacokinetic studies suggest that azithromycin may effectively penetrate epididymal tissue when given in multiple doses [374]. Fluoroquinolones remain effective for oral treatment of *Enterobacterales* although resistance is increasing and local advice should be sought. Fluoroquinolones should not be considered for gonorrhoea. Single high parenteral dose of a third generation cephalosporin is effective against *N. gonorrhoeae*; current resistance patterns and local public health recommendations should guide choice of agent. Clinical response to antibiotics in men with severe epididymitis should be assessed after approximately three days. Men with likely or proven STI should be assessed at fourteen days to check cure and ensure tracing and treatment of contacts according to local public health recommendations.

3.12.4 **Evidence Summary**

Relating to this chapter, four guidelines based on systematic reviews were identified [277, 369, 375, 376]. No evidence quality assessments were detailed. A high quality RCT demonstrated that a ten-day course of ciprofloxacin was superior to pivampicillin for clinical cure (80% vs. 60%) in men aged > 40 years [377]. Data from a large comparative case series suggested that young age and history of sexual activity are not sufficiently predictive of a sexually transmitted pathogen to guide antibiotic treatment in acute epididymitis [366].

Empiric antibiotic regimens from existing guidelines [277, 369, 375, 376] and panel consensus:

1. For men with acute epididymitis at low risk of gonorrhoea (e.g. no discharge) a single agent or combination of two agents of sufficient dose and duration to eradicate *C. trachomatis* and *Enterobacterales* should be used. Appropriate options are:

   A. A fluoroquinolone active against *C. trachomatis* orally once daily for ten to fourteen days*

   OR

   B. Doxycycline 200 mg initial dose by mouth and then 100 mg twice daily for ten to fourteen days* plus an antibiotic active against *Enterobacterales*** for ten to fourteen days*

2. For men with likely gonorrhoeal acute epididymitis a combination regimen active against *Gonococcus* and *C. trachomatis* must be used such as:

   A. Ceftriaxone 1000 mg intramuscularly single dose plus doxycycline 200 mg initial dose by mouth and then 100 mg twice daily for ten to fourteen days*
3. For non-sexually active men with acute epididymitis a single agent of sufficient dose and duration to eradicate Enterobacterales should be used. Appropriate option is a fluoroquinolone by mouth once daily for ten to fourteen days*

*Depending upon pathogen identification and clinical response.

** A parenteral option will be required for men with severe infection requiring hospitalisation.

Surgical exploration may be required to drain abscesses or debride tissue. A comparative cohort study found that lack of separation of epididymis and testis on palpation and the presence of abscess on US may predict requirement for surgery following initial antibiotic treatment [378].

A cohort study found semen parameters may be impaired during epididymitis but recovered following successful treatment [379]. Comparative clinician cohort studies suggest adherence to guidelines for assessment and treatment of epididymitis is low, particularly by urologists compared to sexual health specialists [380] and by primary care physicians [381].

3.12.5 Screening

A large cohort screening study for carriage of C. trachomatis including a randomly selected group of 5,000 men of whom 1,033 were tested showed no benefit in terms of reduction in risk of epididymitis over nine years of observation [382].

*Despite the lack of RCTs there is increasing evidence that intravenous treatment with ceftriaxone is safe and effective for the treatment of gonorrhoeal infections and avoids the discomfort of an intramuscular injection for patients [316].
**3.13 Fournier’s Gangrene (Necrotising fasciitis of the perineum and external genitalia)**

### 3.13.1 Epidemiology, Aetiology and Pathophysiology

Fournier’s gangrene is an aggressive and frequently fatal polymicrobial soft tissue infection of the perineum, peri-anal region, and external genitalia [383]. It is an anatomical sub-category of necrotising fasciitis with which it shares a common aetiology and management pathway.

### 3.13.2 Diagnostic Evaluation

Typically, there is painful swelling of the scrotum or perineum with sepsis [383]. Examination shows small necrotic areas of skin with surrounding erythema and oedema. Crepitus on palpation and a foul-smelling exudate occurs with more advanced disease. Patient risk factors for occurrence and mortality include being immunocompromised, most commonly diabetes or malnutrition, recent urethral or perineal surgery, and high body mass index (BMI). In up to 40% of cases, the onset is more insidious with undiagnosed pain often resulting in delayed treatment [384]. A high index of suspicion and careful examination, particularly of obese patients, is required. Computed tomography or MRI can help define para-rectal involvement, suggesting the need for bowel diversion [383].

### 3.13.3 Disease Management

The degree of internal necrosis is usually vastly greater than suggested by external signs, and consequently, adequate, repeated surgical debridement with urinary diversion by suprapubic catheter is necessary to reduce mortality [383]. Consensus from case series suggests that surgical debridement should be early (< 24 hours) and complete, as delayed and/or inadequate surgery may result in higher mortality [383]. Immediate empiric

\* Despite the lack of RCTs there is increasing evidence that intravenous treatment with ceftriaxone is safe and effective for the treatment of gonorrhoeal infections and avoids the discomfort of an intramuscular injection for patients [316].
parenteral antibiotic treatment should be given that covers all probable causative organisms and can penetrate inflammatory tissue. A suggested regime would comprise a broad-spectrum penicillin or third-generation cephalosporin, gentamicin and metronidazole or clindamycin [383]. This can then be refined, guided by microbiological culture.

3.13.4 Evidence Summary
A systematic literature search from 1980 to July 2017 was performed. From 640 references one RCT [385], two systematic reviews [386, 387], one narrative review [383], three registry studies [388-390], one prospective cohort study [391] and two retrospective comparative cohort studies with at least 25 patients [392, 393] were selected. The three registry studies from the United States [388-390], found mortality rates of 10%, 7.5% and 5% from 650, 1,641 and 9,249 cases, respectively. Older age, diabetes and high BMI were associated with higher risk. A prospective cohort study showed that disease-specific severity scores did predict outcome, but were not superior to generic scoring systems for critical care [391]. The evidence questions addressed were:

1. What is the best antimicrobial treatment strategy to reduce mortality?
2. What is the best debridement and reconstruction strategy to reduce mortality and aid recovery?
3. Are there any effective adjuvant treatments that improve outcome?

Concerning the evidence questions:
A. A low quality retrospective case series [392] with 168 patients found no significant difference in mortality between patients given ≤ 10 days of parenteral antibiotics (80 patients) and those given > 10 days (88 patients).
B. A systematic review of wound closure techniques [387] found low-quality evidence from 16 case series involving 425 male patients. They recommended primary or secondary wound closure for scrotal defects ≤ 50% with the use of flaps or skin grafts for defects involving > 50% of the scrotum or with extension outside the scrotum.
C. A systematic review on the use of hyperbaric oxygen therapy [386] included three comparative case series and four other case series. All were retrospective and published prior to 2000. No consistent evidence of benefit was found; an RCT was advised. A more recent comparative case series [393] suggested benefit for use of hyperbaric oxygen therapy in sixteen patients compared to twelve cases without use of such therapy in terms of reduced mortality and fewer debridements (low quality evidence). A low-quality RCT [385] with 30 patients found that use of honey soaked dressings resulted in a shorter hospital stay (28 vs. 32 days) than dressing soaked with Edinburgh solution of lime (EUSOL). No evidence of benefit for use of negative-pressure (vacuum) wound therapy in Fournier’s gangrene was found.

3.14 Management of Human papilloma virus in men
3.14.1 Epidemiology
Human papilloma virus (HPV) is one of the most frequently sexually transmitted viruses encompassing both oncogenic (low- and high-risk variants) and non-oncogenic viruses. HPV16 is the most common oncogenic variant, detected in 20% of all HPV cases [395]. A recent meta-analysis revealed a prevalence of 49% of any type of HPV and 35% of high-risk HPV in men [396]. Similar to the female genital tract, half of all HPV infections in the male genital tract are co-infections (≥ 2 HPV strains) [397].

HPV presence is dependent on study setting. In men attending urological clinics HPV was detected in 6% of urine samples [398]. A meta-analysis reported seminal HPV in 4.5-15.2% of patients resulting in seminal HPV being associated with decreased male fertility [395]. A cross sectional study of 430 men presenting for fertility treatment detected HPV in 14.9% of semen samples [399]. The presence of HPV in semen was not associated with impaired semen quality [399]. However, another systematic review reported a possible association between HPV and altered semen parameters, and in women possible miscarriage or premature rupture of the membrane during pregnancy [400]. HPV6 and/or 11 were the most common genotypes detected in an observational study of anogenital warts, whilst HPV16 is correlated with severity of anal cytology [401]. The incidence of non-oncogenic HPV infection has been shown to be higher in men than women [402]. In males, approximately 33% of penile cancers and up to 90% of anal cancers are attributed to high-risk HPV infections, primarily with HPV16 [403]. The EAU Penial Cancer Guidelines will publish a comprehensive update in March 2022 including the results of two systematic reviews on HPV and penile cancer. Oral HPV is associated with oropharyngeal carcinomas approximately 22.4%, 4.4% and 3.5% of oral cavity, oropharynx and larynx cancers, respectively are attributed to HPV [403]. Systematic reviews have reported prevalence rates of oral HPV from 5.5-7.7%, with HPV16 present in 1-1.4% of patients [404, 405].

3.14.2 Risk factors
Risk factors for HPV infection include early age of first sexual intercourse, sexual promiscuity, higher frequency of sexual intercourse, smoking and poor immune function [406-410]. Incidence and prevalence of overall HPV was considerably higher in men who have sex with men (MSM) compared to heterosexuals [404, 407]. Overall, the prevalence of HPV in different sites seems to be higher in young, sexual-active adults compared to other population groups [406]. Stable sexual habits, circumcision and condom use are protective factors against HPV [396, 410-414]. Added risk factors of oral HPV infection are alcohol consumption, poor oral hygiene and sexual behaviours (oral and vaginal) [404, 406]. Positive HIV status, phimosis, and HPV status of the partner have also been associated with anogenital HPV status and decreased clearance in a number of studies [411].

3.14.3 Transmission
HPV typically spreads by sustained direct skin-to-skin or mucosal contact, with vaginal, oral and anal sex being the most common transmission route [408]. In addition, HPV has been found on surfaces in medical settings and public environments raising the possibility of object-to-skin/mucosa transmission [415]. Further studies on non-sexual and non-penetrative sexual transmission are needed to understand the complexity of HPV transmission. HPV transmission may also be influenced by genotype, with a higher incidence of HPV51 and HPV52 and a high prevalence of HPV16 and HPV18 in the general and high-risk male population [408].
3.14.4 Clearance
HPV time-to-clearance ranges from 1.3 to 42.1 months [416]. Clearance may be influenced by HPV genotype, patients’ characteristics and affected body site [407, 411, 416]. HPV16 has the highest incidence of high-risk HPV variants and has the lowest clearance across sites [411].

3.14.5 Diagnosis
There is currently no approved test for HPV in men. Routine testing to check for HPV or HPV-related disease in men is not recommended. A physical examination to identify HPV lesions should be carried out. An acetic acid test to diagnose sub-clinical HPV lesions may be performed. If the diagnosis is uncertain or there is a suspicion of cancer a biopsy should be carried out. Intra-urethral condylomas are relatively uncommon and are usually limited to the distal urethral meatus [417, 418]. Urethrocystoscopy may be used to diagnose the presence of intra-urethral or bladder warts [418]; however, there is no high-level evidence for the use of invasive diagnostic tools for localisation of intra-urethral HPV. For detailed recommendations on the diagnosis of anogenital warts please refer to the IUSTI-European guideline for the management of anogenital warts [419].

3.14.6 Treatment of HPV related diseases
Approximately 90% of HPV infections do not cause any problems and are cleared by the body within two years. However, treatment is required when HPV infection manifests as anogenital warts to prevent the transmission of HPV-associated anogenital infection and to minimise the discomfort caused to patients [419]. Of the treatment options available only surgical treatment has a primary clearance rate approaching 100%.

3.14.6.1 Treatments suitable for self-application
Patient-applied treatments include podophyllotoxin, salicylic acid, imiquimod, polyphenon E, 5-fluoracil and potassium hydroxide [419]. Imiquimod 5% cream showed a total clearance of external genital or perianal warts in 50% of immunocompetent patients [420] as well as in HIV positive patients successfully treated with highly active antiretroviral therapy [421]. A Cochrane review of published RCTs found imiquimod to be superior to placebo in achieving complete clearance of warts (RR: 4.03, 95% CI: 2.03–7.99) [422]. The recommended treatment schedule is imiquimod 5% cream applied to all external warts overnight three times each week for sixteen weeks [419]. In an RCT involving 502 patients with genital and/or perianal warts sinecatechins 15% and 10% showed a complete clearance of all baseline and newly occurring warts in 57.2% and 56.3% of patients, respectively vs. 33.7% for placebo [423]. In addition, sinecatechins 10% has been shown to be associated with lower short-term recurrence rates when used as sequential therapy after laser CO₂ ablative therapy [424]. Sinecatechins is applied three times daily until complete clearance, or for up to sixteen weeks. Clearance rates of 36–83% for podophyllotoxin solution and 43–70% for podophyllotoxin cream have been reported [419]. A systematic review and meta-analysis confirmed the effectiveness of podophyllotoxin 0.5% solution relative to placebo (RR: 19.86, 95% CI: 3.88–101.65) [425]. Podophyllotoxin is self-applied to lesions twice daily for three days, followed by four rest days, for up to four or five weeks. An RCT has also shown potassium hydroxide 5% to be an effective, safe, and low-cost treatment modality for genital warts in men [426].

3.14.6.2 Physician-administered treatment
Physician-administered treatments included cryotherapy (79-88% clearance rate; 25-39% recurrence rate), surgical treatment (61-94% clearance rate), including excision, electrosurgery, electrocautery and laser therapy (75% clearance rate) [427, 428]. Physician-administered therapies are associated with close to 100% clearance rates, but they are also associated with high rates of recurrence as they often fail to eliminate invisible HPV-infected lesions [427, 428]. No data about the superiority of one treatment over another are available. However, among all interventions evaluated in a recent systematic review and network meta-analysis, surgical excision appeared to be the most effective treatment at minimising risk of recurrence [429].

3.14.7 **Circumcision for reduction of HPV prevalence**

Male circumcision is a simple surgical procedure which has been shown to reduce the incidence of sexually transmitted infections including HIV, syphilis and HSV-2 [430]. Two systematic reviews and meta-analyses, showed an inverse association between male circumcision and genital HPV prevalence in men [414, 416]. It has been suggested that male circumcision could be considered as an additional one-time preventative intervention likely to reduce the burden of HPV-related diseases in both men and women, particularly among those countries in which HPV vaccination programs and cervical screening are not available [416].

**Summary of evidence LE**

| Two systematic reviews and meta-analyses, showed an inverse association between male circumcision and genital HPV prevalence in men. |
| 1a |

**Recommendation**

| Discuss male circumcision with patients as an additional one-time preventative intervention for HPV-related diseases. |
| Strong |

3.14.8 **Therapeutic vaccination**

Three different vaccines against HPV have been licensed to date, but routine vaccination of males is currently implemented in only a few countries including Australia, Canada, the USA and Austria. The aim of male vaccination is to reduce the rate of anal and penile cancers as well as head and neck cancers [403, 431].

A systematic review including a total of 5,294 patients reported vaccine efficacy against persisting (at least six months) anogenital HPV16 infections of 46.9% (28.6-60.8%) and against persisting oral infections of 88% (2–98%). A vaccine efficacy of 61.9% (21.4–82.8%) and 46.8% (20–77.9%) was observed against anal intraepithelial neoplasia grade 2 and 3 lesions, respectively [403]. The systematic review reported no meaningful estimates on vaccine efficacy against penile intraepithelial neoplasia grade 2 or 3, and no data were identified for anal, penile or head and neck squamous cell cancers [403].

A phase 3 clinical trial including 180 male patients evaluated the potential of MVA E2 recombinant vaccinia virus to treat intraepithelial lesions associated with papillomavirus infection [432]. The study showed promising results in terms of immune system stimulation against HPV lesions as well as regression in intraepithelial lesions.

**Summary of evidence**

| The role of therapeutic HPV vaccination in males in terms of effectiveness and safety is limited by the small number of relevant studies. |
| 2 |

| Therapeutic HPV vaccination in males is moderately effective against persistent anogenital HPV16 infection [(46.9% (28.6-60.8%)] and high-grade anal intraepithelial lesions [grade 2: 61.9% (21.4–82.8%); grade 3: 46.8% (20-77.9%)]. |
| 1b |

**Recommendation**

| Offer HPV vaccine to males after surgical removal of high-grade anal intraepithelial neoplasia. |
| Weak |

3.14.9 **Prophylactic vaccination**

A systematic review and meta-analysis reported that vaccination is moderately effective against genital HPV-related diseases irrespective of an individual’s HPV status; however, higher vaccine efficacy was observed in HPV-naive males [403]. Supporting the early vaccination of boys with the goal of establishing optimal vaccine-
induced protection before the onset of sexual activity [403]. An RCT including 1,124 patients demonstrated high efficacy of the quadrivalent HPV vaccine vs. placebo against HPV6/11/16/18-related persistent infections [433]. Furthermore, the vaccine elicited a robust immune response and was well tolerated with mild vaccination-related adverse events e.g. injection-site pain and swelling [433]. In addition, a Cochrane review, demonstrated that the quadrivalent HPV vaccine appears to be effective in the prevention of external genital lesions and genital warts in males [434].

Despite the fact quadrivalent HPV vaccines were approved for use in young adult males in 2010 vaccination rates have remained low at 10-15% [435]. Barriers to uptake in this patient group include lack of awareness about HPV vaccines and HPV-related diseases, concerns about vaccine safety and efficacy, economic/cost issues related to vaccine uptake, underestimation of HPV infection risks and sexual activity [435]. Healthcare professionals should provide easily understood and accessible communication resources regarding these issues, in order to educate young adult males and their families on the importance of HPV vaccination to reduce the incidence of certain cancers in later life [435, 436].

**Figure 3: Diagnostic and treatment algorithm for the management of HPV in men**

**Diagnosis**

Physical examination to identify HPV lesion:
- Use a good light source
- Magnification with a lens may be useful
- Inspect the urethral meatus

**Positive**

Physical diagnosis uncertain
- Acetic acid test to diagnose sub-clinical HPV lesions
- Biopsy if there is diagnostic uncertainty or suspicion of pre-cancer or cancer
- Consider a dermatological consultation

**Negative**

**Treatment of HPV lesion**

- Patient-applied treatments - imiquimod 5%; sinecatechins 15% and 10%; and podophyllotoxin 0.5%
- Physician-administered treatment - cryotherapy and surgical treatment including excision, electrosurgery, electrocautery and laser therapy

**Switch treatment**

- Follow-up visit when treatment complete;
- And again at 6 months.

**Persistent/infection, relapse or recurrence**

- Yes
- No

**Discuss:**
- HPV natural history, onward transmission and the partial protection of condoms against HPV
- Self-surveillance for new lesions
- The role of HPV vaccine in motivated patients
3.15 Peri-Procedural Antibiotic Prophylaxis

3.15.1 General Principles

3.15.1.1 Definition of infectious complications

The European Centre for Disease Prevention and Control (ECDC) and the CDC have both presented similar definitions recommended for the evaluation of infectious complications [437, 438].

3.15.1.2 Non-antibiotic measures for asepsis

There are a number of non-antibiotic measures designed to reduce the risk of surgical site infection (SSI), many are historically part of the routine of surgery. The effectiveness of measures tested by RCTs are summarised in systematic reviews conducted by the Cochrane Wounds Group (http://wounds.cochrane.org/news/reviews). Urological surgeons and the institutions in which they work should consider and monitor maintenance of an aseptic environment to reduce risk of infection from pathogens within patients (microbiome) and from outside the patient (nosocomial/healthcare-associated). This should include use of correct methods of instrument cleaning and sterilisation, frequent and thorough cleaning of operating rooms and recovery areas and thorough disinfection of any contamination. The surgical team should prepare to perform surgery by effective hand washing [439], donning of appropriate protective clothing and maintenance of asepsis. These measures should continue as required in recovery and ward areas.

Patients should be encouraged to shower pre-operatively, but use of chlorhexidine soap does not appear to be beneficial [440]. Although evidence quality is low, any required hair removal appears best done by clipping, rather than shaving, just prior to incision [441]. Mechanical bowel preparation should not be used as evidence review suggests harm not benefit [442, 443]. There is some weak evidence that skin preparation using alcoholic solutions or chlorhexidine result in a lower rate of SSI than iodine solutions [444]. Studies on the use of plastic adherent drapes showed no evidence of benefit in reducing SSI [445].

3.15.1.3 Detection of bacteriuria prior to urological procedures

Identifying bacteriuria prior to diagnostic and therapeutic procedures aims to reduce the risk of infectious complications by controlling any pre-operative detected bacteriuria and to optimise antimicrobial coverage in conjunction with the procedure. A systematic review of the evidence identified eighteen studies comparing the diagnostic accuracy of different index tests (dipstick, automated microscopy, dipslide culture and flow cytometry), with urine culture as the reference standard [446]. The systematic review concluded that none of the alternative urinary investigations for the diagnosis of bacteriuria in adult patients prior to urological interventions can currently be recommended as an alternative to urine culture [446].

3.15.1.4 Choice of agent

Urologists should have knowledge of local pathogen prevalence for each type of procedure, their antibiotic susceptibility profiles and virulence in order to establish written local guidelines. These guidelines should cover the five modalities identified by the ECDC following a systematic review of the literature [447]. The agent should ideally not be one that may be required for treatment of infection. When risk of skin wound infection is low or absent, an aminoglycoside (gentamicin) should provide cover against likely uropathogens provided the eGFR is > 20 mL/min; second generation cephalosporins are an alternative [448]. Recent urine culture results including presence of any multi-resistant organisms, drug allergy, history of C. difficile associated diarrhoea, recent antibiotic exposure, evidence of symptomatic infection pre-procedure and serum creatinine should be checked. The panel have decided not to make recommendations for specific agents for particular procedures as there is considerable variation in Europe and worldwide regarding bacterial pathogens, their susceptibility and availability of antibiotic agents.

3.15.2 Specific procedures and evidence question

An updated literature search from February 2017 (cut-off of last update) to June 2021 identified RCTs, systematic reviews and meta-analyses that investigated the benefits and harms of using antibiotic prophylaxis prior to specific urological procedures. The available evidence enabled the panel to make recommendations concerning urodynamics, cystoscopy, stone procedures (extracorporeal shockwave lithotripsy [ESWL], ureteroscopy and percutaneous nephrolithotomy [PCNL], transurethral resection of the prostate (TURP) and transurethral resection of the bladder (TURB). For nephrectomy and prostatectomy the scientific evidence was too weak to allow the panel to make recommendations either for or against antibiotic prophylaxis. The general evidence question was: Does antibiotic prophylaxis reduce the rate of post-operative symptomatic UTI in patients undergoing each named procedure?

3.15.2.1 Urodynamics

The literature search identified one systematic review for antibiotic prophylaxis in women only [449]. This included three RCTs (n=325) with the authors reporting that prophylactic antibiotics reduced the risk of
bacteriuria but not clinical UTI after urodynamics [449]. A previous Cochrane review identified nine RCTs enrolling 973 patients with overall low quality and high or unclear risks of bias [450]. The outcome of clinical UTI was reported in four trials with no benefit found for antibiotic prophylaxis vs. placebo [RR (95%CI) 0.73 (0.52-1.03)]. A meta-analysis of nine trials showed that use of antibiotics reduced the rate of post-procedural bacteriuria [RR (95%CI) 0.35 (0.22-0.56)] [450].

3.15.2.2 Cystoscopy

Three systematic reviews and meta-analyses [451-453] and one additional RCT [454] on cystoscopy for stent removal were identified. Garcia-Perdomo et al., included seven RCTs with a total of 3,038 participants. The outcome of symptomatic UTI was measured by five trials of moderate overall quality and meta-analysis showed a benefit for using antibiotic prophylaxis [RR (95%CI) 0.53 (0.31 – 0.90)]; ARR 1.3% (from 2.8% to 1.5%) with a NNT of 74 [452]. This benefit was not seen if only the two trials with low risk of bias were used in the meta-analysis. Carey et al., included seven RCTs with 5,107 participants. Six trials were included in meta-analysis of the outcome of symptomatic bacteriuria which found benefit for use of antibiotic prophylaxis [RR (95%CI) 0.34 (0.27 – 0.47)]; ARR 3.4% (from 6% to 2.6%) with NNT of 28 [451]. Zeng et al., included twenty RCTs and two quasi-RCTs with a total of 7,711 participants. The outcome of symptomatic UTI was measured by eleven RCTs of low overall quality and meta-analysis showed a possible benefit for using antibiotic prophylaxis [RR (95% CI) 0.49 (0.28 – 0.86)] [453]. For systemic UTI, antibiotic prophylaxis showed no effect compared with placebo or no treatment in five RCTs [RR (95% CI) 1.12 (0.38 - 3.32)]. However, prophylactic antibiotics may increase bacterial resistance [RR (95% CI) 1.73 (1.04 – 2.87)].

Given the low absolute risk of post-procedural UTI in well-resourced countries, the high number of procedures being performed, and the high risk of contributing to increasing antimicrobial resistance the panel consensus was to strongly recommend not to use antibiotic prophylaxis in patients undergoing urethroscopy (flexible or rigid).

3.15.2.3 Interventions for urinary stone treatment

3.15.2.3.1 Extracorporeal shockwave lithotripsy

For patients without bacteriuria undergoing ESWL two systematic reviews and meta-analyses were identified with latest search dates of November 2011 and October 2012, respectively [455, 456] and one further RCT [457]. Lu et al., included nine RCTs with a total of 1,364 patients and found no evidence of benefit in terms of reducing the rate of post-procedural fever or bacteriuria [455]. Mrkobrada et al., included eight RCTs with a total of 940 participants and found no evidence of benefit for antibiotic prophylaxis to reduce rate of fever or trial-defined infection [456]. A RCT with 274 patients and severe risk of bias found no reduction in fever at all by one week post-procedure using a single dose of levofloxacin 500 mg and no difference in the rate of bacteriuria [457]. Another RCT (n=600) again with severe risk of bias found no difference in UTI and positive urine culture rates at two weeks post-procedure using 200 mg ofloxacin post-operatively for three-days vs. placebo [457a].

For patients with bacteriuria or deemed at high risk of complications one RCT comparing the use of ofloxacin or trimethoprim-sulphamethoxazole for three days prior and four days subsequent to ESWL in 56 patients with ureteric stents was identified [458]. They found no difference in rate of clinical UTI at seven days (no events) and no difference in post-ESWL bacteriuria.

3.15.2.3.2 Ureteroscopy

One updated systematic review and meta-analysis with last search date of June 2017 was identified and included eleven RCTs with 4,591 patients [459]. The meta-analysis found that post-operative pyuria and bacteriuria rates were significantly lower in patients who received pre-operative antibiotic prophylaxis pyuria (OR: 0.42, 95% CI 0.25–0.69 and OR: 0.25, 95% CI 0.11–0.58, respectively). Five studies assessed post-operative febrile UTI (fUTI) and found no difference in the rate of fUTIs between patients who did or did not receive antibiotic prophylaxis (OR: 0.82, 95% CI 0.40–1.67). However, a significantly higher risk of post-operative fever in the pre-operative antibiotic prophylaxis group (OR: 1.75, 95% CI 1.22–2.50) was reported. A subgroup analysis on the type of pre-operative antibiotic prophylaxis found no difference between a single dose of oral vs. intravenous antibiotics [459].

A RCT comparing different ciprofloxacin-based antibiotic prophylaxis regimens on the incidence of SIRS after URS found there was no difference in the incidences of SIRS between the regimens including the zero dose regime [460]. However, there was a greater risk of SIRS in patients who did not receive antibiotic prophylaxis when the stone size was > 200 mm³ [460]. Another RCT comparing the use of two oral doses of 3 g fosfomycin tromethamine before surgery to standard of care did not find any difference in the incidence of infections, bacteriuria or fever [461].

Panel discussion considered that despite low-quality evidence suggesting no benefit in reducing risk of clinical UTI, clinicians and patients would prefer to use prophylaxis to prevent kidney infection or sepsis. Ideally this should be examined in a robustly designed clinical study.
3.15.2.3.3 Percutaneous nephrolithotomy (PNL)
The largest systematic review and meta-analysis performed, latest search date April 2019, included 1,549 patients in thirteen comparative studies on antibiotic prophylaxis strategies for PNL [462]. Compared with a single dose before surgery pre-operative antibiotic prophylaxis significantly reduced post-operative sepsis and fever (OR 0.31, 95%CI 0.20-0.50 and OR 0.26, 95%CI 0.14-0.48, respectively) [462]. Similarly, the rate of positive pelvic urine and positive stones culture were reduced when pre-operative prophylaxis was given. There was no difference in sepsis rates between patients receiving or not receiving post-operative prophylaxis; however, patients who received post-operative antibiotic prophylaxis had more fever [462].

Four RCTs with overall low risk of bias comparing different antibiotic regimes in PNL were identified [463-466]. Seyrek et al., compared the rate of SIRS following PNL in 191 patients receiving either a combination of sulbactam/ampicillin or cefuroxime. There was no difference in SIRS or urosepsis rates [463]. Tuzel et al., investigated single dose ceftriaxone vs. ceftriaxone and subsequently an oral third-generation cephalosporin until after nephrostomy catheter withdrawal at mean of three days in 73 participants undergoing PNL. They found no difference in rate of infectious complications between the two antibiotic regimes [464]. Taken et al., compared the administration of 1 g ceftriaxone and 1 g cefazoline both administered 30 minutes before surgery and continued till nephrostomy removal. They found no difference in terms of SRIS or sepsis between groups [466]. Omar et al., compared ciprofloxacin 200 mg i.v. vs. 2 mg cefotaxime 30 minutes before and 12 hours after surgery and found a higher rate of fever in the cefotaxime group [465]. However, these results remain limited by the high risk of bias and the lack of data regarding post-operative infection. These studies give moderate evidence that a single dose of a suitable agent was adequate for prophylaxis against clinical infection after PNL.

3.15.2.4 Transurethral resection of the prostate
A systematic review of 39 RCTs with search date up to 2009 was identified [467]. The update search to February 2017 did not reveal any further relevant studies. Of the 39 RCTs reviewed by Dahm et al., six trials involving 1,666 men addressed the risk of septic episodes, seventeen trials reported procedure related fever and 39 investigated bacteriuria. Use of prophylactic antibiotics compared to placebo showed a relative risk reduction (95% CI) for septic episode of 0.51 (0.27-0.96) with ARR of 2% (3.4% - 1.4%) and a NNT of 50. The risk reduction (95% CI) for fever was 0.64 (0.55-0.75) and 0.37 (0.32-0.41) for bacteriuria.

3.15.2.5 Transurethral resection of the bladder
One systematic review which included seven trials with a total of 1,725 participants was identified [468]. Antimicrobial prophylaxis showed no significant effect on post-operative UTIs [OR (95% CI) 1.55 (0.73 - 3.31)] and asymptomatic bacteriuria [OR (95% CI) 0.43 (0.18 - 1.04)] [468]. The review did not attempt sub-group analysis according to presence of risk factors for post-operative infection such as tumour size. Risk factors for development of post-operative UTIs were evaluated only by three of the included studies and most of the parameters were analysed by no more than one study.

A RCT (n=100) comparing oral fosfomycin 3 g (the night before surgery) vs. intravenous cefoxitin 2 g (30 minutes pre- and 24 hours post-surgery) on post-operative UTIs found that a single oral administration of fosfomycin was non-inferior to intravenous administration of cefoxitin in the prevention of post-TURB UTI, even in patients considered at higher risk [469].

Panel discussion concluded that a weak recommendation to use antibiotic prophylaxis for patients undergoing TURB who had a high risk of suffering post-operative sepsis would be appropriate.

3.15.2.6 Midurethral slings
One systematic review and meta-analysis identified one study assessing the role of pre-operative antibiotics for midurethral sling surgery alone [470]. The study was halted due to low rate of infectious outcomes seen at the first scheduled interim analysis. The study enrolled 29 women in the antibiotic prophylaxis (cefazolin) group and 30 in the placebo group with a total follow-up of six months. No statistically significant difference between the cefazolin and placebo groups, with respect to wound infections [1 (3.3%) vs. 0 (0%)] or bacteriuria [3 (10%) vs. 1 (3.5%)] was found [470].

3.15.2.7 Renal tumour ablation
One systematic review publication date 2018 included 6,952 patients across 51 studies [471]. Infectious complications were reported in 74 patients including fever (60.8%), abscess (21.6%) and UTI (8.1%). Prophylactic antibiotic use was reported in 5.4% of patients, but it was not possible to study its association to infectious complications due to lack of reporting.
3.15.2.8 Prostate biopsy

3.15.2.8.1 Transperineal prostate biopsy

A total of seven randomised studies including 1,330 patients compared the impact of biopsy route on infectious complications. Infectious complications were significantly higher following transrectal biopsy (37 events among 657 men) compared to transperineal biopsy (22 events among 673 men), [RR (95% CIs) 1.81 (1.09 to 3.00)] [472]. In addition, a systematic review including 165 studies with 162,577 patients described sepsis rates of 0.1% and 0.9% for transperineal and transrectal biopsies, respectively [473]. Finally, a population-based study from the UK (n=73,630) showed lower re-admission rates for sepsis in patients who had transperineal vs. transrectal biopsies (1.0% vs. 1.4%, respectively) [474]. The available evidence demonstrates that the transrectal approach should be abandoned in favour of the transperineal approach despite any possible logistical challenges. To date, no RCT has been published investigating different antibiotic prophylaxis regimens for transperineal prostate biopsy.

3.15.2.8.2 Transrectal prostate biopsy

Meta-analysis of eight RCTs including 1,786 men showed that use of a rectal povidone-iodine preparation before biopsy, in addition to antimicrobial prophylaxis, resulted in a significantly lower rate of infectious complications [RR (95% CIs) 0.55 (0.41 to 0.72)] [472]. Single RCTs showed no evidence of benefit for perineal skin disinfection [475], but reported an advantage for rectal povidone-iodine preparation before biopsy compared to after biopsy [476].

A meta-analysis of four RCTs including 671 men evaluated the use of rectal preparation by enema before transrectal biopsy. No significant advantage was found regarding infectious complications [RR (95% CIs) 0.96 (0.64 to 1.54)] [472].

A meta-analysis of 26 RCTs with 3,857 patients found no evidence that use of peri-prostatic injection of local anaesthesia resulted in more infectious complications than no injection [RR (95% CIs) 1.07 (0.77 to 1.48)] [472]. A meta-analysis of nine RCTs including 2,230 patients found that extended biopsy templates showed comparable infectious complications to standard templates [RR (95% CIs) 0.80 (0.53 to 1.22)] [472]. Additional meta-analyses found no difference in infections complications regarding needle guide type (disposable vs. reusable), needle type (coaxial vs. non-coaxial), needle size (large vs. small), and number of injections for peri-prostatic nerve block (standard vs. extended) [472].

A meta-analysis of eleven studies with 1,753 patients showed significantly reduced infections after transrectal prostate biopsy when using antimicrobial prophylaxis as compared to placebo/control [RR (95% CIs) 0.56 (0.40 to 0.77)] [477].

Fluoroquinolones have been traditionally used for antibiotic prophylaxis in this setting; however, overuse and misuse of fluoroquinolones has resulted in an increase in fluoroquinolone resistance. In addition, the European Commission has implemented stringent regulatory conditions regarding the use of fluoroquinolones resulting in the suspension of the indication for peri-operative antibiotic prophylaxis including prostate biopsy [121].

A systematic review and meta-analysis on antibiotic prophylaxis for the prevention of infectious complications following prostate biopsy concluded that in countries where fluoroquinolones are allowed as antibiotic prophylaxis, a minimum of a full one-day administration, as well as targeted therapy in case of fluoroquinolone resistance, or augmented prophylaxis (combination of two or more different classes of antibiotics) is recommended [477]. In countries where use of fluoroquinolones are suspended cephalosporins or aminoglycosides can be used as individual agents with comparable infectious complications based on meta-analysis of two RCTs [477]. A meta-analysis of three RCTs reported that fosfomycin trometamol was superior to fluoroquinolones [RR (95% CIs) 0.49 (0.27 to 0.87)] [477], but routine general use should be critically assessed due to the relevant infectious complications reported in non-randomised studies [478]. Another possibility is the use of augmented prophylaxis without fluoroquinolones, although no standard combination has been established to date. Finally, targeted prophylaxis based on rectal swap/stool culture is plausible, but no RCTs are available on non-fluoroquinolones. See figure 4 for prostate biopsy workflow to reduce infections complications.

3.15.3 Summary of evidence and recommendations for peri-procedural antibiotic prophylaxis

<table>
<thead>
<tr>
<th>Summary of evidence</th>
<th>LE</th>
</tr>
</thead>
<tbody>
<tr>
<td>The outcome of clinical UTI was reported in four out of eleven RCTs with no benefit found for antibiotic prophylaxis vs. placebo in patients following filling and voiding cystometry.</td>
<td>1b</td>
</tr>
<tr>
<td>A meta-analysis of five trials of moderate quality showed a benefit for using antibiotic prophylaxis for the reduction of symptomatic UTI in patients undergoing cystoscopy. However, this benefit was not seen if only the two trials with low risk of bias were used in the meta-analysis.</td>
<td>1a</td>
</tr>
</tbody>
</table>
Two meta-analyses found no benefit for antibiotic prophylaxis following ESWL in terms of reducing the rate of post-procedural fever and bacteriuria or trial-defined infection in patients without bacteriuria.  

Two meta-analyses found no evidence of benefit for antibiotic prophylaxis prior to ureteroscopy in reducing the rate of clinical UTI; however, the rate of bacteriuria was reduced.  

A meta-analysis of five RCTs demonstrated a moderate level of evidence that antibiotic prophylaxis was associated with a statistically significant reduction in the risk of post-procedural UTI following PNL.  

Two RCTs concluded that a single dose of a suitable agent was adequate for prophylaxis against clinical infection after PNL.  

A systematic review of 39 RCTs concluded that antibiotic prophylaxis reduced the rate of infectious complications in men undergoing TURP.  

A systematic review of two RCTs found no benefit for antibiotic prophylaxis in patients undergoing TURB.  

A meta-analysis of five RCTs demonstrated a moderate level of evidence that antibiotic prophylaxis was associated with a statistically significant reduction in the risk of post-procedural UTI following PNL.  

Two RCTs concluded that a single dose of a suitable agent was adequate for prophylaxis against clinical infection after PNL.  

A systematic review of 39 RCTs concluded that antibiotic prophylaxis reduced the rate of infectious complications in men undergoing transperineal biopsy as compared to transrectal biopsy.  

A meta-analysis of eight RCTs including 1,786 men showed that use of a rectal povidone-iodine preparation before transrectal biopsy, in addition to antimicrobial prophylaxis, resulted in a significantly lower rate of infectious complications.  

A meta-analysis on eleven studies with 1,753 patients showed significantly reduced infections after transrectal biopsy when using antimicrobial prophylaxis as compared to placebo/control.  

<table>
<thead>
<tr>
<th>Recommendations</th>
<th>Strength rating</th>
</tr>
</thead>
</table>
| Do not use antibiotic prophylaxis to reduce the rate of symptomatic urinary infection following:  
  • urodynamics;  
  • cystoscopy;  
  • extracorporeal shockwave lithotripsy. | Strong |
| Use antibiotic prophylaxis to reduce the rate of symptomatic urinary infection following ureteroscopy. | Weak |
| Use single dose antibiotic prophylaxis to reduce the rate of clinical urinary infection following percutaneous nephrolithotomy. | Strong |
| Use antibiotic prophylaxis to reduce infectious complications in men undergoing transurethral resection of the prostate. | Strong |
| Use antibiotic prophylaxis to reduce infectious complications in high-risk patients undergoing transurethral resection of the bladder. | Weak |
| Perform prostate biopsy using the transperineal approach due to the lower risk of infectious complications. | Strong |
| Use routine surgical disinfection of the perineal skin for transperineal biopsy. | Strong |
| Use rectal cleansing with povidone-iodine in men prior to transrectal prostate biopsy. | Strong |
| Do not use fluoroquinolones for prostate biopsy in line with the European Commission final decision on EMEA/H/A-31/1452. | Strong |
| Use either target prophylaxis based on rectal swab or stool culture; augmented prophylaxis (two or more different classes of antibiotics); or alternative antibiotics (e.g. fosfomycin trometamol, cephalosporin, aminoglycoside) for antibiotic prophylaxis for transrectal biopsy. | Weak |

**Table 12: Suggested regimens for antimicrobial prophylaxis prior to urological procedures.**  
As stated in section 3.15.1.4 the panel has decided not to make recommendations for specific agents for particular procedures, those listed below represent possible choices only. Urologists should choose a specific antimicrobial based on their knowledge of local pathogen prevalence for each type of procedure, their antibiotic susceptibility profiles and virulence.

Figure 4: Prostate biopsy workflow to reduce infectious complications

1. No RCTs available, but reasonable intervention.
2. Be informed about local antimicrobial resistance.
3. Banned by European Commission due to side effects.
5. Fosfomycin trometamol (3 RCTs), cephalosporins (2 RCTs), aminoglycosides (2 RCTs).
6. Only one RCT comparing targeted and augmented prophylaxis.
7. Originally introduced to use alternative antibiotics in case of fluoroquinolone resistance.
8. Various schemes: fluoroquinolone plus aminoglycoside (3 RCTs); and fluoroquinolone plus cephalosporin (1 RCT).
9. Significantly inferior to targeted and augmented prophylaxis.

Suggested workflow on how to reduce post biopsy infections. GRADE Working Group grades of evidence. High certainty: (⊕⊕⊕⊕) very confident that the true effect lies close to that of the estimate of the effect. Moderate certainty: (⊕⊕⊕) moderately confident in the effect estimate: the true effect is likely to be close to the estimate of the effect, but there is a possibility that it is substantially different. Low certainty: (⊕⊕) confidence in the effect estimate is limited: the true effect may be substantially different from the estimate of the effect. Very low certainty: (⊕) very little confidence in the effect estimate: the true effect is likely to be substantially different from the estimate of effect. Figure reproduced from Pilatz et al., [479] with permission from Elsevier.

i.m. = intramuscular; i.v. intravenously; p.o. = orally.

8. CONFLICT OF INTEREST 113

9. CITATION INFORMATION 113
1. INTRODUCTION

1.1 Aims and scope
The European Association of Urology (EAU) Urolithiasis Guidelines Panel has prepared these guidelines to help urologists assess evidence-based management of stones/calculi in the urinary tract and incorporate recommendations into clinical practice. This document covers most aspects of the disease, which is still a cause of significant morbidity despite technological and scientific advances. The Panel is aware of the geographical variations in healthcare provision. Originally available as a separate document, information on the management of bladder stones is now also included in these guidelines.

It must be emphasised that clinical guidelines present the best evidence available to the experts but following guideline recommendations will not necessarily result in the best outcome. Guidelines can never replace clinical expertise when making treatment decisions for individual patients, but rather help to focus decisions - also taking personal values and preferences/individual circumstances of patients into account. Guidelines are not mandates and do not purport to be a legal standard of care.

1.2 Panel composition
The EAU Urolithiasis Guidelines Panel consists of an international group of clinicians with particular expertise in this area. All experts involved in the production of this document have submitted potential conflict of interest statements, which can be viewed on the EAU website: http://uroweb.org/guideline/urolithiasis/.

1.3 Available publications
A quick reference document (Pocket guidelines) is available, both in print and as an app for iOS and Android devices. These are abridged versions, which may require consultation together with the full text versions. Several scientific publications are also available [1-3]. All documents can be accessed through the EAU website: http://uroweb.org/guideline/urolithiasis/.

1.4 Publication history and summary of changes
1.4.1 Publication history
The EAU Urolithiasis Guidelines were first published in 2000. This 2022 document presents a limited update of the 2021 version.

1.4.2 Summary of changes
The literature for the entire document has been checked and, wherever relevant, updated (see Methods section 2.1). References and supporting text have also been refreshed.

For 2022, several new sections have been added to these guidelines. These include chapter 3.5. Radiation exposure and protection during endourology and chapter 5. Follow-up of urinary stones. Throughout the text passages on best clinical practice for the use of different interventions have been added to the relevant sections. In addition, chapter 3.4.3 Medical expulsive therapy has been thoroughly revised and the Bladder Stones guidelines, previously a separate document, have been integrated into this text. Four new algorithms have also been added:

- Figure 4.2: Diagnostic algorithm for calcium oxalate stones
- Figure 4.6: Diagnostic algorithm for uric acid stones
- Figure 5.1: Follow-up duration of urinary stone patients after treatments
- Figure 5.2: Consensus on follow-up frequency and imaging modality to use after treatment

2. METHODS

2.1 Data identification
For the 2022 Urolithiasis Guidelines, new and relevant evidence has been identified, collated, and appraised through a structured assessment of the literature.

A broad and comprehensive scoping exercise covering all areas of the guideline was performed. The search was limited to studies representing high levels of evidence only (i.e., systematic reviews with meta-analysis (MA), randomised controlled trials (RCTs), and prospective non-randomised comparative studies) published in the English language. The search was restricted to articles published between 1st May 2020 and 12th May 2021. A total of 737 unique records were identified and screened for relevance.

For the 2022 Bladder Stones section, new and relevant evidence was identified, collated, and
appraised through a structured assessment of the literature. The search was limited to studies representing high levels of evidence only published in the English language. The search was restricted to articles published between April 2020 and April 2021. A total of 235 unique records were identified and screened for relevance.

In addition to this, several ancillary searches limited to studies representing high levels of evidence only and published in the English language were also carried out to underpin the new chapter 3.5. radiation exposure and protection during endourology, and to formulate best clinical practice statements. The five-year search, from 2016 to May 2021, on radiation exposure and urolithiasis returned a total of 117 unique records which were identified and screened for relevance. The remainder of the searches on specific interventions that could be used to formulate best clinical practice statements returned a total of 1,080 records which were identified and screened for relevance. These include a four-year search (2018-2021) on URS thulium fiber laser; five-year searches (2017-2021) on URS internal temperature, URS suction with fragmentation, URS intrarenal pressure, fluoroless URS, PNL suction, and PNL fluoroless; a six-year search (2016-2021) on single vs. reusable URS, and ten-year searches (2011-2021) on SWL, URS fibreoptic vs. digital, optimal laser, URS time limit operation, PNL anaesthesia, PNL thermal and PNL renal puncture.

Databases covered by the searches included Medline, EMBASE, Ovid and the Cochrane Libraries. The search strategies are published online: http://uroweb.org/guideline/urolithiasis/?type=appendices-publications.

A total of 59 new references have been added to the 2022 Urolithiasis Guidelines publication.

The chapters on the treatment of bladder stones in adults and children are based on a systematic review [4]. For each recommendation within the guidelines there is an accompanying online strength rating form, the basis of which is a modified GRADE methodology [5, 6]. Each strength-rating form addresses a number of key elements, namely:

1. the overall quality of the evidence which exists for the recommendation, references used in this text are graded according to a classification system modified from the Oxford Centre for Evidence-Based Medicine Levels of Evidence [7];
2. the magnitude of the effect (individual or combined effects);
3. the certainty of the results (precision, consistency, heterogeneity and other statistical or study related factors);
4. the balance between desirable and undesirable outcomes;
5. the impact of patient values and preferences on the intervention;
6. the certainty of those patient values and preferences.

These key elements are the basis which panels use to define the strength rating of each recommendation. The strength of each recommendation is represented by the words ‘strong’ or ‘weak’ [8]. The strength of each recommendation is determined by the balance between desirable and undesirable consequences of alternative management strategies, the quality of the evidence (including certainty of estimates), and nature and variability of patient values and preferences.

Additional information can be found in the general Methodology section of this print, and online at the EAU website: http://www.uroweb.org/guideline/.

A list of associations endorsing the EAU Guidelines can also be viewed online at the above address.

2.2 Review
The 2015 Urolithiasis Guidelines were subjected to peer-review prior to publication. Chapter 6, detailing the treatment and follow-up of bladder stones was peer reviewed in 2019.

2.3 Future goals
For the 2023 text update the Urolithiasis Guidelines Panel aim to provide further guidance on the following topics:

- Further evaluate the highest evidence for best clinical practice in endourology.
- Perform a systematic review on patient and personnel radiation protection during endourology.
- Questioning the accuracy of stone size as the surrogate index for deciding upon the treatment of urinary stones.
3. GUIDELINES

3.1 Prevalence, aetiology, risk of recurrence

3.1.1 Introduction
Stone incidence depends on geographical, climatic, ethnic, dietary, and genetic factors. The recurrence risk is basically determined by the disease or disorder causing the stone formation. Accordingly, the prevalence rates for urinary stones vary from 1% to 20% [9]. In countries with a high standard of life such as Sweden, Canada or the USA, renal stone prevalence is notably high (> 10%). For some areas, an increase of more than 37% over the last 20 years has been reported [10-12]. There is emerging evidence linking nephrolithiasis to the risk of chronic kidney disease (CKD) [13].

Stones can be stratified into those caused by: infections, non-infectious causes, genetic defects [14]; or adverse drug effects (drug stones) (Table 3.1). See also section 3.2.

3.1.2 Stone composition
Stone composition is the basis for further diagnostic and management decisions. Stones are often formed from a mixture of substances. Table 3.2 lists the most clinically relevant substances and their mineral components.

3.1.3  **Risk groups for stone formation**  

The risk status of stone formers is of particular interest because it defines the probability of recurrence or regrowth, the risk of CKD and mineral and bone disorder, and is imperative for pharmacological treatment. About 50% of recurrent stone formers have just one lifetime recurrence [11, 16]. A recent review of first-time stone formers calculated a recurrence rate of 26% in five years’ time [17]. Highly recurrent disease is observed in slightly more than 10% of patients. Stone type and disease severity determine low- or high-risk stone formers (Table 3.3) [18, 19].

</table>

A comprehensive evaluation of stone risk in patients should also include the risk of developing CKD, end-stage kidney disease (ESKD), and metabolic stone disease (Tables 3.4, 3.5 and 3.6). Urolithiasis can compromise renal function because of the renal stone (obstruction, infection), renal tissue damage due to the primary condition causing stone formation (some genetic diseases, nephrocalcinosis, enteric hyperoxaluria, etc.), or urological treatments for the condition [35]. Certain risk factors have been shown to be associated with such a risk in stone formers, as shown below.

3.2 Classification of stones

Urinary stones can be classified according to size, location, X-ray characteristics, aetiology of formation, composition, and risk of recurrence [11, 36, 37].
3.2.1 **Stone size**
Stone size is usually given in one or two dimensions, and stratified into those measuring up to 5, 5-10, 10-20, and > 20 mm in largest diameter.

3.2.2 **Stone location**
Stones can be classified according to anatomical position: upper, middle, or lower calyx; renal pelvis; upper, middle, or distal ureter; and urinary bladder.

3.2.3 **X-ray characteristics**
Stones can be classified according to plain X-ray appearance [kidney-ureter-bladder (KUB) radiography] (Table 3.6), which varies according to mineral composition [37]. Non-contrast-enhanced computed tomography (NCCT) can be used to classify stones according to density, inner structure, and composition, which can affect treatment decisions (Section 3.3) [36, 37].

3.3 **Diagnostic evaluation**

3.3.1 **Diagnostic imaging**
The most appropriate imaging modality will be determined by the clinical situation, which will differ depending on if a ureteral or renal stone is suspected.

Standard evaluation includes a detailed medical history and physical examination. Patients with ureteral stones usually present with loin pain, vomiting, and sometimes fever, but may also be asymptomatic [38]. Immediate evaluation is indicated in patients with solitary kidney, fever or when there is doubt regarding a diagnosis of renal colic. Ultrasound (US) should be used as the primary diagnostic imaging tool, although pain relief, or any other emergency measures, should not be delayed by imaging assessments. Ultrasound is safe (no risk of radiation), reproducible and inexpensive. It can identify stones located in the calyces, pelvis, and pyeloureteric and vesico-ureteral junctions (US with filled bladder), as well as in patients with upper urinary tract (UUT) dilatation. Ultrasound has a sensitivity of 45% and specificity of 94% for ureteral stones and a sensitivity of 45% and specificity of 88% for renal stones [39, 40].

The sensitivity and specificity of KUB is 44-77% [41]. Kidney-ureter-bladder radiography should not be performed if NCCT is being considered [42]; however, it is helpful in differentiating between radiolucent and radiopaque stones and should be used for comparison during follow-up.

3.3.1.1 **Evaluation of patients with acute flank pain/suspected ureteral stones**
Non-contrast-enhanced computed tomography has become the standard for diagnosing acute flank pain and has replaced intravenous urography (IVU). Non-contrast-enhanced CT can determine stone diameter and density. When stones are absent, the cause of abdominal pain should be identified. In evaluating patients with suspected acute urolithiasis, NCCT is significantly more accurate than IVU or US [43].

Non-contrast-enhanced CT can detect uric acid and xanthine stones, which are radiolucent on plain films, but not indinavir stones [44]. Non-contrast-enhanced CT can determine stone density, inner structure of the stone, skin-to-stone distance, and surrounding anatomy; all of which affect selection of treatment modality [37, 45-47]. The advantage of non-contrast imaging must be balanced against loss of information on renal function and urinary collecting system anatomy, as well as higher radiation dose [48-51].

Radiation risk can be reduced by low-dose CT, which may, however, be difficult to introduce in standard clinical practice [52-56]. In patients with a body mass index (BMI) < 30, low-dose CT has been shown to have a sensitivity of 86% for detecting ureteral stones < 3 mm and 100% for calculi > 3 mm [57]. A meta-analysis (MA) of prospective studies [54] has shown that low-dose CT diagnosed urolithiasis with a pooled sensitivity of 93.1% (95% CI: 91.5-94.4), and a specificity of 96.6% (95% CI: 95.1-97.7%). Dual-energy CT can differentiate uric acid containing stones from calcium-containing stones [58, 59].

3.3.2 Diagnostics - metabolism-related

Besides imaging, each emergency patient with urolithiasis needs a succinct biochemical work-up of urine and blood test. At this point, no distinction is made between high- and low-risk patients for stone formation.

3.3.2.1 Basic laboratory analysis - non-emergency urolithiasis patients

Biochemical work-up is similar for all stone patients. However, if no intervention is planned, examination of sodium, potassium, C-reactive protein (CRP), and blood coagulation time can be omitted. Only patients at high risk for stone recurrence should undergo a more specific analytical programme [19]. Stone-specific metabolic evaluation is described in chapter 4.

The easiest method for diagnosing stones is by analysis of a passed stone using a validated method as listed in section 3.3.2.3. Once the mineral composition is known, a potential metabolic disorder can be identified.

3.3.2.2 Analysis of stone composition

Stone analysis should be performed in all first-time stone formers.

In clinical practice, repeat stone analysis is needed in the case of:
- recurrence under pharmacological prevention;
- early recurrence after interventional therapy with complete stone clearance;
- late recurrence after a prolonged stone-free period [60, 61].

Patients should be instructed to filter their urine to retrieve a concrement for analysis. Stone passage and restoration of normal renal function should be confirmed.

The preferred analytical procedures are infrared spectroscopy (IRS) or X-ray diffraction (XRD) [62-64]. Equivalent results can be obtained by polarisation microscopy. Chemical analysis (wet chemistry) is generally deemed to be obsolete [62, 65].

Perform a coagulation test (partial thromboplastin time and international normalised ratio) if intervention is likely or planned. **Strong**

Perform stone analysis in first-time formers using a valid procedure (X-ray diffraction or infrared spectroscopy). **Strong**

Repeat stone analysis in patients presenting with:
- recurrent stones despite drug therapy;
- early recurrence after complete stone clearance;
- late recurrence after a long stone-free period because stone composition may change. **Strong**

### 3.3.3 Diagnosis in special groups and conditions

#### 3.3.3.1 Diagnostic imaging during pregnancy

In pregnant women radiation exposure may cause non-stochastic (teratogenesis) or stochastic (carcinogenesis, mutagenesis) effects. Teratogenic effects are cumulative with increasing dose and require a threshold dose (< 50 mGy are considered as safe) and depend on the gestation age (minimum risk prior to 8th week and after the 23rd week). Carcinogenesis (doses even < 10 mGy present a risk) and mutagenesis (500-1000 mGy doses are required, far in excess of the doses in common radiographic studies) get worse with increasing dose but they do not require a dose threshold and are not dependent on the gestational age [68].

There is no imaging modality that should be routinely repeated in pregnant women. Scientific societies and organisations agree on the safety of the diagnostic evaluation when US [69], X-ray imaging [70, 71], and MRI [72, 73] are used as and when indicated [74-80]. A radiographic procedure should not be withheld from a pregnant woman if the procedure is clearly indicated and doing so will affect her medical care.

It is generally recommended that an investigation resulting in an absorbed dose to the foetus of greater than 0.5 mGy requires justification.

Ultrasound (when necessary, using changes in renal resistive index and transvaginal/transabdominal US with a full bladder) has become the primary radiological diagnostic tool when evaluating pregnant patients suspected of renal colic. However, normal physiological changes in pregnancy can mimic ureteral obstruction [76-78].

Magnetic resonance imaging can be used, as a second-line option [74], to define the level of urinary tract obstruction, and to visualise stones as a filling defect [72]. As 3 Tesla (T) MRI has not been evaluated in pregnancy, the use of 1.5T is currently recommended [75, 80]. The use of gadolinium is not routinely recommended in pregnancy to avoid toxic effects to the embryo [76].

For the detection of urolithiasis during pregnancy, low-dose CT is associated with a higher positive predictive value (95.8%), compared to MRI (80%) and US (77%). As per White et al., low-dose CT offers improved diagnostic accuracy that can avoid negative interventions such as ureteroscopy [81]. Although low-dose CT protocols reduce the radiation exposure, judicious use is currently recommended in pregnant women as a last-line option [76].

**Summary of evidence LE**

| Only low-level data exist for imaging in pregnant women supporting US and MRI. | 3 |

**Recommendations**

| Use ultrasound as the preferred method of imaging in pregnant women. | Strong |
| Use magnetic resonance imaging as a second-line imaging modality in pregnant women. | Strong |
| Use low-dose computed tomography as a last-line option in pregnant women. | Strong |

#### 3.3.3.2 Diagnostic imaging in children

Children with urinary stones have a high risk of recurrence; therefore, standard diagnostic procedures for high-risk patients apply, including a valid stone analysis (section 3.1.3 and chapter 4). The most common non-metabolic disorders facilitating stone formation are vesico-ureteral reflux (VUR), UPJ obstruction, neurogenic bladder, and other voiding difficulties [82].

When selecting diagnostic procedures to identify urolithiasis in children, it should be remembered that these patients might be uncooperative, require anaesthesia, and may be sensitive to ionising radiation. Again, the principle of ALARA (As Low As Reasonably Achievable) should be observed [83-85].

**Ultrasound**

Ultrasound is the primary imaging technique [86] in children. Its advantages are absence of radiation and no need for anaesthesia. Imaging should include both the fluid-filled bladder with adjoining portion of the ureters, as well
as the upper ureter [87-91]. Colour Doppler US shows differences in the ureteral jet [88] and resistive index of the arciform arteries of both kidneys, which are indicative of the grade of obstruction [89]. Nevertheless, US fails to identify stones in > 40% of children [90-93] and provides limited information on renal function.

Plain films (KUB radiography)
Kidney-ureter-bladder radiography can help to identify stones and their radiopacity and facilitate follow-up.

Intravenous urography
The radiation dose for IVU is comparable to that for voiding cysto-urethrography (0.33 mSV) [94]. However, the need for contrast medium injection is a major drawback.

Non-contrast-enhanced computed tomography
Recent low-dose CT protocols have been shown to significantly reduce radiation exposure [51, 95, 96]. In children, only 5% of stones escape detection by NCCT [88, 96, 97]. Sedation or anaesthesia is rarely needed with modern high-speed CT equipment.

Magnetic resonance urography
Magnetic resonance urography (MRU) cannot be used to detect urinary stones. However, it might provide detailed anatomical information about the urinary collecting system, the location of an obstruction or stenosis in the ureter, and renal parenchymal morphology [98].

3.4 Disease Management

3.4.1 Renal colic

Pain relief
Non-steroidal anti-inflammatory drugs (NSAIDs) (including metamizol edipyrene), and paracetamol are effective in patients with acute stone colic [99], and have better analgesic efficacy than opioids [100]. Ibuprofen compared to ketorolac is a more rapid acting drug in controlling pain caused by renal colic with a similar side effect profile [101].

Pain relief from intramuscular (i.m.) diclofenac compared favourably with those from intravenous (i.v.) ibuprofen and i.v. ketorolac; however, no recommendation can be given due to the manner in which the results have been reported [102]. The addition of antispasmodics to NSAIDs does not result in better pain control. Patients receiving NSAIDs are less likely to require further analgesia in the short term. It should be taken into consideration that the use of diclofenac and ibuprofen increased major coronary events [99, 100]. Diclofenac is contraindicated in patients with congestive heart failure (New York Heart Association class II-IV), ischaemic heart disease and peripheral arterial- and cerebrovascular disease. Patients with significant risk factors for cardiovascular events should be treated with diclofenac only after careful consideration. As risks increase with dose and duration, the lowest effective dose should be used for the shortest duration [103, 104].

Opioids, particularly pethidine, are associated with a high rate of vomiting compared to NSAIDs and carry a greater likelihood of further analgesia being needed [99, 105]. If an opioid is used, it is recommended that it is not pethidine. Data on other types of non-opioid and non-NSAID medication is increasing. Ketamine in
combination with morphine, compared to morphine alone, leads to morphine consumption reduction, less pain, nausea and vomiting [106-108]. Patients receiving ketamine and NSAIDs attained greater reduction in pain scores with less side effects, and better functional state, as well as less further analgesic requirement than those administered pethidine [109]. However, when comparing ketamine vs. NSAID (ketorolac) alone, equal efficacy but higher rates of dizziness, agitation and hypertension with ketamine were observed [110]. Conflicting results have been reported regarding the utility of i.v. lidocaine. Acupuncture seems to be effective in renal colic alone or in combination, but there is limited data [111, 112].

Prevention of recurrent renal colic
Facilitation of passage of ureteral stones is discussed in Section 3.4.9. For patients with ureteral stones that are expected to pass spontaneously, NSAID tablets or suppositories (e.g., diclofenac sodium, 100-150 mg/day, 3-10 days) may help reduce inflammation and the risk of recurrent pain [113, 114]. Although diclofenac can affect renal function in patients with already reduced function, it has no functional effect in patients with normal renal function [115].

The systematic review and MA by Hollingsworth et al., [116] addressed pain reduction as a secondary outcome and concluded that medical expulsive therapy (MET) seems efficacious in reducing pain episodes of patients with ureteral stones.

If analgesia cannot be achieved medically, drainage, using stenting, percutaneous nephrostomy, or stone removal, is indicated [117].

* Maximum single oral dose recommended 1000 mg, total daily dose up to 5000 mg, not recommended in the last three months of pregnancy [118].
** Affects glomerular filtration rate (GFR) in patients with reduced renal function.
*** Recommended to counteract recurrent pain after ureteral colic.

3.4.2  Management of sepsis and/or anuria in obstructed kidney
The obstructed kidney with all signs of urinary tract infection (UTI) and/or anuria is a urological emergency. Urgent decompression is often necessary to prevent further complications in infected hydronephrosis secondary to stone-induced, unilateral or bilateral, renal obstruction.

Decompression
Currently, there are two options for urgent decompression of obstructed collecting systems:
- placement of an indwelling ureteral stent;
- percutaneous placement of a nephrostomy tube.

There is little evidence to support the superiority of percutaneous nephrostomy over retrograde stenting for primary treatment of infected hydronephrosis. There is no good quality evidence to suggest that ureteral stenting has more complications than percutaneous nephrostomy [119, 120].

Only one RCT [121] compared different modalities of decompression of acute infected hydronephrosis. The complications of percutaneous nephrostomy insertion have been reported consistently, but those of ureteral stent insertion are less well described [119]. Definitive stone removal should be delayed until the infection is cleared following a complete course of antimicrobial therapy. A small RCT showed the feasibility of immediate ureteroscopic stone removal combined with an appropriate antibiotic regimen, however, at the cost of longer hospital stay and higher analgesic requirements [122].
Further measures
Following urgent decompression of the obstructed and infected urinary collecting system, both urine- and blood samples should be sent for culture-antibiogram sensitivity testing and antibiotics should be initiated immediately thereafter or continued, if initiated prior to testing. The regimen should be re-evaluated in the light of the culture-antibiogram results. Although clinically well accepted, the impact of a second antibiogram test on treatment outcome has not yet been evaluated. Intensive care might become necessary [123].

3.4.3 Medical expulsive therapy
Several drug classes including α-blockers, calcium channel inhibitors and phosphodiesterase type 5 inhibitors (PDEI-5) are used for MET [124-127]. A class effect of α-blockers in MET has been demonstrated in MAs although this is an off-label indication [128-130]. However, there is contradictory evidence between these studies and several well-designed, multicentre, placebo-controlled, double-blinded randomised studies showing limited, or no, benefit using α-blockers, besides some advantage for distal ureteral stones > 5 mm [131-135]. Based on studies with a limited number of patients [127, 128, 136, 137], no recommendation for the use of PDEI-5 or corticosteroids in combination with α-blockers in MET can be made. The panel concludes that MET using α-blockers seems efficacious in the treatment of patients with distal ureteral stones > 5 mm who are amenable to conservative management. Medical expulsive therapy in special situations is addressed in the relevant chapters.

3.4.4 Chemolysis
Percutaneous irrigation chemolysis
Percutaneous chemolysis is rarely used nowadays, for practical reasons. Percutaneous irrigation chemolysis may be an option for infection-stones and theoretically also for uric acid stones. For dissolution of struvite stones, Suby's G solution (10% hemiacidrin; pH 3.5-4) can be used. The method has been described in case series and literature reviews [138-140].
Oral chemolysis

Stones composed of uric acid, but not sodium or ammonium urate stones, can be dissolved by oral chemolysis. Prior stone analysis may provide information on stone composition. Urinary pH measurement and X-ray characteristics can provide information on the type of stone.

Oral chemolitholysis is based on alkalisation of urine by application of alkaline citrate or sodium bicarbonate. The pH should be adjusted to 7.0-7.2. Chemolysis is more effective at a higher pH, which might, however, promote calcium phosphate stone formation. Patients will need to adjust the dosage of alkalisers by self-monitoring the pH of their urine. No RCTs are available for this therapy, which has been in use for decades. Rodman, *et al.*, [141] reviewed the principles and provided guidance to its clinical use, which was supported by Becker, *et al.*, in 2007 [142] and Elsawy *et al.*, in 2019 [143]. Monitoring of radiolucent stones during therapy is the domain of US; however, repeat-NCCT might be necessary [141, 142].

In the case of uric acid obstruction of the collecting system, oral chemolysis in combination with urinary drainage is indicated [144]. A combination of alkalisers with tamsulosin can increase the frequency of spontaneous passage of distal ureteral uric acid stones as shown in one RCT for stones > 5 mm [144]. Additional shock wave lithotripsy (SWL) might help to improve the results but evidence is weak [145].

### 3.4.5 Extracorporeal shock wave lithotripsy (ESWL)

The success of SWL depends on the efficacy of the lithotripter and the following factors:

- size, location (ureteral, pelvic or calyceal), and composition (hardness) of the stones (Section 3.4.9.3);
- patient’s habitus (Section 3.4.10.3);
- performance of SWL (best practice, see below).

Each of these factors significantly influences the retreatment rate and final outcome of SWL.

**Best clinical practice**

**Stenting**

Routine use of internal stents before SWL does not improve stone free rates (SFRs), nor lowers the number of auxiliary treatments. It may, however, reduce formation of steinstrasse [146-149].

**Pacemaker**

Patients with a pacemaker can be treated with SWL, provided that appropriate technical precautions are taken. Patients with implanted cardioverter defibrillators must be managed with special care (firing mode temporarily reprogrammed during SWL treatment). However, this might not be necessary with new-generation lithotripters [150].

**Shock wave rate**

Lowering shock wave frequency from 120 to 60-90 shock waves/min improves SFRs [151-159]. Ultraslow frequency 30 shock waves/min may increase SFR [160]. Tissue damage increases with shock wave frequency [161-164].

**Number of shock waves, energy setting and repeat treatment sessions**

The number of shock waves that can be delivered at each session depends on the type of lithotripter and shock wave power. There is no consensus on the maximum number of shock waves [165]. Starting SWL on a lower energy setting with stepwise power (and SWL sequence) ramping can achieve vasoconstriction during
treatment [161], which prevents renal injury [166-168]. Animal studies [169] and a prospective randomised study [170] have shown better SFRs (96% vs. 72%) using stepwise power ramping, but no difference has been found for fragmentation or evidence of complications after SWL, irrespective of whether ramping was used [171, 172].

There are no conclusive data on the intervals required between repeated SWL sessions. However, clinical experience indicates that repeat sessions are feasible (within one day for ureteral stones) [173].

**Improvement of acoustic coupling**
Proper acoustic coupling between the cushion of the treatment head and the patient’s skin is important. Defects (air pockets) in the coupling gel deflect 99% of shock waves [174]. Ultrasound gel is probably the most widely-used agent available as a lithotripsy coupling agent [175].

**Procedural control**
Results of treatment are operator dependent, and experienced clinicians obtain better results. During the procedure, careful imaging control of localisation contributes to outcome quality [176].

**Pain Control**
Careful control of pain during treatment is necessary to limit pain-induced movements and excessive respiratory excursions [177-180].

**Antibiotic prophylaxis**
No standard antibiotic prophylaxis before SWL is recommended. However, prophylaxis is recommended in the case of internal stent placement ahead of anticipated treatments and in the presence of increased bacterial burden (e.g., indwelling catheter, nephrostomy tube, or infectious stones) [67, 181, 182].

**Medical therapy following ESWL**
Despite conflicting results, most RCTs and several MAs support MET after SWL for ureteral or renal stones as adjunct to expedite expulsion and to increase SFRs. Medical expulsion therapy might also reduce analgesic requirements [183-192].

**Post-treatment management**
Mechanical percussion and diuretic therapy can significantly improve SFRs and accelerate stone passage after SWL [193-196].

**Complications of extracorporeal shock wave lithotripsy**
Compared to percutaneous nephrolithotomy (PNL) and ureteroscopy (URS), there are fewer overall complications with SWL [197, 198] (Table 3.8). The relationship between SWL and hypertension or diabetes is unclear. Published data are contradictory; however, no evidence exists supporting the hypothesis that SWL may cause long-term adverse effects [199-205].

3.4.5.1 Summary of evidence and guidelines for SWL

Summary of evidence

| Stepwise power ramping prevents renal injury. | LE |
| Clinical experience has shown that repeat sessions are feasible (within one day for ureteral stones). | 1b |
| Optimal shock wave frequency is 1.0 to 1.5 Hz. | 4 |
| Proper acoustic coupling between the cushion of the treatment head and the patient's skin is important. | 1a |
| Careful imaging control of localisation of stone contributes to outcome of treatment. | 2a |
| Careful control of pain during treatment is necessary to limit pain-induced movements and excessive respiratory excursions. | 1a |
| Antibiotic prophylaxis is recommended in the case of internal stent placement, infected stones, or bacteriuria. | 1a |

Recommendations

| Ensure correct use of the coupling agent because this is crucial for effective shock wave transportation. | Strength rating |
| Maintain careful fluoroscopic and/or ultrasonographic monitoring during shock wave lithotripsy (SWL). | Strong |
| Use proper analgesia because it improves treatment results by limiting pain-induced movements and excessive respiratory excursions. | Strong |
| Prescribe antibiotics prior to SWL in the case of infected stones or bacteriuria. | Strong |

3.4.6 Ureteroscopy (retrograde and antegrade)

The current standard for rigid ureteroscopes is a tip diameter of < 8 French (F). Rigid URS can be used for the whole ureter [199]. However, technical improvements, as well as the availability of digital scopes, also favour the use of flexible ureteroscopes in the ureter [221].

Percutaneous antegrade removal of ureteral stones is a consideration in selected cases, i.e., large (> 15 mm), impacted proximal ureteral calculi in a dilated renal collecting system [222-224], or when the ureter is not amenable to retrograde manipulation [224-228].

Ureteroscopy for renal stones (RIRS)

Technical improvements including endoscope miniaturisation, improved deflection mechanism, enhanced optical quality and tools, and introduction of disposables have led to an increased use of URS for both renal and ureteral stones. Major technological progress has been achieved for RIRS. A recent systematic review addressing renal stones > 2 cm showed a cumulative SFR of 91% with 1.45 procedures/patient; 4.5% of the complications were > Clavien 3 [221, 229, 230]. Digital scopes demonstrate shorter operation times due to the improvement in image quality [229].

Stones that cannot be extracted directly must be disintegrated. If it is difficult to access stones within the lower renal pole that need disintegration; it may help to displace them into a more accessible calyx [231].

Best clinical practice in ureteroscopy

Access to the upper urinary tract

Most interventions are performed under general anaesthesia, although local or spinal anaesthesia is possible [232]. Intravenous sedation is suitable for female patients with distal ureteral stones [233]. Antegrade URS is an option for large, impacted, proximal ureteral calculi [222-224, 234]. Reduction of flexible ureteroscope diameter may provide similar vision, deflection, and manoeuvrability to standard flexible ureteroscopes potentially with improved ureteric access [235]. Disposable ureteroscopes provides similar safety and clinical effectiveness to reusable scopes. Concerns regarding the cost effectiveness remain [236, 237].

Safety aspects

Fluoroscopic equipment must be available in the operating room. The Panel recommend placement of a safety wire, even though some groups have demonstrated that URS can be performed without it [238-240]. Balloon and plastic dilators should be available, if necessary.

Prior rigid URS can be helpful for optical dilatation followed by flexible URS, if necessary. If ureteral access is not possible, insertion of a JJ stent followed by URS after seven to fourteen days offers an alternative [241]. Bilateral URS during the same session is feasible resulting in equivalent-to-lower SFRs, but slightly higher overall complication rates (mostly minor, Clavien 1 and 2) [242, 243].
Difficult lower pole anatomy such as steep infundibulopelvic angle predisposes to failure during RIRS [244]. Prolonged operative times are linked to increased complication rates in ureteroscopy, and efforts must be made to keep it below 90 minutes [245].

**Ureteral access sheaths**

Hydrophilic-coated ureteral access sheaths, which are available in different calibres (inner diameter from 9 F upwards), can be inserted (via a guide wire) with the tip placed in the proximal ureter.

Ureteral access sheaths allow easy, multiple, access to the UUT and therefore significantly facilitate URS. The use of ureteral access sheaths improves vision by establishing a continuous outflow, decreases intrarenal pressure, and potentially reduces operating time [246, 247].

The insertion of ureteral access sheaths may lead to ureteral damage, the risk is lowest in presented systems [248]. No data on long-term side effects are available [248, 249]. Whilst larger cohort series showed no difference in SFRs and ureteral damage (striction rates of about 1.8%), they did show lower post-operative infectious complications [250, 251]. The use of ureteral access sheath is safe and can be useful for large and multiple renal stones or if long procedural time is expected [252].

**Stone extraction**

The aim of URS is complete stone removal. “Dust and go” strategies should be limited to the treatment of large (renal) stones [253]. Stones can be extracted by endoscopic forceps or baskets. Only baskets made of nitinol can be used for flexible URS [254].

**Intracorporeal lithotripsy**

The most effective lithotripsy system is the holmium: yttrium-aluminium-garnet (Ho:YAG) laser, which is currently the optimum standard for URS and flexible nephroscopy (Section 3.4.6), because it is effective in all stone types [255, 256]. Compared to low-power lasers, high-power laser reduces procedural time although the reported difference in clinical outcomes were non-significant [257] (J Pneumatic and US systems can be used with high disintegration efficacy in rigid URS [258, 259]). However, stone migration into the kidney is a common problem, which can be prevented by placement of special anti-migration tools proximal of the stone [260]. Medical expulsion therapy following Ho:YAG laser lithotripsy increases SFRs and reduces colic episodes [261]. Thulium fiber laser (TFL) for stone disease has a promising role and offers good clinical outcomes, which seem to be comparable to Ho:YAG laser (holmium) laser. More comparative clinical studies are, however, needed between these two modalities [262, 263].

**Stenting before and after URS**

Routine stenting is not necessary before URS. However, pre-stenting facilitates ureteroscopic management of stones, improves the SFR, and reduces intra-operative complications [264, 265].

Randomised prospective trials have found that routine stenting after uncomplicated URS (complete stone removal) is not necessary; stenting might be associated with higher post-operative morbidity and costs [266-269]. A ureteral catheter with a shorter indwelling time (one day) may also be used, with similar results [270].

Stents should be inserted in patients who are at increased risk of complications (e.g., ureteral trauma, residual fragments, bleeding, perforation, UTIs, or pregnancy), and in all doubtful cases, to avoid stressful emergencies. The ideal duration of stenting is not known. Most urologists favour one to two weeks after URS. Alpha-blockers reduce the morbidity of ureteral stents and increase tolerability [271, 272].

**Medical expulsive therapy before and after ureteroscopy**

Medical expulsion therapy before URS might reduce the risk for intra-operative ureteral dilatation, protect against ureteral injury and increase stone free rates four weeks after URS [273].

Medical expulsion therapy following Ho:YAG laser lithotripsy accelerates the spontaneous passage of fragments and reduces episodes of colic [261].

**Complications of ureteroscopy**

The overall complication rate after URS is 9-25% [199, 274, 275]. Most complications are minor and do not require intervention. There is evidence suggesting a risk of post-operative urosepsis of up to 5% [276, 277]. Ureteral avulsion and strictures are rare (<1%). Previous perforations, pre-operative positive urine cultures and longer operation time are the most important risk factor for complications [245, 278]. Infectious complications following URS can be minimised using prophylactic antibiotics, limiting stent dwell and procedural time, identification and treatment of UTI, and planning in patients with large stone burden and multiple comorbidities [279].
High intrarenal pressure (IRP) predisposes to URS complications, and measures should be used to reduce IRP. Currently there are no accurate ways to measure intra-operative IRP [280].

</tr>
</tbody>
</table>

3.4.7 Percutaneous nephrolithotomy

Percutaneous nephrolithotomy remains the standard procedure for large renal calculi. Different rigid and flexible endoscopes are available, and the selection is mainly based on the surgeon’s own reference. Standard access tracts are 24-30 F. Smaller access sheaths, < 18 F, were initially introduced for paediatric use, but are now increasingly utilised in the adult population [281, 282].

Contraindications

Patients receiving anti-coagulant therapy must be monitored carefully pre- and post-operatively. Anti-coagulant therapy must be discontinued before PNL [283].

Other important contraindications include:
• untreated UTI;
• tumour in the presumptive access tract area;
• potential malignant kidney tumour;
• pregnancy (Section 3.4.14.1).

Best clinical practice

Intracorporeal lithotripsy

Several methods for intracorporeal lithotripsy during PNL are available. Ultrasonic and pneumatic systems are most commonly used for rigid nephroscopy, whilst laser is increasingly used for miniaturised instruments [284]. Flexible endoscopes also require laser lithotripsy to maintain tip deflection, with the Ho:YAG laser having become the standard.

Pre-operative imaging

Pre-procedural imaging evaluations are summarised in Section 3.3.1. In particular, US or CT of the kidney and the surrounding structures can provide information regarding interposed organs within the planned percutaneous path (e.g., spleen, liver, large bowel, pleura, and lung).
**Positioning of the patient**
Both prone and supine positions are equally safe, although the supine position confers some advantages, it depends on appropriate equipment being available to position the patient correctly, for example, X-ray devices and an operating table. Most studies cannot demonstrate an advantage of supine PNL in terms of operation time. Prone position offers more options for puncture and is therefore preferred for upper pole or multiple accesses [285, 286]. On the other hand, supine position allows simultaneous retrograde access to the collecting system, using flexible ureteroscope (ECIRS) [287].

**Puncture**
Although fluoroscopy is the most common intra-operative imaging method, the (additional) use of US reduces radiation exposure [288-290]. Pre-operative CT or intra-operative US allows identification of the tissue between the skin and kidney and lowers the incidence of visceral injury. The calyceal puncture may be done under direct visualisation using simultaneous flexible URS [289, 291, 292].

**Dilatation**
Dilatation of the percutaneous access tract can be achieved using a metallic telescope, single (serial) dilators, or a balloon dilatator. During PNL, safety and effectiveness are similar for different tract dilatation methods [293]. Although there are papers demonstrating that single step dilation is equally effective as other methods and that US only can be used for the dilatation, the difference in outcomes is most likely related to surgeon experience rather than to the technology used [293, 294].

**Choice of instruments**
The Panel performed a systematic review assessing the outcomes of PNL using smaller tract sizes (< 22 F, mini-PNL) for removing renal calculi [282]. Stone-free rates were comparable in miniaturised and standard PNL procedures. Procedures performed with small instruments tend to be associated with significantly lower blood loss, but the duration of procedure tends to be significantly longer. There were no significant differences in any other complications. However, the quality of the evidence was poor with only two RCTs and the majority of the remaining studies were single-arm case series only. Furthermore, the tract sizes used, and types of stones treated, were heterogeneous; therefore, the risk of bias and confounding were high. There is some evidence of using suction during PNL to reduce intra-renal pressure and increase stone free rate [295].

**Nephrostomy and stents**
The decision on whether, or not, to place a nephrostomy tube at the conclusion of the PNL procedure depends on several factors, including:
- presence of residual stones;
- likelihood of a second-look procedure;
- significant intra-operative blood loss;
- urine extravasation;
- ureteral obstruction;
- potential persistent bacteriuria due to infected stones;
- solitary kidney;
- bleeding diathesis;
- planned percutaneous chemolitholysis.

Small-bore nephrostomies seem to have advantages in terms of post-operative pain [282, 296, 297]. Tubeless PNL is performed without a nephrostomy tube. When neither a nephrostomy tube nor a ureteral stent is introduced, the procedure is known as totally tubeless PNL [298]. In uncomplicated cases, the latter procedure results in a shorter hospital stay, with no disadvantages reported [299].

**Complications of percutaneous nephrolithotomy**
A systematic review of almost 12,000 patients shows the incidence of complications associated with PNL: fever 10.8%, transfusion 7%, thoracic complication 1.5%, sepsis 0.5%, organ injury 0.4%, embolisation 0.4%, urinoma 0.2%, and death 0.05% [300].

Peri-operative fever can occur, even with a sterile pre-operative urinary culture and peri-operative antibiotic prophylaxis, because the renal stones themselves may be a source of infection. Intra-operative renal stone culture may therefore help to select post-operative antibiotics [301, 302]. Intra-operative irrigation pressure < 30 mmHg and unobstructed post-operative urinary drainage may be important factors in preventing post-operative sepsis [303]. Bleeding after PNL may be treated by briefly clamping the nephrostomy tube. Super-selective embolic occlusion of the arterial branch may become necessary in the case of severe bleeding.
High intrarenal pressure (IRP) predisposes to PNL complications, and measures should be used to reduce IRP. Currently there are no accurate ways to measure intra-operative intrarenal pressure [280].

### 3.4.8 General recommendations and precautions for stone removal

#### 3.4.8.1 Antibiotic therapy

Urinary tract infections should always be treated if stone removal is planned. In patients with clinically significant infection and obstruction, drainage should be performed for several days before starting stone removal. A urine culture or urinary microscopy should be performed before treatment [304].

**Peri-operative antibiotic prophylaxis**

For prevention of infection following URS and percutaneous stone removal, no clear-cut evidence exists [279, 305]. In a review of a large database of patients undergoing PNL, it was found that in patients with negative baseline urine culture, antibiotic prophylaxis significantly reduced the rate of post-operative fever and other complications [306]. Single dose administration was found to be sufficient [307]. Pre-operative prophylactic antibiotics compared to single dose before anaesthesia significantly reduced post-operative sepsis (OR: 0.31, 95% CI: 0.20–0.50; P < 0.0001) and fever (OR: 0.26, 95% CI: 0.14–0.48; P < 0.0001) [301].

#### 3.4.8.2 Antithrombotic therapy and stone treatment

Patients with a bleeding disorder, or receiving antithrombotic therapy, should be referred to an internist for appropriate therapeutic measures before deciding on stone management [308-312]. In patients with an uncontrolled bleeding disorder, the following are at elevated risk of haemorrhage or perinephric haematoma (PNH) (high-risk procedures):

- SWL [hazard ratio of PNH up to 4.2 during anti-coagulant/anti-platelet medication [313-315]];
- PNL;
- percutaneous nephrostomy;
- laparoscopic surgery;
- open surgery [308].

Shock wave lithotripsy is feasible and safe after correction of the underlying coagulopathy [316-320]. In the case of an uncontrolled bleeding disorder or continued antithrombotic therapy, URS in contrast to SWL and PNL, might offer an alternative approach since it is associated with less morbidity [321-323]. Despite
appropriate cessation of anti-platelet agents, following standardised protocols prolonged haematuria in tube drainage after PNL has been reported [324]. Only data on flexible URS are available which support the superiority of URS in the treatment of proximal ureteral stones [325, 326]. Although URS is safe in patients with bleeding disorders or anticoagulation, an individualised patient-approach is necessary [323].

3.4.8.3 Obesity
A high BMI can pose a higher anaesthetic risk and a lower success rate after SWL and PNL and may influence the choice of treatment [328].

3.4.8.4 Stone composition
Stones composed of brushite, calcium oxalate monohydrate, or cystine are particularly hard, as well as homogeneous stones with a high density on NCCT [45, 329]. Percutaneous nephrolithotomy or RiRS and URS are alternatives for removal of large SWL-resistant stones.

3.4.8.5 Contraindications of procedures

Contraindications of extracorporeal SWL
There are several contraindications to the use of extracorporeal SWL, including:
- pregnancy, due to the potential effects on the foetus [330];
- bleeding disorders, which should be compensated for at least 24 hours before and 48 hours after treatment [331];
- uncontrolled UTIs;
- severe skeletal malformations and severe obesity, which prevent targeting of the stone;
- arterial aneurysm in the vicinity of the stone [332];
- anatomical obstruction distal to the stone.

Contraindications of URS
Apart from general problems, for example with general anaesthesia or untreated UTIs, URS can be performed in all patients without any specific contraindications.

Contraindications of PNL
Patients receiving anti-coagulant therapy must be monitored carefully pre- and post-operatively. Anti-coagulant therapy must be discontinued before PNL [323]. Other important contraindications include:
- untreated UTI;
- tumour in the presumptive access tract area;
- potential malignant kidney tumour;
- pregnancy (Section 3.4.14.1).
**General contraindication for endourological procedures**

Endourological interventions do not adversely affect renal function although care must be taken in those with poor pre-operative renal function, diabetes and hypertension [333].

### 3.4.9 Specific stone management of ureteral stones

#### 3.4.9.1 Conservative treatment/observation

There are only limited data regarding spontaneous stone passage according to stone size [334]. It is estimated that 95% of stones up to 4 mm pass within 40 days [199]. Based on an analysis of available evidence, an exact cut-off size for stones that are likely to pass spontaneously cannot be provided [199].

Spontaneous stone passage was reported for 49% of upper ureteral stones, 58% of mid ureteral stones and 68% of distal ureteral stones. Considering stone size almost 75% of stones < 5 mm and 62% of stones ≥ 5 mm passed spontaneously, with an average time to stone expulsion about seventeen days (range 6-29 days) [335]. The Panel is aware of the fact that spontaneous stone expulsion decreases with increasing stone size and that there are differences between individual patients.

Sexual intercourse has been reported to be beneficial in facilitating stone expulsion in men with ureteral stones, in one MA consisting of three RCTs [336].

#### 3.4.9.2 Pharmacological treatment, medical expulsive therapy

Medical expulsive therapy should only be used in informed patients if active stone removal is not indicated. Treatment should be discontinued if complications develop (infection, refractory pain, deterioration of renal function). In case of known uric acid stones in the distal ureter, a combination of alkalinisation with tamsulosin can increase the frequency of spontaneous passage. For details see sections 3.4.3 and 3.4.4.

#### 3.4.9.3 Indications for active removal of ureteral stones

Indications for active removal of ureteral stones are [199, 334, 337]:

- stones with a low likelihood of spontaneous passage;
- persistent pain despite adequate analgesic medication;
- persistent obstruction;
- renal insufficiency (renal failure, bilateral obstruction, or single kidney).

#### 3.4.9.4 Selection of procedure for active removal of ureteral stones

Overall, SFRs after URS or SWL for ureteral stones are comparable. However, larger stones achieve earlier stone-free status with URS. Although URS is effective for ureteral calculi, it has greater potential for complications. However, in the current endourological era, the complication rate and morbidity of URS has been significantly reduced [338]. It has been demonstrated that URS is a safe option in obese patients (BMI > 30 kg/m²) with comparable SFRs and complication rates. However, in morbidly obese patients (BMI > 35 kg/m²) the overall complication rates double [339].

The Panel performed a systematic review to assess the benefits and harms of URS compared to SWL [340]. Compared with SWL, URS was associated with a significantly greater SFR of up to four weeks, but the difference was not significant at three months in the included studies. Ureteroscopy was associated with fewer retreatments and need for secondary procedures, but with a higher need for adjunctive procedures, greater complication rates and longer hospital stay. Counterbalancing for URS’s higher SFRs, SWL is associated with lower morbidity. Clavien-Dindo grade complications were, if reported, less frequent in patients treated with SWL.

**Bleeding disorder**

Ureteroscopy can be performed in patients with bleeding disorders, with a moderate increase in complications (see also section 3.4.8.2) [323].

3.4.10 Specific stone management of renal stones

The natural history of small, non-obstructing asymptomatic calculi is not well defined, and the risk of progression is unclear. There is still no consensus on the follow-up duration, timing, and type of intervention. Treatment options are chemolysis or active stone removal.

3.4.10.1 Conservative treatment (observation)

Observation of renal stones, especially in calyces, depends on their natural history (section 3.4.10.3). The recommendations provided are not supported by high-level literature [341]. There is a prospective trial supporting annual observation for asymptomatic inferior calyceal stones, < 10 mm. In case stone growth is detected, the follow-up interval should be lowered. Intervention is advised for growing stones > 5 mm [342]. In a systematic review of patients with asymptomatic renal stones on active surveillance spontaneous stone passage rates varied from 3-29%, symptom development from 7-77%, stone growth from 5-66%, surgical intervention from 7-26% [341].

3.4.10.2 Pharmacological treatment of renal stones

Dissolution of stones through pharmacological treatment is an option for uric acid stones only, but information on the composition of the stone will need to guide the type of treatment selected. See sections 3.4.4. and 3.4.8.4.

3.4.10.3 Indications for active stone removal of renal stones

Indications for the removal of renal stones, include:

- stone growth;
- stones in high-risk patients for stone formation;
- obstruction caused by stones;
- infection;
- symptomatic stones (e.g., pain or haematuria) [343];
- stones > 15 mm;
- stones < 15 mm if observation is not the option of choice;
- patient preference;
- comorbidity;
- social situation of the patient (e.g., profession or travelling);
- choice of treatment.

The risk of a symptomatic episode or need for intervention in patients with asymptomatic renal stones seems to be ~10-25% per year, with a cumulative five-year event probability of 48.5% [342, 344, 345]. A prospective RCT with more than two years clinical follow-up reported no significant difference between SWL and observation when comparing asymptomatic calyceal stones < 15 mm in terms of SFR, symptoms, requirement for additional treatment, quality of life (QoL), renal function, or hospital admission [346]. Although some have recommended prophylaxis for these stones to prevent renal colic, haematuria, infection, or stone growth, conflicting data have been reported [345, 347, 348]. In a follow-up period of almost five years after SWL, two series have demonstrated that up to 25% of patients with small residual fragments needed treatment [208, 349]. Although the question of whether calyceal stones should be treated is still unanswered, stone growth, de novo obstruction, associated infection, and acute and/or chronic pain are indications for treatment [343, 350, 351].

3.4.10.4 Selection of procedure for active removal of renal stones

For general recommendations and precautions see section 3.4.8.

3.4.10.4.1 Stones in renal pelvis or upper/middle calyces

Shock wave lithotripsy, PNL and RIRS are available treatment modalities for renal calculi. While PNL efficacy is hardly affected by stone size, the SFRs after SWL or URS are inversely proportional to stone size [352-355]. Shock wave lithotripsy achieves good SFRs for stones to 20 mm, except for those at the lower pole [354, 356, 357]. Endourology is considered an alternative because of the reduced need for repeated procedures and consequently a shorter time until stone-free status is achieved. Stones > 20 mm should be treated primarily by PNL, because SWL often requires multiple treatments, and is associated with an increased risk of ureteral obstruction (colic or steinstrasse) with a need for adjunctive procedures (Figure 3.2) [197]. Retrograde renal surgery cannot be recommended as first-line treatment for stones > 20 mm in uncomplicated cases as SFRs decrease, and staged procedures will be required [358-360]. However, it may be a first-line option in patients where PNL is not an option or contraindicated.
3.4.10.4.2 Stones in the lower renal pole

The stone clearance rate after SWL seems to be lower for stones in the inferior calyx than for other intra-renal locations. Although the disintegration efficacy of SWL is not limited compared to other locations, the fragments often remain in the calyx and cause recurrent stone formation. The reported SFR of SWL for lower pole calculi is 25-95%. The preferential use of endoscopic procedures is supported by some current reports, even for stones < 1 cm [197, 352, 353, 355, 356, 360-373].

The following can impair successful stone treatment by SWL [363, 374-379]:
- steep infundibular-pelvic angle;
- long calyx;
- long skin-to-stone distance;
- narrow infundibulum;
- shock wave-resistant stones (calcium oxalate monohydrate, brushite, or cystine).

Further anatomical parameters cannot yet be established. Supportive measures such as inversion, vibration or hydration may facilitate stone clearance (See section 3.4.5 ESWL) [194, 196, 380].

If there are negative predictors for SWL, PNL and RIRS might be reasonable alternatives, even for smaller calculi [361]. Retrograde renal surgery seems to have comparable efficacy to SWL [197, 353, 356, 381]. Recent clinical experience has suggested a higher SFR of RIRS compared to SWL, but at the expense of greater invasiveness. Depending on operator skills, stones up to 3 cm can be treated by RIRS [230, 382-384]. However, staged procedures are frequently required.

In complex stone cases, open or laparoscopic approaches are possible alternatives although they are infrequently used.

3.4.10.5 Summary of evidence and guidelines for the management of renal stones

**Summary of evidence**

| LE |
|-----------------|-----------------|
| 4               | It is still debatable whether renal stones should be treated, or whether annual follow-up is sufficient for asymptomatic calyceal stones that have remained stable for six months. |
| 3               | Although the question of whether asymptomatic calyceal stones should be treated is still unanswered, stone growth, de novo obstruction, associated infection, and acute and/or chronic pain are indications for treatment. |
| 1a              | Percutaneous nephrolithotomy is indicated in renal stones > 2 cm as primary option. |

**Recommendations**

<table>
<thead>
<tr>
<th>Strength rating</th>
</tr>
</thead>
<tbody>
<tr>
<td>Follow-up periodically in cases where renal stones are not treated (initially after six months then yearly, evaluating symptoms and stone status, either by ultrasound, kidney-ureter bladder radiography or computed tomography (CT)).</td>
</tr>
<tr>
<td>Offer active treatment for renal stones in case of stone growth, de novo obstruction, associated infection, and acute and/or chronic pain.</td>
</tr>
<tr>
<td>Evaluate stone composition before deciding on the method of removal, based on patient history, former stone analysis of the patient or Hounsfield unit (HU) on unenhanced CT. Stones with density &gt; 1,000 HU (and with high homogeneity) on non-contrast-enhanced CT are less likely to be disintegrated by shock wave lithotripsy (SWL).</td>
</tr>
<tr>
<td>Perform percutaneous nephrolithotomy (PNL) as first-line treatment of larger stones &gt; 2 cm.</td>
</tr>
<tr>
<td>Treat larger stones (&gt; 2 cm) with flexible ureteroscopy or SWL, in cases where PNL is not an option. However, in such instances there is a higher risk that a follow-up procedure and placement of a ureteral stent may be needed.</td>
</tr>
<tr>
<td>Perform PNL or retrograde intrarenal surgery for the lower pole, even for stones &gt; 1 cm, as the efficacy of SWL is limited (depending on favourable and unfavourable factors for SWL).</td>
</tr>
</tbody>
</table>
3.4.11 Laparoscopy and open surgery

Advances in SWL and endourological surgery (URS and PNL) have significantly decreased the indications for open or laparoscopic stone surgery [385-390]. There is a consensus that most complex stones, including partial and complete staghorn stones, should be approached primarily with PNL. Additionally, a combined approach with PNL and RIRS may also be an appropriate alternative. However, if percutaneous approaches are not likely to be successful, or if multiple endourological approaches have been performed unsuccessfully; open or laparoscopic surgery may be a valid treatment option [391-397].

Few studies have reported laparoscopic stone removal. These procedures are usually reserved for special cases. When expertise is available, laparoscopic ureterolithotomy can be performed for large proximal ureteral stones as an alternative to URS or SWL [398, 399]. These more invasive procedures have yielded high SFRs and lower auxiliary procedure rates [223, 234, 400]. A recent systematic review showed no difference in the post-operative phase for stented or unstented laparoscopic ureterolithotomy [400].

Laparoscopic pyelolithotomy could be offered for solitary stones > 2 cm located in renal pelvis as an alternative to PNL [401]. In addition, in selected cases with an extrarenal and dilated pelvis, RLP can be considered as an alternative management of staghorn calculi [402].

A few studies with limited numbers of patients have reported using robotic surgery in the treatment of urinary stones [403]. Open surgery should be considered as the last treatment option, after all other possibilities have been explored.

Studies on laparoscopy should be interpreted with caution due to their weak design and low quality of evidence.

---

*The term ‘Endourology’ encompasses all PNL and URS interventions.
PNL = percutaneous nephrolithotomy; RIRS = retrograde intrarenal surgery; SWL = shock wave lithotripsy; URS = ureteroscopy.

</table>

3.4.12 Steinstrasse

Steinstrasse is an accumulation of stone fragments or stone gravel in the ureter and may interfere with the passage of urine [404]. Steinstrasse occurs in 4-7% cases of SWL [218], and the major factor in the development of steinstrasse formation is stone size [405].

A major problem of steinstrasse is ureteral obstruction, which may be silent in up to 23% of cases. A MA including eight RCTs (n = 876) suggested a benefit of stenting before SWL in terms of steinstrasse formation, but did not result in a benefit on SFRs or less auxiliary treatments [147]. When steinstrasse is asymptomatic, conservative treatment is an initial option. Medical expulsion therapy increases stone expulsion and reduces the need for endoscopic intervention [406, 407]. Ureteroscopy and SWL are effective in treatment of steinstrasse [220, 408]. In the event of UTI or fever, the urinary system should be decompressed, preferably by percutaneous nephrostomy [120, 122].

3.4.13 Management of patients with residual stones

Following initial treatment with SWL, URS or PNL, residual fragments may remain and require additional intervention [349, 409, 410]. Most of the studies indicate that initial imaging is performed on the first day or the first week after treatment. However, false positive results from dust or residual fragments, that will pass spontaneously without causing any stone-related event, might lead to over-treatment. Therefore, imaging at four weeks seems most appropriate [411-413]. Compared to US, KUB and IVU, NCCT scan has a higher sensitivity to detect small residual fragments after definitive treatment of ureteral or kidney stones [414, 415]. However, more than half of the patients with a residual fragment on NCCT images may not experience a stone-related event [416].

It is clear that NCCT has the highest sensitivity to detect residual fragments; however, this must be balanced against the increased detection of clinically insignificant fragments and the exposure to ionising radiation when compared with KUB and US. In the absence of high-level supporting evidence, the timing of follow-up imaging studies and need for secondary intervention is left to the discretion of the treating physician. Recurrence risk in patients with residual fragments after treatment of infection stones is higher than for other stones [417]. For all stone compositions, 21-59% of patients with residual stones required treatment within five years. Fragments > 5 mm are more likely than smaller ones to require intervention [208, 418, 419]. There is evidence that fragments > 2 mm are more likely to grow, although this is not associated with increased re-intervention rates at one year follow-up [409].

3.4.14 Management of specific patient groups

3.4.14.1 Management of urinary stones and related problems during pregnancy

Clinical management of a pregnant urolithiasis patient is complex and demands close collaboration between patient, radiologist, obstetrician, and urologist. For diagnostic imaging see section 3.3.1.

If spontaneous passage does not occur, or if complications develop (e.g., intractable symptoms, severe hydronephrosis, spontaneous renal fornix rupture [420] or induction of premature labour), placement of a ureteral stent or a percutaneous nephrostomy tube is necessary as it is more effective than conservative treatment for symptom relief [421-423].

Unfortunately, these temporising therapies are often associated with poor tolerance, and they require multiple exchanges during pregnancy, due to the potential for rapid encrustation [424].

Ureteroscopy has become a reasonable alternative in these situations [413, 425]. When compared to temporary ureteral JJ stenting until after delivery, ureteroscopy resulted in fewer needs for stent exchanges, less irritative LUTS and better patient satisfaction [426].

Non-urgent ureteroscopy in pregnant women is best performed during the second trimester by an experienced urologist. Counselling of the patient should include access to neonatal and obstetric services [76].

Although feasible, percutaneous removal of renal stones during pregnancy remains an individual decision and should be performed only in experienced centres [427]. Pregnancy remains an absolute contraindication for SWL.

Treat all uncomplicated cases of urolithiasis in pregnancy conservatively (except when there are clinical indications for intervention).

**Strength rating**

Strong

3.4.14.2 Management of stones in patients with urinary diversion

**Aetiology**

Patients with urinary diversion are at high risk for stone formation in the renal collecting system and ureter or in the conduit or continent reservoir [428, 429]. Metabolic factors (hypercalciuria, hyperoxaluria and hypocitraturia), infection with urease-producing bacteria, foreign bodies, mucus secretion, and urinary stasis are responsible for stone formation [430] (section 3.1.3). One study has shown that the risk for recurrent upper tract stones in patients with urinary diversion subjected to PNL was 63% at five years [431].

**Management**

Smaller upper-tract stones can be treated effectively with SWL [227, 432]. In the majority of cases, endourological techniques are necessary to achieve stone-free status [225]. In individuals with long, tortuous conduits or with
invisible ureter orifices, a retrograde endoscopic approach might be difficult or impossible [433].

For stones in the conduit, a trans-stomal approach can be used to remove all stone material (along with the foreign body) using standard techniques, including intracorporeal lithotripsy and flexible endoscopes. Trans-stomal manipulations in continent urinary diversion must be performed carefully to avoid disturbance of the continence mechanism [434].

Before considering any percutaneous approach in these cases, CT should be undertaken to assess the presence of overlying bowel, which could make this approach unsafe [435], and if present, an open surgical approach should be considered.

**Prevention**

Recurrence risk is high in these patients [431]. Metabolic evaluation and close follow-up are necessary to obtain the risk parameters for effective long-term prevention. Preventive measures include medical management of metabolic abnormalities, appropriate therapy of urinary infections, and hyperdiuresis or regular irrigation of continent reservoirs [436].

### 3.4.14.3 Management of stones in patients with neurogenic bladder

**Aetiology, clinical presentation and diagnosis**

Patients with neurogenic bladder develop urinary calculi because of additional risk factors such as bacteriuria, hydronephrosis, VUR, renal scarring and lower urinary tract reconstruction [437]. The most common causes are urinary stasis and infection (section 3.1.3). Indwelling catheters and surgical interposition of bowel segments for treatment of bladder dysfunction both facilitate UTI. Although calculi can form at any level of the urinary tract, they occur more frequently in the bladder; especially if bladder augmentation has been performed [438, 439].

Diagnosis of stones may be difficult and delayed in the absence of clinical symptoms due to sensory impairment and vesico-urethral dysfunction. Difficulties in self-catheterisation should lead to suspicion of bladder calculi. Imaging studies are needed (US, CT) to confirm the clinical diagnosis prior to surgical intervention.

**Management**

Management of calculi in patients with neurogenic bladder is similar to that described in section 3.3.3. In myelomeningocele patients, latex allergy is common; therefore, appropriate measures need to be taken regardless of the treatment [440]. Any surgery in these patients must be performed under general anaesthesia because of the impossibility of using spinal anaesthesia. Bone deformities often complicate positioning on the operating table [441]. The risk of stone formation after augmentation cystoplasty in immobile patients with sensory impairment can be significantly reduced by irrigation protocols [436].

For efficient long-term stone prevention in patients with neurogenic bladder, correction of the metabolic disorder, appropriate infection control, and restoration of normal storing/voiding function of the bladder are needed.

3.4.14.4 Management of stones in patients with transplanted kidneys

Stones in transplanted kidneys can either be transplanted or present de novo allograft stones. Usually they are detected by routine US examination, followed by NCCT in cases of unclear diagnosis [442].

Aetiology

Transplant patients depend on their solitary kidney for renal function. Impairment causing urinary stasis/obstruction therefore requires immediate intervention or drainage of the transplanted kidney. Stones in kidney allografts have an incidence of 1% [443]. Risk factors for de novo stone formation in these patients are multi-fold:
- Immunosuppression increases the infection risk, resulting in recurrent UTIs.
- Hyperfiltration, excessively alkaline urine, renal tubular acidosis (RTA), and increased serum calcium caused by persistent tertiary hyperparathyroidism [444] are biochemical risk factors.

Management

Selecting the appropriate technique for stone removal in a transplanted kidney is difficult, although management principles are similar to those applied in other single renal units [445-447]. Additional factors such as transplant function, coagulative status, and anatomical obstacles due to the iliacal position of the organ directly influence the surgical strategy.

For large or ureteral stones, careful percutaneous access and subsequent antegrade endoscopy are more favourable. The introduction of small flexible ureteroscopes and the holmium laser has made URS a valid treatment option for transplant calculi; however, one must be aware of potential injury to adjacent organs [446, 448, 449]. Retrograde access to transplanted kidneys is difficult due to the anterior location of the ureteral anastomosis, and ureteral tortuosity [450-452]. Treatment of donor stones may be needed pre-transplant and increases the pool available for renal transplants. Post-transplant stone disease may also need treatment to maintain the allograft function. A systematic review evaluating the outcomes of pre- vs. post-transplant URS demonstrated a 100% SFR with an overall 7.5% complication rate, compared to SFR of 60-100% with an overall complication rate of 12.9% for post-transplant URS; most complications were Clavien 1 [453].

3.4.14.5 Special problems in stone removal

Table 3.11: Special problems in stone removal

| Calyceal diverticulum stones | • SWL, PNL [454] (if possible) or RIRS [454, 455].
| • Can also be removed using laparoscopic retroperitoneal surgery [456, 457].
| • Patients may become asymptomatic due to stone disintegration (SWL), whilst well-disintegrated stone material remains in the original position due to narrow calyceal neck. |
| Horseshoe kidneys | • Can be treated in line with the options described above [458].
| • Passage of fragments after SWL might be poor.
| • Acceptable SFRs (up to 76%) with low major complication rates (2.4%) can be achieved with flexible ureteroscopy [459, 460]. |
| Stones in pelvic kidneys | • SWL, RIRS, PNL or laparoscopic surgery [461]. |
Stones formed in a continent reservoir • Each stone must be considered and treated individually.

Patients with obstruction of the UPJ • When outflow abnormality requires correction, stones can be removed by PNL together with percutaneous endopyelotomy or open/laparoscopic reconstructive surgery.
• URS together with endopyelotomy with Ho:YAG laser.
• Incision with an Accuise® balloon catheter might be considered, provided the stones can be prevented from falling into the pelvic-ureteral incision [462-465].
• Open surgery with correction of the UPJ obstruction (pyeloplasty) and stone removal is a feasible option [466].

3.4.15 Management of stones in children

The true incidence of nephrolithiasis in children remains unclear due to the global lack of large epidemiological studies. Data derived from nationwide epidemiological studies, studies performed in different counties worldwide [467] and large-scale databases [468, 469] indicate that the incidence and prevalence of paediatric urinary stone disease has increased over the last few decades. Although boys are most commonly affected in the first decade of life [470] the greatest increase in incidence has been seen in older female adolescents [467].

Stone composition is similar in children as in adults, with a predominance of calcium oxalate stones. Compared to historical data, metabolic abnormalities responsible for stone formation are less commonly identified in children nowadays [471-473]. Hypocitraturia, low urine volume and hypercalciuria predominate [85, 471-473]. Age may affect the predominant metabolic abnormality with hypercalciuria and hypocitraturia being the most common disorder present in children < 10 and > 10 years old, respectively [473]. Genetic or systemic diseases (e.g., cystinuria or nephrocalcinosis) contributing to stone formation are relatively frequent in children accounting for less than 17% of the identifying causes [471, 474]. The role of diet remains unclear in children, although there is some evidence that children are drinking less water and taking greater daily amounts of sodium than is recommended [475-477].

For diagnostic procedures see section 3.3.3.2, for acute decompression see section 3.4.2. and for metabolic evaluation see chapter 4.

3.4.15.1 Clinical presentation

Children with urinary stones can be asymptomatic or present with non-specific symptoms that necessitate a high index of suspicion for proper diagnosis. Symptoms are age-dependent with infants presenting with crying, irritability and vomiting in 40% of cases [478] while in older children flank pain, micro or gross haematuria and recurrent UTIs are more common [479].

3.4.15.2 Conservative management

There is a lack of evidence on conservative management of paediatric stones with evidence for ureteric calculi coming from the placebo arms of medical expulsive trials, while evidence for renal stones comes from small cohort studies, either on primary stones [480, 481] or residual fragments remained after SWL, RIRS or PNL [482]. Expectant management for single, asymptomatic lower-pole renal stones could be the initial approach with increased odds of stone passage, especially in patients with non-struvite, non-cystine stones < 7 mm, with no anatomic abnormalities [480]. Intervention may be needed for stones located elsewhere independently of their size [480-482].

3.4.15.3 Medical expulsive therapy in children

There are limited studies on MET as off-label expulsive therapy for children with stones which show conflicting outcomes. A recent MA of five trials showed that adrenergic α-antagonists (tamsulosin 0.2-0.4 mg/day and doxazosin 0.03 mg/kg/day) are effective for MET increasing SFR compared to control (OR = 2.7, p = 0.001) without significantly increasing the treatment-emergent adverse events (OR = 2.01, p = 0.17) [483]. Similarly, an updated systematic review of six placebo-controlled studies showed that α-blockers might increase SFR of distal ureteric stones (RR: 1.34, 95% CI: 1.16 - 1.54) [484]. Due to study limitations and very serious imprecision, no conclusion could be drawn regarding the effect of MET on hospital stay, pain episodes or secondary procedures for residual fragments after definitive stone treatment [484].

3.4.15.4 Extracorporeal shock wave lithotripsy

Shock wave lithotripsy is still the first-line treatment for most ureteral stones in children. However, it is less likely to be successful for stones > 10 mm in diameter, impacted stones, calcium oxalate monohydrate or cystine stones, or for stones in children with unfavourable anatomy and in whom localisation is difficult [485].
Studies on extracorporeal SWL in children suggest an overall SFR of 70-90%, retreatment rate of 4-50% and need for auxiliary procedures in 4-12.5% of cases [486-490]. A MA of fourteen studies reporting on 1,842 paediatric patients treated with SWL found significantly higher SFR for stones < 10 mm than for stones > 10 mm and higher retreatment rates as the stone size increased [485]. For best clinical practice see section 3.4.5. A recent MA on slow SWL vs. rapid SWL for renal stones revealed very low-quality evidence about the effects of SWL on SFRs, serious adverse events or complications of treatment and secondary procedures for residual fragments [484]. Shock wave lithotripsy is well tolerated; however, good treatment outcomes are more likely to require the administration of general anaesthesia to children. With improvements in modern (second and third generation) lithotripters, successful treatment using intravenous sedation, patient-controlled analgesia or no medication at all has been increasingly performed in a select population of older, co-operative children [491].

Based on the results of a recent MA which compared SWL to dissolution therapy for intra-renal stones, and SWL to ureteroscopy with holmium laser or pneumatic lithotripsy for renal and distal ureteric stones, no firm conclusions can be drawn about the effects of SWL on SFR, serious adverse events or complications of treatment and secondary procedures for residual fragments [484]. When SWL was compared to mini-percutaneous nephrolithotomy for lower pole renal stones 1-2 cm in size SWL resulted in lower SFRs (RR: 0.88, 95% CI: 0.80 - 0.97; moderate-quality evidence) and higher rates of secondary procedures (RR: 2.50, 95% CI: 1.01 - 6.20; low-quality evidence); however, SWL showed less severe adverse events (RR: 0.13, 95% CI: 0.02 - 0.98; low-quality evidence) [492].

3.4.15.5 Endourological procedures
Rigid/semi-rigid ureteroscopy
In recent years ureteroscopy is increasingly used in children with ureteral stones [493]. Ureteroscopy proved to be effective with SFR of 81-98% [494-496], retreatment rates of 6.3%-10% [497] and complication rates of 1.9-23% [494-496, 498]. Similar to adults, routine stenting is not necessary before URS. Pre-stenting may facilitate URS, increase SFR and decrease complication rates [499, 500].

Flexible ureteroscopy/retrograde intrarenal surgery
Retrograde intra-renal surgery with flexible ureteroscopes (FURS) has become an efficacious treatment modality for paediatric renal stones. Recent studies report SFRs of 76-100%, retreatment rates of 0-19% and complication rates of 0-28% [501-504]. Younger age, cystine composition [505], large stone diameter [504] and lack of pre-stenting predispose to FURS failure in children [499].

Although high-level evidence is lacking to support a strong recommendation [484], FURS may be a particularly effective treatment option for lower calyceal stones in the presence of unfavourable factors for SWL [496, 502, 506].

For large and complex kidney stones RIRS has a significantly lower SFR compared to PNL (71% vs. 95%), but is associated with less radiation exposure, lower complication rates and a shorter hospital stay [507]. Similarly, retrospectively data indicate that RIRS may achieve lower SFRs compared to minor micropercutaneous surgery in favour of shorter operative time, shorter fluoroscopy time, and less hospitalisation time [508, 509]. A recently published MA confirmed these results [510].

Percutaneous nephrolithotomy
Indications for PNL in children are similar to those in adults, and include renal stones > 2 cm, or smaller stones resistant to SWL and ureteroscopic treatment. Reported SFRs with paediatric PNL are 71.4-95% after a single session [507-509, 511, 512] with an overall complication rate of 20% [513]. High degree of hydronephrosis, increased number of tracts and operative time [514] and large tract size [512, 515-517] are associated with increased blood loss. Child age [516] and stone burden [512] predispose to the use of larger instruments during PNL in children. Miniaturisation of equipment increases the opportunity to perform tubeless PNL in appropriately selected children, which can reduce the length of hospital stay and post-operative pain [518, 519].

Concerns have been raised regarding possible adverse effects of PNL on the renal parenchyma of the developing child. However, focal damage is only reported in 5% of cases [520]. Using pre- and post-PNL dimercaptosuccinic acid (DMSA) scans, Cicciobilek et al., demonstrated that PNL tracts between 12-24 Charrière in size did not cause significant harm to paediatric kidneys [511].

3.4.15.6 Open and laparoscopic/robot-assisted stone surgery
With the advances in ESWL, PNL and RIRS, very few cases of paediatric urolithiasis require open surgery. Data extracted from the National Inpatient Sample (NIS) databases for 2001-2014 showed that in the USA incisional procedures (mainly nephrolithotomy, pyelolithotomy and ureterotomy) were performed in 2.6% of hospitalised patients (52% aged 15-17 years) who required surgical intervention for urinary stones [521]. Laparoscopy
for the management of paediatric renal and ureteric stones is a safe and effective procedure when specific indications are followed. Stone free rates of 100% were reported when laparoscopic pyelolithotomy was applied for a > 1 cm single stone located in an extra-renal pelvis [522], or when laparoscopic ureterolithotomy was applied to impacted ureteric stones ≥ 1.5 cm, or to ureteric stones that were refractory to SWL or URS [523]. There are extremely limited data available on efficacy and complications of robot-assisted laparoscopic management of paediatric urolithiasis [524].

3.4.15.7 Special considerations on recurrence prevention
All paediatric stone formers need metabolic evaluation and recurrence prevention with respect to the detected stone type. Children are in the high-risk group for stone recurrence (See chapter 4).

3.5 Radiation exposure and protection during endourology
The diagnosis and treatment of nephrolithiasis is associated with high levels of ionising radiation exposure to patients [525, 526]. Currently, there are no studies estimating the lifetime radiation exposure of stone formers or the subsequent risk of malignancy development. The radiation exposure of endourologists has been extensively studied. Still, there are no studies assessing the risk of radiation induced malignancies in urologists or operating theatre staff members [527-529].

Current evidence from atomic bomb patients [530, 531], retrospective epidemiological data on medical exposure [532, 533] and modelling studies [534, 535] suggest an age and dose dependent risk of secondary malignancy from ionising radiation.

The International Commission on Radiological Protection (ICRP) recommends a maximum annual occupational exposure of 50mSv [536]. However, the risk of radiation induced malignancy follows a stochastic model having no known safe threshold of exposure. Taking this into consideration as well as the length of a urologists career the upper limit of 50mSv is still highly concerning.

Table 3.12 shows the EAU Urolithiasis guidelines panel recommended protection methods to reduce radiation exposure to patients, surgical, anaesthesiologic and nursing staff.

4. METABOLIC EVALUATION AND RECURRENT PREVENTION

4.1 General metabolic considerations for patient work-up

4.1.1 Evaluation of patient risk

After stone passage, every patient should be assigned to a low- or high-risk group for stone formation (Figure 4.1). For correct classification, two items are mandatory:

- reliable stone analysis by infrared spectroscopy or X-ray diffraction;
- basic analysis (section 3.3.2).

Only high-risk stone formers require specific metabolic evaluation. Stone type is the deciding factor for further diagnostic tests. The different stone types include:

- calcium oxalate;
- calcium phosphate;
- uric acid;
- ammonium urate;
- struvite (and infection stones);
- cystine;
- xanthine;
- 2,8-Dihydroxyadenine;
- drug stones;
- stones of unknown composition.

Availability of fluoroscopy is mandatory for endourological procedures. There is an increasing interest on fluoroless and fluoroscopy-free operations in urology. Several RCTs have been published showing a good outcome in means of stone-free and complication rates [176, 289, 537-539]. These trials have been limited to non-complex cases and they were not sufficiently powered to show non-inferiority of fluoroscopy in PNL [289, 527] or superiority of US in URS [540, 541].
4.1.2 **Urine sampling**
Specific metabolic evaluation requires collection of two consecutive 24-hour urine samples [542, 543]. The collecting bottles should be prepared with 5% thymol in isopropanol or stored at < 8°C during collection to prevent the risk of spontaneous crystallisation in the urine. Pre-analytical errors can be minimised by carrying out urinalysis immediately after collection. Alternatively, boric acid (10 g powder per urine container) can also be used. The collecting method should be chosen in close cooperation with the laboratory. Urine pH should be assessed during collection of freshly voided urine at different times throughout the day using sensitive pH-dipsticks or a pH-meter [25, 544, 545].

Spot urine samples are an alternative method of sampling, particularly when 24-hour’s urine collection is difficult, for example, in non-toilet trained children [546]. Spot urine studies normally link the excretion rates to creatinine [547], but these are of limited use because the results may vary with collection time and patients’ sex, body weight and age.

4.1.3 **Timing of specific metabolic work-up**
For the initial specific metabolic work-up, the patient should stay on a self-determined diet under normal daily conditions and should ideally be stone free for at least twenty days [548]. Follow-up studies are necessary in patients taking medication for recurrence prevention [549]. The first follow-up 24-hour urine measurement is suggested eight to twelve weeks after starting pharmacological prevention of stone recurrence. This enables drug dosage to be adjusted if urinary risk factors have not normalised, with further 24-hour urine measurements, if necessary. Once urinary parameters have been normalised, it is sufficient to perform 24-hour urine evaluation every twelve months. On this issue the Panel realise that there is only very limited published evidence.
4.1.4 Reference ranges of laboratory values

Tables 4.1-4.4 provide the internationally accepted reference ranges for the different laboratory values in serum and urine.

Table 4.1: Normal laboratory values for blood parameters in adults [549, 550]

<table>
<thead>
<tr>
<th>Blood parameter</th>

BE = base excess (loss of buffer base to neutralise acid); HCO₃ = bicarbonate; pCO₂ = partial pressure of carbon dioxide; pO₂ = partial pressure of oxygen.

4.1.5 Risk indices and additional diagnostic tools

Several risk indices have been developed to describe the crystallisation risk for calcium oxalate or calcium phosphate in urine [551-554]. However, clinical validation of these risk indices for recurrence prediction or therapy improvement is ongoing.

* There is low-level evidence regarding the importance of magnesium.

4.2 General considerations for recurrence prevention

All stone formers, independent of their individual risk, should follow the preventive measures in Table 4.5. The main focus is normalisation of dietary habits and lifestyle risks. Stone formers at high risk need specific prophylaxis for recurrence, which is usually pharmacological treatment based on stone analysis and urinary risk profile.

Table 4.5: General preventive measures

</tr>
</tbody>
</table>

Caution: Protein requirements are age dependent; therefore, protein restriction in childhood should be handled carefully.

* Avoid excessive consumption of vitamin supplements.

4.2.1 Fluid intake

An inverse relationship between high fluid intake and stone formation has been repeatedly demonstrated [556-559]. The effect of fruit juices is mainly determined by the presence of citrate or bicarbonate [560]. If hydrogen ions are present, the net result is neutralisation. However, if potassium is present, both pH and citrate are increased [561, 562]. One large moderate quality RCT randomly assigned men with more than one past renal stone of any type and soft drink consumption of at least 160 mL/day to reduced soft drink intake or no treatment. Although the intervention significantly reduced the risk for symptomatic recurrent stones (RR: 0.83; CI: 0.71-0.98), the level of evidence for this outcome is low because results were from only one trial [563].
analysis on the three Channing’s cohorts (194,095 participants) over a median follow-up of more than eight years has shown that consumption of sugar-sweetened soda and punch is associated with a higher risk of stone formation, whereas consumption of coffee, tea, beer, wine, and orange juice is associated with a lower risk [564].

4.2.2 Diet
A common-sense approach to diet should be taken, that is, a mixed, balanced diet with contributions from all food groups, without any excesses [557, 565, 566].

Fruit, vegetables and fibre: Fruit and vegetable intake should be encouraged because of the beneficial effects of fibre, although the role of the latter in preventing stone recurrences is debatable [567-570]. The alkaline content of a vegetarian diet also increases urinary pH.

Oxalate: Excessive intake of oxalate-rich products should be limited or avoided to prevent high oxalate load [571], particularly in patients who have high oxalate excretion.

Vitamin C: Although vitamin C is a precursor of oxalate, its role as a risk factor in calcium oxalate stone formation remains controversial [572]. However, it seems wise to advise calcium oxalate stone formers to avoid excessive intake.

Animal protein: Animal protein should not be consumed in excess [573, 574] and limited to 0.8-1.0 g/kg body weight. Excessive consumption of animal protein has several effects that favour stone formation, including hypocitraturia, low urine pH, hyperoxaluria and hyperuricosuria.

Calcium intake: Calcium should not be restricted, unless there are strong reasons for doing so, due to the inverse relationship between dietary calcium and stone formation [568, 575]. The daily requirement for calcium is 1,000 to 1,200 mg [25]. Calcium supplements are not recommended except in enteric hyperoxaluria, when additional calcium should be taken with meals to bind intestinal oxalate [557, 571, 573, 576]. Older adults who do not have a history of renal stones but who take calcium supplements should ensure adequate fluid intake since it may prevent increases in urine calcium concentration, and thereby reduce or eliminate any increased risk of renal stones formation associated with calcium supplement use [577].

Sodium: Daily sodium (NaCl) intake should not exceed 3-5 g [25]. High intake adversely affects urine composition:
- calcium excretion is increased by reduced tubular re-absorption;
- urinary citrate is reduced due to loss of bicarbonate;
- increased risk of sodium urate crystal formation.

Calcium stone formation can be reduced by restricting sodium and animal protein [573, 574]. A positive correlation between sodium consumption and risk of first-time stone formation has been confirmed only in women [575]. There have been no prospective clinical trials on the role of sodium restriction as an independent variable in reducing the risk of stone formation.

Urate: Intake of purine-rich food should be restricted in patients with hyperuricosuric calcium oxalate [578, 579] and uric acid stones. Intake should not exceed 500 mg/day [25].

4.2.3 Lifestyle
Lifestyle factors may influence the risk of stone formation, for example, obesity [580] and arterial hypertension [581, 582].

### 4.3 Stone-specific metabolic evaluation and pharmacological recurrence prevention

#### 4.3.1 Introduction

Pharmacological treatment is necessary in patients at high risk for stone formation. The ideal drug should halt stone formation, have no side effects, and be easy to administer. Each of these aspects is important to achieve good compliance. Table 4.6 highlights the most important characteristics of commonly used medication.

Cystine

* Patients on hydrochlorothiazides should be advised to get their skin checked on a regular basis as they have a higher risk of developing a non-melanoma skin cancer (NMSC). In patients with history of NMSC the indication for the intake of hydrochlorothiazides should be thoroughly reviewed [614, 615].

** No information is available on maximum dose and patients may be initiated on a very low dose if they have had previously had reactions to tiopronin or penicillamine. For all patients, dosage should be titrated according to frequency of stone episodes, side effects and renal function under expert supervision with close monitoring.

4.4 Calcium oxalate stones
The criteria for identification of calcium oxalate stone formers with high recurrence risk are listed in section 3.1.3.

4.4.1 Diagnosis
Blood analysis requires measurement of creatinine, sodium, potassium, chloride, ionised calcium (or total calcium + albumin), phosphate, uric acid; and, in the case of increased calcium levels, parathyroid hormone (PTH) and vitamin D. Urinalysis requires measurement of urine volume, urine pH profile, specific weight, calcium, oxalate, uric acid, citrate, sodium and magnesium. Figure 4.2 summarises the diagnostic steps for calcium oxalate stones.

4.4.2 Interpretation of results and aetiology
The most common metabolic abnormalities associated with calcium stone formation are hypercalciuria, which affects 30-60% of adult stone formers, and hyperoxaluria (26-67%), followed by hyperuricosuria (15-46%), hypomagnesuria (7-23%), and hypocitraturia (5-29%). However, ranges tend to differ based on ethnicity [616].

- Elevated levels of ionised calcium in serum (or total calcium and albumin) require assessment of intact PTH to confirm or exclude suspected hyperparathyroidism (HPT).
- “Acidic arrest” (circadian urine pH constantly < 5.8) may promote co-crystallisation of uric acid and calcium oxalate.
- Similarly, increased uric acid excretion (> 4 mmol/day in adults or > 12 mg/kg/day in children) can act as a promoter.
- Urine pH levels constantly > 5.8 in the day profile may indicate RTA, provided UTI has been excluded. An ammonium chloride loading test confirms RTA and identifies RTA subtype (section 4.6.5).
- Hypercalciuria may be associated with normocalcemia (idiopathic hypercalciuria, or granulomatous diseases) or hypercalcaemia (hyperparathyroidism, granulomatous diseases, vitamin D excess, or malignancy).
- Hypocitraturia (male < 1.7 mmol/day, female < 1.9 mmol/day) may be idiopathic or secondary to metabolic acidosis or hypokalaemia.
- Oxalate excretion > 0.5 mmol/day in adults (> 0.37 mmol/1.73 m²/day in children) confirms hyperoxaluria.
  - primary hyperoxaluria (oxalate excretion mostly > 1 mmol/day), appears in three genetically determined forms;
  - secondary hyperoxaluria (oxalate excretion mostly > 0.5 mmol/day, usually < 1 mmol/day), occurs due to intestinal hyperabsorption of oxalate or extreme dietary oxalate intake;
  - mild hyperoxaluria (oxalate excretion 0.45-0.85 mmol/day), commonly found in idiopathic calcium oxalate stone formers.
- Hypomagnesuria (< 3.0 mmol/day) may be related to poor dietary intake or to reduced intestinal absorption (chronic diarrhoea).

1 Be aware of excess calcium excretion.
2 tid = three times/day (24h).
3 No magnesium therapy for patients with renal insufficiency.
4 There is no evidence that combination therapy (thiazide + citrate) or (thiazide + allopurinol) is superior to thiazide therapy alone [584, 617].
5 Febuxostat 80 mg/day.
6 low evidence (see text)
**Calcuiura is a continuous variable and treatment may be adjusted to clinical need even when below the threshold indicated.
***Patients on hydrochlorothiazides should be advised to get their skin checked on a regular basis as they have a higher risk for developing non-melanoma skin cancer (NMSC). In patients with history of NMSC the indication for the intake of hydrochlorothiazides should be thoroughly reviewed [614, 615].
4.4.3 **Specific treatment**
General preventive measures are recommended for fluid intake and diet. Hyperoxaluric stone formers should consume foods with low oxalate content, whereas hyperuricosuric stone formers benefit from daily dietary reduction of purine. Figure 4.3 summarises the pharmacological treatment of calcium oxalate stones [557, 562, 583-586, 589, 590, 592, 595, 598-600, 602-609, 616, 618-620]. There is only low-level evidence for the efficacy of preventing stone recurrence based on pre-treatment stone composition examination and biochemistry measures, or on-treatment biochemistry measures [557].

4.4.4 **Summary of evidence and guidelines for pharmacological treatments for patients with specific abnormalities in urine composition (based on 24-hour urine samples)**

* Patients on hydrochlorothiazides should be advised to get their skin checked on a regular basis as they have a higher risk of developing a non-melanoma skin cancer (NMSC). In patients with history of NMSC the indication for the intake of hydrochlorothiazides should be thoroughly reviewed [614, 615].

4.5 **Calcium phosphate stones** [557, 583, 592, 602, 603, 607, 621]
Some calcium phosphate stone formers are at high risk of recurrence. Further information on identifying high-risk patients is provided in section 3.1.3.

Calcium phosphate mainly appears in two completely different minerals: carbonate apatite and brushite. Carbonate apatite crystallisation occurs at a pH > 6.8 and may be associated with infection. Brushite crystallises at an optimum pH of 6.5-6.8 at high urinary concentrations of calcium (> 8 mmol/day) and phosphate (> 35 mmol/day). Its occurrence is not related to UTI. Possible causes of calcium phosphate stones include HPT, RTA and UTI; each of which requires different therapy.

4.5.1 **Diagnosis**
Diagnosis requires blood analysis for: creatinine, sodium, potassium, chloride, ionised calcium (or total calcium + albumin), phosphate, and PTH (in the case of increased calcium levels). Urinalysis includes measurement of: volume, urine pH profile, specific weight, calcium, phosphate and citrate.

4.5.2 **Interpretation of results and aetiology**
General preventative measures are recommended for fluid intake and diet. The diagnostic and therapeutic algorithm for calcium phosphate stones is shown in Figure 4.4.
HPT = hyperparathyroidism; RTA = renal tubular acidosis; UTI = urinary tract infection.
* Patients on hydrochlorothiazides should be advised to get their skin checked on a regular basis as they have a higher risk for developing non-melanoma skin cancer (NMSC). In patients with history of NMSC the indication for the intake of hydrochlorothiazides should be thoroughly reviewed [614, 615].

4.5.3 **Pharmacological therapy** [557, 583, 592, 602, 603, 607, 621]
Hyperparathyroidism and RTA are common causes of calcium phosphate stone formation. Most patients with primary HPT require surgery. Renal tubular acidosis can be corrected pharmacologically including with bicarbonate or alkaline citrate therapy. If primary HPT and RTA have been excluded, pharmacotherapy for calcium phosphate calculi depends on effective reduction of urinary calcium levels using thiazides. For infection-associated calcium phosphate stones, it is important to consider the guidance given for infection stones.

4.5.4 **Summary of evidence and guidelines for the management of calcium phosphate stones**

4.6 **Disorders and diseases related to calcium stones**

4.6.1 **Hyperparathyroidism** [622-624]
Primary HPT is responsible for an estimated 5% of all calcium stone formation. Renal stones occur in approximately 20% of patients with primary HPT. Elevated levels of PTH significantly increase calcium turnover, leading to hypercalcaemia and hypercalciuria and bone disease. Serum calcium may be mildly elevated and serum PTH may be within the upper normal limits and, therefore, repeated measurements may be needed;
preferably with the patient fasting. Stones of HPT patients may contain both calcium oxalate and calcium phosphate. Nephrocalcinosis and CKD may also occur.

If HPT is suspected, neck exploration should be performed to confirm the diagnosis. Primary HPT can only be cured by surgery.

4.6.2 Granulomatous diseases [625]
Granulomatous diseases, such as sarcoidosis, may be complicated by hypercalcaemia and hypercalciciuria secondary to increased calcitriol production. The latter is independent of PTH control, leading to increased calcium absorption in the gastrointestinal tract and suppression of PTH. Treatment focuses on the activity of the granulomatous diseases and may require steroids, hydroxychloroquine or ketoconazole. Treatment should be reserved for a specialist.

4.6.3 Primary hyperoxaluria [601]
Patients with primary hyperoxaluria (PH) should be referred to specialised centres, as successful management requires an experienced interdisciplinary team. The main therapeutic aim is to reduce endogenous oxalate production, which is increased in patients with PH. In approximately one-third of patients with PH type I, pyridoxine therapy normalises or significantly reduces urinary oxalate excretion. The goal of adequate urine dilution is achieved by adjusting fluid intake to 3.5–4.0 L/day in adults (children 1.5 L/m² body surface area) and following a circadian drinking regimen.

Therapeutic options for preventing calcium oxalate crystallisation include hyperdiuresis, alkaline citrates, magnesium and Lumasiran, an RNAi agent, a new treatment for reducing the synthesis of oxalate of PH type 1 [626]. However, in end-stage renal failure, PH requires simultaneous liver-kidney transplantation.

Treatment regimens are:
- pyridoxine in PH type I: 5-20 mg/kg/day according to urinary oxalate excretion and patient tolerance;
- alkaline citrate: 9-12 g/day in adults, 0.1-0.15 mq/kg/day in children;
- magnesium: 200-400 mg/day (no magnesium in the case of renal insufficiency);
- Lumarisan: Subcutaneous injection with dose and timing adjusted according to body weight and duration of treatment.

4.6.4 Enteric hyperoxaluria [571, 576, 627-629]
Enteric hyperoxaluria is a particularly problematic condition in patients with intestinal malabsorption of fat. This abnormality is associated with a high risk of stone formation and is seen after intestinal resection and malabsorptive bariatric surgery, as well as in Crohn’s disease and pancreas insufficiency. In addition to hyperoxaluria, these patients usually present with hypocitraturia due to loss of alkali. Urine pH is usually low, as are urinary calcium and urine volume. All these abnormalities contribute to high levels of supersaturation with calcium oxalate, crystalluria, stone formation, and less frequently to nephrocalcinosis and CKD. Specific preventive measures are:
- restricted intake of oxalate-rich foods [571];
- restricted fat intake [571];
- calcium supplementation at meal times to enable calcium oxalate complex formation in the intestine [576, 627-629];
- sufficient fluid intake to balance intestinal loss of water caused by diarrhoea;
- alkaline citrates to raise urinary pH and citrate.

4.6.5 Renal tubular acidosis [557, 592, 630, 631]
Renal tubular acidosis is caused by severe impairment of proton or bicarbonate handling along the nephron. Kidney stone formation most probably occurs in patients with distal RTA type I. Figure 4.5 outlines the diagnosis of RTA. Table 4.7 shows acquired and inherited causes of RTA.

Figure 4.5: Diagnosis of renal tubular acidosis

**BGA = blood gas analysis; RTA = renal tubular acidosis.**

*An alternative ammonium chloride loading test using NH4Cl load with 0.05 g/kg body weight over three days might provide similar results and may be better tolerated by the patient. A second alternative in these cases could be the furosemide/fludrocortisone acidification test [632].

Renal tubular acidosis can be acquired or inherited. Reasons for acquired RTA can be chronic obstructive uropathy, recurrent pyelonephritis, acute tubular necrosis, renal transplantation, analgesic nephropathy, sarcoidosis, Sjögren syndrome and other autoimmune diseases, medullary sponge kidney, liver cirrhosis, sickle cell anaemia, idiopathic hypercalciuria, and primary parathyroidism; it may also be drug-induced (e.g., amphotericin B, foscarnet, lithium, zonisamide).

</tr>
</tbody>
</table>

More rarely biallelic causative variants in FOXI1 and WDR72 genes have also been identified. The main therapeutic aim of RTA treatment is restoring a normal acid-base equilibrium. Despite the alkaline pH of urine in RTA, alkalisation using alkaline citrates or sodium bicarbonate is important for normalising the metabolic changes (intracellular acidosis) responsible for stone formation (Table 4.8) and bone demineralisation. The alkali load reduces tubular re-absorption of citrate, which in turn normalises citrate excretion. Therapeutic success can be monitored by venous blood gas analysis (base excess: ± 2.0 mmol/L) in complete RTA. If excessive calcium excretion (> 8 mmol/day) persists after re-establishing acid-base equilibrium, thiazides may lower urinary calcium excretion.

4.6.6 Nephrocalcinosis [633]

Nephrocalcinosis (NC) refers to increased calcium crystal deposition within the renal cortex or medulla and occurs alone or in combination with renal stones. There are various metabolic causes. The main causes are: HPT, primary and enteric hyperoxalurias, genetic and acquired RTA, medullary sponge kidney, vitamin D metabolic disorders, sarcoidosis, idiopathic hypercalciuria and hypocitraturia, and genetic disorders, including Dent's disease, Bartter’s syndrome. The many causes of NC mean there is no single standard therapy. Therapeutic attention must focus on the underlying metabolic or genetic disease, on the frequent association with CKD while minimising the biochemical risk factors.
4.6.6.1 **Diagnosis**

Diagnosis requires the following blood analysis: PTH (in the case of increased calcium levels), vitamin D and metabolites, vitamin A, sodium, potassium, magnesium, chloride, and bicarbonate. Urinalysis should investigate urine pH profile at different times of the day [634], daily urine volume, specific weight of urine, and levels of calcium, oxalate, phosphate, uric acid, magnesium, and citrate.

4.7 **Uric acid and ammonium urate stones**

All uric acid and ammonium urate stone formers are considered to be at high risk of recurrence [25]. Uric acid nephrolithiasis is responsible for approximately 10% of renal stones [635] and associated with hyperuricosuria or low urinary pH. Hyperuricosuria may be a result of dietary excess, endogenous overproduction (enzyme defects), myeloproliferative disorders, chemotherapy drugs, gout or catabolism [636]. Low urinary pH may be caused by decreased urinary ammonium excretion (insulin resistance or gout), increased endogenous acid production (insulin resistance, metabolic syndrome, or exercise-induced lactic acidosis), increased acid intake (high animal protein intake), or increased base loss (diarrhoea) [636].

Ammonium urate stones are extremely rare, comprising < 1% of all types of urinary stones. They are associated with UTI, malabsorption (inflammatory bowel disease and ileostomy diversion or laxative abuse), phosphate deficiency, hypokalemia and malnutrition. Suggestions on uric acid and ammonium urate nephrolithiasis are based on level 3 and 4 evidence. Chronic kidney disease is frequently observed.

4.7.1 **Diagnosis**

Figure 4.6 shows the diagnostic algorithm for uric acid stones and figure 4.7 shows the therapeutic algorithm for uric acid and ammonium urate stones. Blood analysis requires measurement of creatinine, potassium, and uric acid levels. Urinalysis requires measurement of urine volume, urine pH profile, specific weight of urine, and uric acid level. Urine culture is needed in the case of ammonium urate stones.

4.7.2 **Interpretation of results**

Uric acid and ammonium urate stones form under completely different biochemical conditions. Acidic arrest (circadian urine pH constantly < 5.8) promotes uric acid crystallisation.

Hyperuricosuria is defined as uric acid excretion > 4 mmol/day in adults or > 0.12 mmol/kg/day in children. Hyperuricaemia may be present, but there is only weak evidence for its association with stone formation [637].

Hyperuricosuric calcium oxalate stone formation can be distinguished from uric acid stone formation by urinary pH, which is usually > 5.5 in calcium oxalate stone formation and < 5.5 in uric acid stone formation and occasional absence of hyperuricosuria in patients with pure uric acid stones [638, 639]. Ammonium urate crystals form in urine at pH > 6.5, high uric acid concentration when ammonium is present [640, 641].

4.7.3 **Specific treatment**

General preventive measures are recommended for fluid intake and diet. Hyperuricosuric stone formers benefit from purine reduction in their daily diet. Figure 4.6 describes pharmacological treatment [25, 547, 635, 638-647]. For uric acid stones, allopurinol may change the stone composition distribution in patients with gout to a pattern similar to that in stone formers without gout [648].

1 d: day.
2 tid: three times a day.
3 A higher pH may lead to calcium phosphate stone formation.
4 In patients with high uric acid excretion, allopurinol may be helpful.
4.8 Struvite and infection stones
All infection-stone formers are deemed at high risk of recurrence. Struvite stones represent 2-15% of the stones sent for analysis. Stones that contain struvite may originate *de novo* or grow on pre-existing stones, which are infected with urea-splitting bacteria [649]. There are several factors predisposing patients to struvite stone formation (Table 4.9) [650].

4.8.1 Diagnosis
Blood analysis requires measurement of creatinine, and urinalysis requires repeat urine pH measurements and urine culture.

4.8.2 Interpretation
Infection stones contain the following minerals: struvite and/or carbonate apatite and/or ammonium urate. Urine culture typically provides evidence for urease-producing bacteria, which increase ammonia ions and develop alkaline urine (Table 4.10). Carbonate apatite starts to crystallise at a urine pH level of 6.8. Struvite only precipitates at pH > 7.2 [651, 652]. *Proteus mirabilis* accounts for more than half of all urease-positive UTIs [653, 654].

4.8.3 Specific treatment
General preventive measures are recommended for fluid intake and diet. Specific measures include complete surgical stone removal [650], short- or long-term antibiotic treatment [655], urinary acidification using methionine [597] or ammonium chloride [656], and advice to restrict intake of urease [657, 658]. For severe infections, acetohydroxamic acid may be an option [657, 658] (Figure 4.8); however, it is not licensed/available in all European countries.

Eradication of infection after complete stone removal is desirable. The evidence regarding the duration of post-operative antibiotic administration is inconclusive.

4.9 **Cystine stones**
Cystine stones account for 1-2% of all urinary stones in adults and 6-8% of the stones reported in paediatric studies [36, 659]. All cystine stone formers are deemed at high risk of recurrence and CKD [660, 661].

4.9.1 **Diagnosis**
Blood analysis includes measurement of creatinine, and urinalysis includes measurement of urine volume, pH profile, specific weight, and cystine.

**Interpretation**
- Cystine is poorly soluble in urine and crystallises spontaneously within the physiological urinary pH range.
- Cystine solubility depends strongly on urine pH: at pH 6.0, the limit of solubility is 1.33 mmol/L.
- Routine analysis of cystine is not suitable for therapeutic monitoring.
- Regardless of phenotype or genotype of the cystinuric patient, the clinical manifestations are the same [662].
- There is no role for genotyping patients in the routine management of cystinuria [663, 664].
- Reductive therapy targets the disulphide binding in the cystine molecule. For therapy monitoring, it is essential to differentiate between cystine, cysteine and drug-cysteine complexes. Only high-performance liquid chromatography (HPLC)-based analysis differentiates between the different complexes formed by therapy.
- Diagnosis is established by stone analysis. The typical hexagonal crystals are detectable in only 20-25% of urine specimens from patients with cystinuria [665].
- The cyanide nitroprusside colorimetric qualitative test detects the presence of cystine at a threshold concentration of 75 mg/L, with a sensitivity of 72% and specificity of 95%. False-positive results in patients with Fanconi’s syndrome, homocystinuria, or those taking various drugs, including infection stones [666].
- Quantitative 24-hour urinary cystine excretion confirms the diagnosis in the absence of stone analysis.
- Levels above 0.125 mmol/day (30 mg/day) are considered abnormal [667, 668].

4.9.2 **Specific treatment**
General preventative measures for fluid intake and diet are recommended. A diet low in methionine may theoretically reduce urinary excretion of cystine; however, patients are unlikely to comply sufficiently with such a diet. A restricted intake of sodium is more easily achieved and is more effective in reducing urinary cystine. Patients are usually advised to avoid sodium consumption > 2 g/day (5 g NaCl) [669]. A high level of diuresis is of fundamental importance, aiming for a 24-hour urine volume of > 3 L [662, 665, 669, 670]. A considerable fluid intake evenly distributed throughout the day is necessary.

4.9.2.1 **Pharmacological treatment of cystine stones**
The main therapeutic option for avoiding cystine crystallisation is to maintain urine pH > 7.5, to improve cysteine solubility and ensure appropriate hydration with a minimum of 3.5 L/day in adults, or 1.5 L/m² body surface area in children [662, 665, 669, 670].

Free cystine concentration can be decreased by reductive substances, which act by splitting the disulphide binding of cystine.

Tiopronin is currently the best choice for cystine reduction. However, side effects often lead to treatment termination, for example when nephrotic syndrome develops or when there is poor compliance, especially with long-term use. After carefully considering the risk of early tachyphylaxis, put into place a dose-escape phenomenon for long-term use, and recurrence risk, tiopronin is recommended at cystine levels > 3.0 mmol/day (720 mg/day) or in the case of recurring stone formation, notwithstanding other preventive measures [662, 665, 669, 670].

4.10 2,8-Dihydroxyadenine stones and xanthine stones

All 2,8-Dihydroxyadenine and xanthine stone formers are considered to be at high risk of recurrence. Both stone types are rare. Diagnosis and specific prevention are similar to those for uric acid stones [25].

4.10.1 2,8-Dihydroxyadenine stones

A genetically determined defect of adenine phosphoribosyl transferase causes high urinary excretion of poorly soluble 2,8-Dihydroxyadenine [671]. High-dose allopurinol or febuxostat are important options but should be given with regular monitoring [672].

4.10.2 Xanthine stones

Patients who form xanthine stones usually show decreased levels of serum uric acid. There is no available pharmacological intervention.

4.10.3 Fluid intake and diet

Recommendations for general preventive measures apply. Pharmacological intervention is difficult; therefore, high fluid intake ensures optimal specific weight levels of urine < 1.010 (urine specific gravity). A purine-reduced diet decreases the risk of spontaneous crystallisation in urine.

4.11 Drug-induced stones

Drug stones are induced by pharmacological treatment [583, 673] (Table 4.10). Two types exist:
- stones formed by crystallised compounds of the drug;
- stones formed due to unfavourable changes in urine composition under drug therapy.

4.12 Matrix Stones

Pure matrix stones are extremely rare with less than 70 cases described in the literature. They are more prevalent in females. The main risk factors are recurrent UTIs, especially due to *P. mirabilis* or *E. coli*, previous surgery for stone disease, chronic renal failure, and haemodialysis. Complete endourological removal, frequently via the percutaneous approach, is critical. Given the rarity of matrix calculi a specific prophylactic regimen to minimise recurrence cannot be recommended. Eliminating infections and prophylactic use of antibiotics are most commonly proposed [674].

4.13 Unknown stone composition [18]

An accurate medical history is the first step towards identifying risk factors as summarised below (see section 4.13.1).

Diagnostic imaging begins with US examination of both kidneys to establish whether the patient is stone free. Stone detection by US should be followed by KUB and unenhanced multislice CT in adults to differentiate between calcium-containing and non-calcium stones.

Blood analysis demonstrates severe metabolic and organic disorders, such as renal insufficiency, HPT or other hypercalcaemic states and hyperuricaemia. In children, hyperoxalaemia should additionally be screened for.

Urinalysis is performed routinely with a dipstick test as described above. Urine culture is required if there are signs of infection. Constant urine pH < 5.8 in the daily profile may indicate acidic arrest, which
could promote uric acid crystallisation. Persistent urine pH > 5.8 in the daily profile may indicate RTA, if UTI is excluded [629, 631].

Microscopy of urinary sediment can help to discover rare stone types because crystals of 2,8-Dihydroxyadenine, cystine and xanthine are pathognomonic for the corresponding disease. In cases in which the presence of cystine is doubtful, a cyanide nitroprusside colorimetric qualitative test can be used to detect the presence of cystine in urine, with a sensitivity of 72% and specificity of 95%. False-positive results are possible in patients with Fanconi’s syndrome or homocystinuria, or in those taking various drugs, including ampicillin or sulfa-containing medication [666, 675].

Following this programme, the most probable stone type can be assumed, and specific patient evaluation can follow. However, if any expelled stone material is available, it should be analysed by diagnostic confirmation or correction.

5. FOLLOW-UP OF URINARY STONES

Patients suffering from urolithiasis have a predisposition to develop symptoms, complications, and recurrence of stones. Despite the rich literature published on urolithiasis very little has been written about how urolithiasis patients should be monitored after their treatment.

There is no general agreement on whether and when stone patients should be released from follow-up, nor when and how follow-up should occur for patients who need it. The main reason for this lack of agreement is the great clinical heterogeneity of stone disease among patients.

The Panel performed a systematic review questioning the benefits and harms of scheduled follow-up for patients who underwent definitive treatment (ESWL, URS, PNL, medical chemoprophylaxis) for upper urinary tract stone disease [676].

The Panel aimed to answer three main questions regarding urolithiasis follow-up: a) In patients with no residual fragments, does imaging follow-up after treatment for upper urinary tract stones offer more clinical benefits than harms compared with no scheduled follow-up?; b) In patients with residual fragments, does imaging follow-up after treatment for upper urinary tract stones offer more clinical benefits than harms compared with...
no scheduled follow-up?; and c) Does biochemical urine analysis follow-up after treatment for upper urinary tract stones offer more clinical benefits than harms compared with no scheduled follow-up? There was a lack of comparative studies regarding follow-up vs. no follow-up, so the primary endpoints were not reached. The Panel used the data from the eligible observational and randomised studies included in the systematic review to identify the time of patient discharge after follow-up according to stone disease status (stone-free patients, patients with residual stones, patients with metabolic abnormalities), and to come to a consensus on frequency of follow-up and use of investigations.

From a pooled analysis of 5,467 stone-free patients, the Panel estimated that for a safety margin of 80%, patients should be followed-up using imaging, for at least two years (radiopaque stones), or at least three years (radiolucent stones) before discharge, while for a safety margin of 90% patients should be discharged after five years of no recurrence. Regarding residual disease, patients with fragments ≤ 4 mm could be offered surveillance for up to four years, since intervention rates range between 17-29%, disease progression between 9-34%, and spontaneous passage between 21-34% at 49 months. Patients with larger residual fragments should be offered further definitive intervention, since intervention rates are high (24-100%). Insufficient data exist for high-risk patients, but current literature dictates that patients who are adherent to targeted medical treatment seem to experience less stone growth or re-growth of residual fragments and may be discharged after 36-48 months of non-progressive disease on imaging (Figure 5.1).

A Panel consensus was reached after extensive discussion of data regarding frequency of follow-up. In stone-free general population, the vast majority of patients remained stone-free during the first year, in contrast with patients with metabolic abnormalities not under targeted medical treatment < 40% were stone-free after three years of follow-up. Therefore, a more extensive follow-up is proposed for patients with metabolic abnormalities. Patients with small residual fragments ≤ 4 mm, showed a spontaneous expulsion at 17.9-46.5% and growth rate at 10.1-40.7% during the first year, while patients with larger fragments (> 4 mm) had only 9% of spontaneous expulsion at three years. Therefore, patients with small < 4 mm, asymptomatic fragments should be followed-up or scheduled for an intervention according to patient preference, while those with larger stones should primarily be offered re-intervention. Proposed imaging consists of plain X-ray KUB and/or US, based on stone characteristics and clinicians’ preferences. Computed tomography scan should be reserved for symptomatic disease or pre-operative imaging, in order to avoid extensive radiation exposure (Figure 5.2) [676].
Figure 5.1: Follow-up duration of urinary stone patients after treatment

- **Not enough data about subgroup analysis of radiolucent and radiopaque stones.**
- **According to patient preference or symptomatic disease.**
- **Patients with diagnosed metabolic abnormalities.**
- **Lifelong follow-up is advised but data are available up to 10 years.**
Figure 5.2: Consensus on follow-up frequency and imaging modality to use after treatment

Stone free = No stone fragments on post-operative imaging (i.e. no stone fragments on CT/KUB/US).
High-risk = Known biochemical abnormality (i.e.; hypercalciuria, hypocitraturia, hyperuricosuria, RTA or high-risk stone type such as struvite). Imaging = plain film KUB &/or kidney ultrasonography (KUS) based on clinicians’ preference and stone characteristics. Consider CT if patient is symptomatic or if intervention is planned.

* Clinicians may choose the imaging-only pathway in patients with fragments < 2 mm.
* Treatment monitoring for side effects, intolerance, and compliance.
* Panel recommends re-intervention however close follow up may be considered for some patients at high risk for re-intervention based on clinicians’ preference.
6. BLADDER STONES

6.1 Prevalence, aetiology, and risk factors of bladder stones

Bladder stones constitute only approximately 5% of all urinary tract stones [677] yet are responsible for 8% of urolithiasis-related mortalities in developed nations [678]. The incidence is higher in developing countries [679]. The prevalence of bladder stones is higher in males, with a reported male to female ratio between 10:1 and 4:1 [680, 681]. The age distribution is bimodal: incidence peaks at three years in children in developing countries [680, 682], and 60 years in adulthood [681].

The aetiology of bladder stones is typically multi-factorial [681]. Bladder stones can be classified as primary, secondary, or migratory [683].

Primary or endemic bladder stones occur in the absence of other urinary tract pathology, typically seen in children in areas with poor hydration, recurrent diarrhoea, and a diet deficient in animal protein [684].

Secondary bladder stones occur in the presence of other urinary tract abnormalities, which include bladder outlet obstruction (BOO), neurogenic bladder dysfunction, chronic bacteriuria, foreign bodies (including catheters), bladder diverticula and bladder augmentation or urinary diversion. In adults, BOO is the most common predisposing factor for bladder stone formation and accounts for 45-79% of vesical calculi [681, 685-688].

Migratory bladder stones are those which have passed from the upper urinary tract where they formed and may then serve as a nidus for bladder stone growth. Patients with bladder calculi are more likely to have a history of upper tract stones and risk factors for their formation [689].

A wide range of metabolic urinary abnormalities can pre-dispose to calculi anywhere in the urinary tract, which is covered in more detailed in section 4. Metabolic Evaluation and Recurrence Prevention. There is a paucity of studies on the specific metabolic abnormalities which predispose to bladder stones.

Bladder stones will form in 3-4.7% of men undergoing surgery for benign prostatic obstruction (BPO) [690, 691], 15-36% of spinal cord injury patients [692-694], and 2.2% of patients with long-term catheters [695]. Of 57 men with chronic urinary retention secondary to BPO, the urine of the 30 men with bladder stones had a higher uric acid concentration (2.2 vs. 0.6 mmol/L, p < 0.01), lower magnesium (106 vs. 167 mmol/L, p = 0.01) and lower pH (5.9 vs. 6.4, p = 0.02) than the 27 men without bladder stones [689]. It is therefore likely that patients with these conditions who form bladder stones also have an abnormal urine composition which pre-dispose them to bladder stone formation.

The metabolic abnormalities which pre-dispose patients to form secondary bladder stones are poorly understood. Stone analysis of 86 men with a BPO-related bladder stone demonstrated 42% had calcium-based stones (oxalate, phosphate), 33% had magnesium ammonium phosphate, 10% had mixed stones and 14% had urate stones [681]. Similar findings were reported in more recent studies [696-698] and it is therefore likely that multiple metabolic factors pre-dispose patients to secondary bladder stone formation.

The exact metabolic basis for primary bladder stones is poorly understood and likely multi-factorial. Low urine volume (poor hydration) is the most consistently demonstrable abnormality [699-701]. Twenty-four-hour urine analysis in children with endemic bladder stones is reported in two studies. Of 57 children in Pakistan, 89.5% had hypocitraturia, 49% had a low urine volume, 44% had hyperoxaluria and 42% had hypocalciuria [699]. Of 61 children in India, stone formers had higher urine calcium and uromucoid concentrations than controls [700]. One study from Thailand compared 24-hour urine analyses from children from a rural area with a high prevalence of bladder stones with those from an urban area: rural children had lower urine volumes and, despite equal calcium, oxalate, and uric acid concentrations, crystalluria with uric acid and calcium oxalate crystals was more prevalent in rural children [701].

BOO = bladder outlet obstruction; BPO = benign prostatic obstruction.

6.2 Presentation

The symptoms most commonly associated with bladder stones are urinary frequency, haematuria (which is typically terminal) and dysuria or suprapubic pain, which are worst towards the end of micturition. Sudden movement and exercise may exacerbate these symptoms. Detrusor over-activity is found in over two thirds of adult male patients with vesical calculi and is significantly more common in patients with larger stones (> 4 cm). However, recurrent UTIs may be the only symptom [686, 687].

In children, symptoms may also include pulling of the penis, difficulties in micturition, urinary retention, enuresis and rectal prolapse (resulting from straining due to bladder spasms). Bladder stones may also be an incidental finding in 10% of cases [684, 702].

6.3 Diagnostic evaluation

6.3.1 Diagnostic investigations for bladder stones

Plain X-ray of KUB has a reported sensitivity of 21%-78% for cystoscopically detected bladder stones in adults [686, 703]. Larger (> 2.0 cm) stones are more likely to be radiopaque [703]. However, plain X-ray provides information on radio-opacity which may guide treatment and follow-up (see section 3.2.3 X-ray characteristics, for further information).

Ultrasound has a reported sensitivity and specificity of 20-83% and 98-100%, respectively for the detection of bladder stones in adults [704, 705]. Computed tomography and cystoscopy have a higher sensitivity for detecting bladder stones than US or X-Ray in adults [704, 705]. No study compares cystoscopy and CT for the diagnosis of bladder stones. Cystoscopy has the advantage of detecting other potential causes for a patient’s symptoms (e.g., bladder cancer), whilst CT can also assess upper tract urolithiasis (see section 3.2.3 X-ray characteristics) [706].

There is a paucity of evidence for the investigation of bladder stones, particularly in children [84, 707]. See also section 3.3 Diagnostic evaluation, for further information on diagnostic imaging for urolithiasis. The principle of ALARA should be applied, especially in children [708].

6.3.2 Diagnosing the cause of bladder stones

The cause of the bladder stone should be considered prior to bladder stone treatment as eliminating the underlying cause will reduce recurrence rates [709]. The following should be performed where possible prior to (or at the time of) bladder stone treatment:

- physical examination of external genitalia, peripheral nervous system (including digital rectal examination, peri-anal tone, and sensation in men);
- uroflowmetry and post-void residual urine assessment;
- urine dipstick to include pH ± culture;
- metabolic assessment (see section 3.3.2.3) including: serum (creatinine, (ionised) calcium, uric acid, sodium, potassium, blood cell count);
- urine pH;
- stone analysis: in first-time formers using a valid procedure (X-ray diffraction or infrared spectroscopy).

The following investigations should also be considered for selected patients:

- upper tract imaging (in patients with a history of urolithiasis or loin pain);
- cysto-urethroscopy or urethrogram.
6.4 Disease Management

6.4.1 Conservative treatment and Indications for active stone removal

Migratory bladder stones in adults may typically be left untreated, especially asymptomatic small stones. Rates of spontaneous stone passage are unknown, but data on ureteric stones suggest stones < 1 cm are likely to pass in the absence of BOO, bladder dysfunction or long-term catheterisation (see section 3.4.9 Specific stone management of ureteral stones).

Primary and secondary bladder stones are usually symptomatic and are unlikely to pass spontaneously: active treatment of such stones is usually indicated.

6.4.2 Medical management of bladder stones

There is a paucity of evidence on chemolitholysis of bladder stones. However, guidance on the medical management of urinary tract stones in section 3.4.9 Specific stone management of ureteral stones, can be applied to urinary stones in all locations. Uric acid stones can be dissolved by oral urinary alkalinisation when a PH > 6.5 is consistently achieved, typically using an alkaline citrate or sodium bicarbonate. Regular monitoring is required during therapy (see section 3.4.4 Chemolysis). Irrigation chemolysis is also possible using a catheter; however, this is time consuming and may cause chemical cystitis and is therefore not commonly employed [141, 710].

6.4.3 Bladder stone interventions

Minimally invasive techniques for the removal of bladder stones have been widely adopted to reduce the risk of complications and shorten hospital stay and convalescence. Bladder stones can be treated with open, laparoscopic, robotic assisted laparoscopic, endoscopic (transurethral or percutaneous) surgery or ESWL [4].

6.4.3.1 Suprapubic cystolithotomy

Open suprapubic cystolithotomy is very effective but is associated with a need for catheterisation and longer hospital stay in both adults and children compared to all other stone removal modalities [360]. In children, a non-randomised study found that, if the bladder was closed meticulously in two layers, “tubeless” (drain-less and catheter-less) cystolithotomy was associated with a significantly shorter length of hospital stay compared with traditional cystolithotomy, without significant differences regarding late or intra-operative complications provided that children with prior UTI, recurrent stones, or with previous surgery for anorectal malformation (or other relevant surgery) were excluded [711].

6.4.3.2 Transurethral cystolithotripsy

In both adults and children, transurethral cystolithotripsy provides high SFRs and appears to be safe, with a very low-risk of unplanned procedures and major post-operative and late complications [4].

6.4.3.2.1 Transurethral cystolithotripsy in adults

In adults, meta-analysis of four RCTs including 409 patients demonstrated that transurethral cystolithotripsy has a shorter hospital stay and convalescence with less pain, but equivalent SFR and complications compared to percutaneous cystolithotripsy [4]. Transurethral cystolithotripsy with a nephroscope was quicker than percutaneous cystolithotripsy in three RCTs, although transurethral cystolithotripsy with a cystoscope was slower than percutaneous cystolithotripsy [4].

Rates of urethral strictures following transurethral procedures were not robustly reported: studies report rates between 2.9% and 19.6% during a follow up of 12 – 24 months [4, 696, 712].

One small RCT demonstrated a shorter duration of catheterisation, hospital stay and procedure with transurethral cystolithotripsy than open cystolithotomy with similar SFR [4]. Meta-analysis of four RCTs found shorter procedure duration for transurethral cystolithotripsy using a nephroscope vs. cystoscope with similar SFRs, hospital stay, convalescence, pain, and complications [4, 696, 713-715]. Two retrospective studies (n=188) reported that using a resectoscope or nephroscope was associated with a shorter procedure duration (p < 0.05) than a cystoscope for transurethral cystolithotripsy [716, 717]. This suggests that transurethral cystolithotripsy is quicker when using a continuous flow instrument.

6.4.3.2.1.1 Lithotripsy modalities used during transurethral cystolithotripsy in adults

When considering lithotripsy modalities for transurethral cystolithotripsy, the Panel’s systematic review found very low-quality evidence from five non-randomised studies (n=385) which found no difference in SFR between modalities (mechanical, laser, pneumatic, ultrasonic, electrohydraulic lithotripsy [EHL] or washout alone) [4]. Unplanned procedures and major post-operative complications were low-rate events and were not significantly different between lithotripsy modalities, although one non-randomised study (NRS) suggested these might be
higher with EHL or mechanical lithotripsy than pneumatic or ultrasonic lithotripsy [718]. All outcomes had very low-quality of evidence (GRADE) [4]. High powered lasers seem to reduce lithotripsy time. Laser lithotripsy was faster than pneumatic lithotripsy (MD 16.6 minutes; CI: 23.51-9.69, p < 0.0001) in one NRS (n=62); however, a laser was used with a resectoscope and the pneumatic device with a cystoscope [719]. Continuous vs. intermittent irrigating instrument may affect the operation time more significantly than the choice of lithotripsy device [4].

6.4.3.2.1 Transurethral cystolithotripsy in children
In children, three NRS suggest that transurethral cystolithotripsy has a shorter hospital stay and catheterisation time than open cystolithotomy, but similar stone-free and complication rates [4, 720]. One small quasi RCT found a shorter procedure time using laser vs. pneumatic lithotripsy for < 1.5 cm bladder stones with no difference in SFR or other outcomes [4, 721].

6.4.3.3 Percutaneous cystolithotripsy
6.4.3.3.1 Percutaneous cystolithotripsy in adults:
One NRS found a shorter duration of procedure and catheterisation and less blood loss for percutaneous, compared with open surgery in adult male patients with urethral strictures; all patients in both groups were rendered stone-free [688].

Meta-analysis of four RCTs comparing transurethral and percutaneous cystolithotripsy found a shorter hospital stay for transurethral cystolithotripsy over percutaneous surgery. Transurethral cystolithotripsy was quicker when using a nephroscope. There were no significant differences in SFRs, major post-operative complications or re-treatment [4].

6.4.3.3.2 Percutaneous cystolithotripsy in children:
In children, three NRS suggest that percutaneous cystolithotripsy has a shorter hospital stay and catheterisation time, but a longer procedure duration and more peri-operative complications than open cystolithotomy; SFRs were similar [4, 702, 720].

Two small NRS compared percutaneous and transurethral cystolithotripsy and both found similar SFRs, but that transurethral surgery offers a shorter duration of catheterisation and hospital stay [702, 720]. One small NRS found a non-significant increased risk of unplanned procedures (within 30 days of primary procedure) and major post-operative complications for percutaneous operations compared with transurethral procedures; however, age and stone size determined which intervention children underwent and all patients were rendered stone-free [702]. Urethral stricture rates were not robustly compared in either study.

6.4.3.4 Extracorporeal shock wave lithotripsy
Extracorporeal SWL is the least invasive therapeutic procedure [4].

6.4.3.4.1 Shock wave lithotripsy in adults
In adults, one RCT compared SWL with transurethral cystolithotripsy in 100 patients with ≤ 2 cm bladder stones presenting with acute urinary retention. Stone free rate after one SWL session favoured transurethral cystolithotripsy (86% vs. 98%, p=0.03); however, following up to three sessions of SWL, there was no significant difference in SFR (94% vs. 98%, p=0.3) [4, 722].

Two NRS compared transurethral cystolithotripsy vs. SWL and found no significant difference in SFR (97.0% vs. 93.9%, p=0.99, 97.7% vs. 89.7% p=0.07) despite larger stones in transurethral cystolithotripsy patients (4.2 vs. 2.5 cm, p=0.014; and 3.6 vs. 2.6 cm [p value not reported]) [723, 724].

Length of hospital stay appeared to favour SWL in all three studies (0 vs. 1 day, 4.8 vs. 0 days, p=0.02, 0.8 vs. 2.4 days, respectively) [722-724]. No significant differences in major post-operative or intra-operative complications were reported in any study [722-724].

One NRS compared SWL vs. open cystolithotomy in just 43 patients. Stone sizes were not comparable (2.5 vs. 7.4 cm, p < 0.001). Stone-free rates were not significantly different (93.9% vs. 100%, p=0.50). Length of stay favoured SWL. There was no significant difference in intra-operative or major post-operative complications [723].

6.4.3.4.2 Shock wave lithotripsy in children
One large NRS found lower SFR for SWL than both transurethral cystolithotripsy and open cystolithotomy,
despite treating smaller stones with SWL. However, the length of hospital stays favoured SWL over open cystolithotomy, although this appeared to be comparable between SWL and transurethral cystolithotripsy [725].

### 6.4.3.5 Laparoscopic cystolithotomy

Laparoscopic cystolithotomy has been described in adults and is typically performed in combination with simple prostatectomy using either traditional laparoscopy or with robotic assistance [726, 727]. A SR found no studies comparing laparoscopic surgery with other procedures [4].

### 6.4.4 Treatment for bladder stones secondary to bladder outlet obstruction in adult men

Bladder stones in men aged over 40 years may be caused by BPO, the management of which should also be considered. Bladder stones were traditionally an indication for a surgical intervention for BPO: a doctrine which has been questioned by recent studies. One prospective study reports urodynamics (cystometrogram) findings in 46 men aged > 60 years before and after bladder stone treatment [687]. Only 51% of men had BOO while 10% had detrusor under-activity. Eighteen percent of men had a completely normal urodynamic study and 68% had detrusor over-activity. There was no significant difference between pre- and post-bladder stone removal urodynamic findings [687].

One NRS compared 64 men undergoing transurethral cystolithotripsy with either transurethral resection of prostate (TURP) or medical management for BPO (α-blocker with or without 5-alpha reductase inhibitor). After 28 months follow-up, no men on medication had had a recurrence, but 34% underwent TURP: a high post-void residual urine volume predicted the need for subsequent TURP [728]. Another observational study of 23 men undergoing cystolithotripsy and commencing medical management for BPO found 22% developed a BPO related complication, including 17% who had recurrent stones [709].

Large studies support the safety of performing BPO and bladder stone procedures during the same operation with no difference in major complications compared to a BPO procedure alone [729-731]. An observational study on 2,271 patients undergoing TURP found no difference in complications except UTIs, which occurred slightly more frequently in patients with simultaneously treated bladder stones: 0% vs. 0.6%, p=0.044 [729]. An observational study of 321 men undergoing Holmium laser enucleation of the prostate (HoLEP) found a higher rate of early post-operative incontinence (26.8% vs. 12.5%, p=0.03) in men having concomitant transurethral cystolithotripsy, but no difference in long-term continence rates [731]. Another larger multicenter observational study of 963 patients undergoing HoLEP found no significant differences in frequency of complications in patients with (n=54 (5.6%)) or without concomitant transurethral cystolithotripsy [732].

### 6.4.5 Special situations

#### 6.4.5.1 Neurogenic bladder and stone formation

Patients with a neurogenic bladder secondary to spinal cord injury or myelomeningocele are at increased risk of forming bladder stones. Within eight to ten years, 15-36% of patients with spinal cord injury will develop a bladder stone [692-694]. The absolute annual risk of stone formation in spinal cord injury patients with an indwelling catheter is 4% compared with 0.2% for those voiding with clean intermittent self-catheterisation (CISC) [733].

A study of 2,825 spinal cord injury patients over eight years found a 3.3% incidence of bladder stones: 2% with CISC, 6.6% with indwelling urethral catheter, 11% with a suprapubic catheter and 11% in patients voiding using reflex micturition [734]. However, another study of 457 spinal cord injury patients for six months found no difference in bladder stones between urethral and suprapubic catheterisation [733]. Spinal cord injury patients with an indwelling urethral catheter are six times more likely to develop bladder stones than patients with normal micturition [694, 734].

The risk of stone recurrence after complete removal in spinal cord injury patients is 16% per year [733]. A RCT of 78 spinal cord injury patients who perform CISC found a significant reduction in bladder stone formation when twice weekly manual bladder irrigations were performed for six months (49% vs. 0%, p= < 0.0001), as well as less symptomatic UTIs (41% vs. 8%; p=0.001) [735]. However, this study excluded patients who developed autonomic dysreflexia during bladder irrigations. The irrigation volume used was not reported.

#### 6.4.5.2 Bladder Augmentation

The incidence of vesical calculus formation after bladder augmentation is 2-44% in adults [736-745], and 4-53% in children [745-759]. Following cystoplasty, stones form after 24-31 months in adults [737, 739, 744], and after 25-68 months in children [750, 753, 754, 758, 760-762]. The reported cumulative incidence of bladder stone formation after ten years is 28-36% and after twenty years is 41% [745, 763].
Risk factors for bladder stone formation after augmentation include excess mucus production, incomplete bladder emptying, non-compliance with CIC or bladder irrigations, bacteriuria or urinary tract infections (due to urease-producing bacteria), foreign bodies (including staples, mesh, non-absorbable sutures), drainage by vesico-entero-cystostomy (Mitrofanoff or Monti) [436, 737, 740, 742, 743, 750, 754, 757, 763] and voiding by CISC compared with those voiding spontaneously [741]. Gastric segment augmentation confers a lower risk of bladder stones than ileal or colonic segment cystoplasty [746, 750, 754, 757].

In previous stone formers, the rate of recurrence is 15-44% in adults [737-739, 741, 744], and 19-56% in children [436, 745, 746, 750, 752-755, 757, 762]. The risk of recurrence is greatest during the first two years, at about 12% per patient per year, with the risk decreasing with time [762].

Daily, or three-times-weekly bladder irrigations reduce the incidence of bladder stones following bladder augmentation or continent urinary diversion [436, 740]. A randomised study found that daily bladder irrigation with 240 mL of saline reduced stone recurrences (p= < 0.0002, p= 0.0152) and symptomatic UTIs (p < 0.0001, p < 0.0001) compared to 60mL or 120mL [740]. The frequency of bladder irrigations required is unclear.

6.4.5.3 Urinary diversion
The incidence of stone formation after urinary diversion with an ileal or colon conduit is 0-3% [764, 765]. The incidence of stone formation is 0-34% in orthotopic ileal neobladders (Hautmann, hemi-Kock, Studer, T-pouch or n-neobladder) [741, 765-774], and 4-6% in orthotopic sigmoid neobladders (Reddy) [770, 775]. The risk of pouch stone formation is 4-43% in adults with an ileocaecal continent cutaneous urinary diversion (Indiana, modified Indiana, Kock or Mainz I) [428, 741, 764, 765, 773, 776]. The average interval from construction of the urinary diversion to stone detection is 71-99 months [769, 777]. In children, the incidence of neobladder stone formation is 30% after Mainz II diversion (rectosigmoid reservoir) [747], and 27% after Kock ileal reservoir construction [759].

6.4.5.4 Treatment of stones in patients with bladder augmentation or urinary diversion
Stones may be removed by open or endoscopic surgery in patients with bladder augmentation or diversion [752]. However, often access cannot be obtained through a continent vesico-entero-cystostomy without damaging the continence apparatus; hence a percutaneous or open approach is typically preferred [752].

No studies comparing outcomes following procedures for stones in reconstructed or augmented bladders were found. Two observational studies indicate that percutaneous lithotomy can be safely performed with US or CT guidance in patients with reconstructed or augmented bladders [778, 779] and is proposed to offer similar advantages over open surgery to those for percutaneous native bladder surgery. Stone recurrence after successful removal has been reported to be 10-42% [778, 779], but appears to be unrelated to the modality used for stone removal [744, 750, 754, 755, 757, 762].
Bladder stones follow-up
There are no studies examining the merits of differing follow-up modalities or frequencies following conservative, medical, or operative treatment of bladder stones in adults or children. Identification and prevention of the cause of bladder stone formation will be crucial to prevent recurrence (see section 6.3.2 Diagnosing the cause of bladder stones).

In adults, there is a paucity of evidence on dietary modification or medical treatment for the prevention of bladder stone recurrence. Recommendations in the EAU Guideline on Urolithiasis, based on evidence from upper tract stones, constitutes the best available recommendations, especially for migratory bladder stones (see section 4. Metabolic Evaluation and Recurrence Prevention).
Where it is possible to address the cause of secondary bladder stones (e.g., treatment of BPO), it is unclear whether metabolic intervention would offer any significant additional benefit in preventing stone recurrence. However, especially where the secondary cause cannot be addressed (e.g., indwelling catheter, neuropathic bladder, bladder augmentation or urinary diversion); metabolic interventions are likely to reduce bladder stone recurrence rates.

Regular bladder irrigation reduces the chances of bladder stone recurrence in adults and children with bladder augmentation or continent cutaneous urinary diversion and adults with spinal cord injury who perform CISC (see section 6.4.5 Special Situations) [735, 740, 765].

In children with primary (endemic) bladder stones maintenance of hydration, avoidance of diarrhoea and a mixed cereal diet with milk and Vitamins A and B supplements, with the addition of eggs, meat, and boiled cows’ milk after one year of age are recommended to prevent recurrence [699].

Finally, there are contradictory reports on a possible association between bladder calculi and future development of bladder cancer [780-782]. The need for follow-up with regular cystoscopy therefore remains controversial.

### Summary of evidence

<table>
<thead>
<tr>
<th>Summary of evidence</th>
<th>LE</th>
</tr>
</thead>
<tbody>
<tr>
<td>The incidence of bladder stones peaks at three years in children (endemic/primary stones in developing countries) and 60 years in adults.</td>
<td>2c</td>
</tr>
<tr>
<td>The aetiology of bladder stones is typically multi-factorial. Bladder stones can be classified as primary (endemic), secondary (associated with lower urinary tract abnormalities e.g., BPO, neuropathic bladder, foreign body, chronic bacteriuria) or migratory (having formed in the upper tract).</td>
<td>4</td>
</tr>
<tr>
<td>In adults, BOO is the most common pre-disposing factor for bladder stone formation.</td>
<td>2C</td>
</tr>
<tr>
<td>Of men undergoing surgery for BPO, 3-4.7% form bladder stones.</td>
<td>2b</td>
</tr>
<tr>
<td>Metabolic abnormalities are also likely to contribute to bladder stone formation in patients with secondary bladder stones.</td>
<td>2b</td>
</tr>
<tr>
<td>Primary (endemic) bladder stones typically occur in children in areas with poor hydration, recurrent diarrhoea, and a diet deficient in animal protein. The following measures are proposed to reduce their incidence: maintenance of hydration, avoidance of diarrhoea, and a mixed cereal diet with milk and Vitamins A and B supplements; with the addition of eggs, meat, and boiled cows’ milk after one year of age.</td>
<td>5</td>
</tr>
<tr>
<td>In adults, US has a sensitivity of 20-83% for diagnosing bladder stones.</td>
<td>2b</td>
</tr>
<tr>
<td>In adults, X-ray-KUB has a sensitivity of 21-78%; sensitivity increases with stone size.</td>
<td>2b</td>
</tr>
<tr>
<td>Computed tomography has a higher sensitivity than US for the detection of bladder stones.</td>
<td>2b</td>
</tr>
<tr>
<td>Cystoscopy has a higher sensitivity than X-ray-KUB or US for the detection of bladder stones.</td>
<td>2b</td>
</tr>
<tr>
<td>Endoscopic bladder stone treatments (trans-urethral or percutaneous) are associated with comparable SFRs, but a shorter length of hospital stay, duration of procedure and duration of catheterisation compared to open cystolithotomy in adults.</td>
<td>1a</td>
</tr>
<tr>
<td>Stone-free rates are lower in patients treated with SWL than those treated with open or endoscopic procedures in both adults and children.</td>
<td>2a</td>
</tr>
<tr>
<td>Transurethral cystolithotripsy is associated with a shorter length of hospital stay, less pain and a shorter convalescence period than percutaneous cystolithotripsy in adults.</td>
<td>1b</td>
</tr>
<tr>
<td>Transurethral cystolithotripsy with a nephroscope is quicker than when using a cystoscope with no difference in SFR in adults.</td>
<td>1a</td>
</tr>
<tr>
<td>Transurethral cystolithotripsy with a resectoscope is quicker than when using a cystoscope with no difference in SFR in adults.</td>
<td>2a</td>
</tr>
<tr>
<td>Mechanical, pneumatic and laser appear equivalent lithotripsy modalities for use in endoscopic bladder stone treatments in adults and children.</td>
<td>2a</td>
</tr>
<tr>
<td>Open cystolithotomy without a retropubic drain or urethral catheter (“tubeless”) is associated with a shorter length of hospital stay than traditional cystolithotomy and can be performed safely in children with primary stones and no prior bladder surgery or infections.</td>
<td>2b</td>
</tr>
<tr>
<td>Bladder stone removal with concomitant treatment for BOO is associated with no significant difference in major post-operative complications when compared to BOO treatment alone in adults. However, concomitant bladder stone treatment does increase the rates of short-term post-operative incontinence and UTI.</td>
<td>2b</td>
</tr>
</tbody>
</table>
The incidence of bladder stone formation in spinal cord injury patients is 15-36% after eight to ten years. The absolute annual risk of stone formation in spinal cord injury patients is significantly higher with an indwelling catheter compared to those voiding with CISC or spontaneously.

The incidence of bladder stone formation after bladder augmentation or vesico-entero-cystostomy is between 2-53% in adults and children.

Urinary diversion including orthotopic ileal neobladders, ileocaecal continent cutaneous urinary diversion and rectosigmoid reservoirs is associated with urinary reservoir stone formation in 0-43%.

The risk of bladder stone formation in spinal cord injury, bladder augmentation or continent urinary diversion patients is reduced by performing regular bladder irrigation.

<table>
<thead>
<tr>
<th>Recommendations</th>
<th>Strength rating</th>
</tr>
</thead>
<tbody>
<tr>
<td>Use ultrasound (US) as first-line imaging with symptoms suggestive of a bladder stone.</td>
<td>Strong</td>
</tr>
<tr>
<td>Use cystoscopy or computed tomography (CT), or kidney-ureter-bladder X-Ray (KUB) to investigate adults with persistent symptoms suggestive of a bladder stone if US is negative.</td>
<td>Strong</td>
</tr>
<tr>
<td>Use X-Ray KUB for adults with confirmed bladder stones to guide treatment options and follow-up.</td>
<td>Weak</td>
</tr>
</tbody>
</table>
| All patients with bladder stones should be examined and investigated for the cause of bladder stone formation, including:  
  - uroflowmetry and post-void residual;  
  - urine dipstick, pH, ± culture;  
  - metabolic assessment and stone analysis (see sections 3.3.2.3 and 4.1 for further details).  
In selected patients, consider:  
  - upper tract imaging (in patients with a history of urolithiasis or loin pain);  
  - cysto-urethroscopy or urethrogram. | Weak            |
| Offer oral chemolitholysis for radiolucent or known uric acid bladder stones in adults. | Weak            |
| Offer adults with bladder stones transurethral cystolithotripsy where possible. | Strong          |
| Perform transurethral cystolithotripsy with a continuous flow instrument in adults (e.g., nephroscope or resectoscope) where possible. | Weak            |
| Offer adults percutaneous cystolithotripsy where transurethral cystolithotripsy is not possible or advisable. | Strong          |
| Suggest open cystolithotomy as an option for very large bladder stones in adults and children. | Weak            |
| Offer children with bladder stones transurethral cystolithotripsy where possible. | Weak            |
| Offer children percutaneous cystolithotripsy where transurethral cystolithotripsy is not possible or is associated with a high risk of urethral stricture (e.g., young children, previous urethral reconstruction, and spinal cord injury). | Weak            |
| Open, laparoscopic, and extracorporeal shock wave lithotripsy are alternative treatments where endoscopic treatment is not advisable in adults and children. | Weak            |
| Prefer “tubeless” procedure (without placing a catheter or drain) for children with primary bladder stones and no prior infection, surgery, or bladder dysfunction where open cystolithotomy is indicated. | Weak            |
| Perform procedures for the stone and underlying bladder outlet obstruction (BOO) simultaneously in adults with bladder stones secondary to BOO, where possible. | Strong          |
| Individualise imaging follow up for each patient as there is a paucity of evidence.  
Factors affecting follow up will include:  
  - whether the underlying functional predisposition to stone formation can be treated (e.g., transurethral resection of the prostate [TURP]);  
  - metabolic risk. | Weak            |
| Recommend regular irrigation therapy with saline solution to adults and children with bladder augmentation, continent cutaneous urinary reservoir or neuropathic bladder dysfunction, and no history of autonomic dysreflexia, to reduce the risk of stone recurrence. | Weak            |

8. CONFLICT OF INTEREST

All members of the Urolithiasis Guidelines working panel have provided disclosure statements on all relationships that they have that might be perceived to be a potential source of a conflict of interest. This information is available on the European Association of Urology website: http://uroweb.org/guideline/urolithiasis/. This guidelines document was developed with the financial support of the European Association of Urology. No external sources of funding and support have been involved. The EAU is a non-profit organisation, and funding is limited to administrative assistance and travel and meeting expenses. No honoraria or other reimbursements have been provided.

9. CITATION INFORMATION

The format in which to cite the EAU Guidelines will vary depending on the style guide of the journal in which the citation appears. Accordingly, the number of authors or whether, for instance, to include the publisher, location, or an ISBN number may vary.

The compilation of the complete Guidelines should be referenced as:

If a publisher and/or location is required, include:

References to individual guidelines should be structured in the following way:
Contributors’ names. Title of resource. Publication type. ISBN. Publisher and publisher location, year.
EAU Guidelines on Paediatric Urology

6. CITATION INFORMATION
1. INTRODUCTION

1.1 Aim
The European Association of Urology (EAU) Paediatric Urology Guidelines Panel has prepared these Guidelines with the aim of increasing the quality of care for children with urological conditions. This Guideline document is limited to a number of common clinical pathologies in paediatric urological practice, as covering the entire field of paediatric urology in a single guideline document is unattainable.

The majority of urological clinical problems in children are specialised and in many ways differ to those in adults. This publication intends to outline a practical and preliminary approach to paediatric urological conditions. Complex and rare conditions that require special care with experienced doctors should be referred to designated centres where paediatric urology practice has been fully established and a multidisciplinary team is available.

Over time, paediatric urology has developed and matured, establishing its diverse body of knowledge and expertise and may now be ready to distinguish itself from its parent specialties. Thus, paediatric urology has recently emerged in many European countries as a distinct subspecialty of both urology and paediatric surgery and presents a unique challenge in the sense that it covers a large area with many different schools of thought and a huge diversity in management.

Knowledge gained by increasing experience, new technological advances and non-invasive diagnostic screening modalities has had a profound influence on treatment modalities in paediatric urology, a trend that is likely to continue in the years to come.

It must be emphasised that clinical guidelines present the best evidence available to the experts but following guideline recommendations will not necessarily result in the best outcome. Guidelines can never replace clinical expertise when making treatment decisions for individual patients, but rather help to focus decisions - also taking personal values and preferences/individual circumstances of children and their caregivers into account. Guidelines are not mandates and do not purport to be a legal standard of care.

1.2 Panel composition
The EAU Paediatric Urology Guidelines Panel consists of an international group of clinicians with particular expertise in this area. All experts involved in the production of this document have submitted potential conflict of interest statements, which can be viewed on the EAU Website: http://uroweb.org/guideline/paediatric-urology/.

1.3 Available publications
A quick reference document (Pocket guidelines) is available, both in print and as an app for iOS and Android devices. These are abridged versions which may require consultation together with the full text version. A number of translated versions, alongside several scientific publications are also available [1-7]. All documents can be viewed through the EAU website: http://uroweb.org/guideline/paediatric-urology/.

1.4 Publication history
The Paediatric Urology Guidelines were first published in 2001 [8]. This 2021 publication includes a number of updated chapters and sections as detailed below.

1.5 Summary of changes
The literature for the complete document has been assessed and updated, wherever relevant. Key changes in the 2022 publication:

- Section 3.11 - Monosymptomatic nocturnal enuresis – bedwetting: Both the literature and the text have been extensively updated;
- Section 3.12 - Management of neurogenic bladder: Both the literature and the text have been updated;
- Section 3.16 - Obstructive pathology of renal duplication: ureterocele and ectopic ureter: The literature has been updated resulting in minor amendments to the text;
- Section 3.19 – Rare Conditions – A new section has been added to the section on bladder tumours on eosinophilic cystitis and nephrogenic adenoma.
3.19  Recommendations for rare conditions in children

3.19.2  Papillary tumours of the bladder in children and adolescents - Eosinophilic cystitis and Nephrogenic adenoma

3.19.2.9  Recommendations for papillary tumours of the bladder in children

2.  METHODS

2.1  Introduction

These Guidelines were compiled based on current literature following a structured review. Databases covered by the searches included Pubmed, Ovid, EMBASE and the Cochrane Central Register of Controlled Trials and the Cochrane Database of Systematic Reviews. Application of a structured analysis of the literature was not possible in many conditions due to a lack of well-designed studies. The limited availability of large randomised controlled trials (RCTs) - influenced also by the fact that a considerable number of treatment options relate to surgical interventions on a large spectrum of different congenital problems - means this document is largely a consensus document. Clearly there is a need for continuous re-evaluation of the information presented in this document.

For each recommendation within the guidelines there is an accompanying online strength rating form, the basis of which is a modified GRADE methodology [9, 10]. Each strength rating form addresses a number of key elements namely:

1. the overall quality of the evidence which exists for the recommendation, references used in this text are graded according to a classification system modified from the Oxford Centre for Evidence-Based Medicine Levels of Evidence [11];
2. the magnitude of the effect (individual or combined effects);
3. the certainty of the results (precision, consistency, heterogeneity and other statistical or study related factors);
4. the balance between desirable and undesirable outcomes;
5. the impact of patient values and preferences on the intervention;
6. the certainty of those patient values and preferences.

These key elements are the basis which panels use to define the strength rating of each recommendation. The strength of each recommendation is represented by the words ‘strong’ or ‘weak’ [12]. The strength of each recommendation is determined by the balance between desirable and undesirable consequences of alternative management strategies, the quality of the evidence (including certainty of estimates), and nature and variability of patient values and preferences. The strength rating forms will be available online.

Additional information can be found in the general Methodology section of this print, and online at the EAU website; http://www.uroweb.org/guideline/.

A list of Associations endorsing the EAU Guidelines can also be viewed online at the above address.

2.2  Peer review

All chapters of the Paediatric Urology Guidelines were peer-reviewed in 2015.
3. **THE GUIDELINE**

3.1 **Phimosis**

This chapter does not deal with neonatal circumcision as practised in the USA, nor mass circumcision as practised in many African countries as part of a national program to prevent HIV. Also “religious and cultural” circumcision is not discussed. At present in some European countries professional organisations do not support circumcision for these reasons and it is no longer covered by insurance in these countries. Special centres have been set up, where well-trained doctors perform circumcisions under sedation and local anaesthetics at a lower cost. In all circumstances facilities have to comply with national regulations regarding hygiene, special equipment, pain protocols and follow-up. Usually these clinics have an agreement with a nearby hospital for the immediate treatment of possible complications. It is estimated that 37-39% of men worldwide are circumcised [13].

3.1.1 **Epidemiology, aetiology and pathophysiology**

At the end of the first year of life, retraction of the foreskin behind the glandular sulcus is possible in approximately 50% of boys; this increases to approximately 89% by the age of three years. The incidence of phimosis is 8% in six to seven year olds and in just 1% in males aged sixteen to eighteen years [14].

3.1.2 **Classification systems**

Phimosis is either primary with no sign of scarring, or secondary (pathological) to a scarring such as balanitis xerotica obliterans (BXO) [14]. Balanitis xerotica obliterans, also termed lichen sclerosis, has been recently found in 35% of circumcised prepuce in children and adolescents and in 17% of boys younger than ten years presenting with phimosis. The clinical appearance of BXO in children may be confusing and does not always correlate with the final histopathological results. Lymphocyte-mediated chronic inflammatory disease was the most common finding [15, 16] (LE: 2b).

Phimosis has to be distinguished from normal agglutination (adhesion) of the foreskin to the glans, which is a more or less lasting physiological phenomenon with clearly-visible meatus and partial retraction [17]. Separation of the prepuce from the glans is based on accumulated epithelial debris (smegma) and penile erections. Forceful preputial retraction should be discouraged to avoid cicatrix formation [18].

Paraphimosis must be regarded as an emergency situation: retraction of a too narrow prepuce behind the glans penis into the glanular sulcus may constrict the shaft and lead to oedema of the glans and retracted foreskin. It interferes with perfusion distally from the constrictive ring and brings a risk of preputial necrosis.

3.1.3 **Diagnostic evaluation**

The diagnosis of phimosis and paraphimosis is made by physical examination. If the prepuce is not retractable, or only partly retractable, and shows a constrictive ring on drawing back over the glans penis, a disproportion between the width of the foreskin and the diameter of the glans penis has to be assumed. In addition to the constricted foreskin, there may be adhesions between the inner surface of the prepuce and the glanular epithelium and/or a fraenulum breve. Paraphimosis is characterised by a retracted foreskin with the constrictive ring localised at the level of the sulcus, which prevents replacement of the foreskin over the glans.

3.1.4 **Management**

Conservative treatment is an option for primary phimosis. The class 4 therapies were more effective over placebo and manual stretching [19]. A corticoid ointment or cream (0.05-0.1%) can be administered twice a day over a period of 4-8 weeks with a success rate of > 80% [20-23] (LE: 1b). A recurrence rate of up to 17% can be expected [24]. This treatment has no side effects and the mean bloodcortisol levels are not significantly different from an untreated group of patients [25] (LE: 1b). The hypothalamic pituitary-adrenal axis was not influenced by local corticoid treatment [26]. Adhesion of the foreskin to the glans does not respond to steroid treatment [20] (LE: 2).

Operative treatment of phimosis in children is dependent on the caregivers’ preferences and can be plastic or radical circumcision after completion of the second year of life. Alternatively, the Shang Ring may be used especially in developing countries [27]. Plastic circumcision has the objective of achieving a wide foreskin circumference with full retractability, while the foreskin is preserved (dorsal incision, partial circumcision, trident preputial plasty, combining 2 Z-plasties and a Y plasty) [28, 29]. However, this procedure carries the potential for recurrence of the phimosis [30]. In the same session, adhesions are released and an associated fraenulum breve is corrected by fraenulotomy. Meatoplasty is added if necessary. In all cases meticulous haemostasis is mandatory and absorbable interrupted sutures are most often used.

An absolute indication for circumcision is secondary phimosis. In primary phimosis (including those not responding to medical treatment), recurrent balanoposthitis and recurrent urinary tract infections
(UTIs) in patients with urinary tract abnormalities are indications for surgical intervention [31-34] (LE: 2b). Male circumcision significantly reduces the bacterial colonisation of the glans penis with regard to both non-uropathogenic and uropathogenic bacteria [35](LE: 2b). Simple ballooning of the foreskin during micturition is not a strict indication for circumcision.

Routine neonatal circumcision to prevent penile carcinoma is not indicated. A meta-analysis could not find any risk in uncircumcised patients without a history of phimosis [36]. Contraindications for circumcision are: an acute local infection and congenital anomalies of the penis, particularly hypospadias or buried penis, as the foreskin may be required for a reconstructive procedure [37, 38]. Circumcision can be performed in children with coagulopathy with 1-5% suffering complications (bleeding), if haemostatic agents or a diathermic blade are used [39, 40]. Childhood circumcision has an appreciable morbidity and should not be recommended without a medical reason and also taking into account epidemiological and social aspects [41-45] (LE: 1b). Balanitis xerotica obliterans is associated with meatal pathology (stenosis) after circumcision in up to 20% of boys and adjuvant local steroid treatment is advised [16, 46].

Treatment of paraphimosis consists of manual compression of the oedematous tissue with a subsequent attempt to retract the tightened foreskin over the glans penis. Injection of hyaluronidase beneath the narrow band or 20% mannitol may be helpful to release the foreskin [47, 48] (LE: 3-4). If this manoeuvre fails, a dorsal incision of the constrictive ring is required. Depending on the local findings, a circumcision is carried out immediately or can be performed in a second session.

3.1.5 Complications
Complications following circumcision vary and have been reported between 0-30% [45]. In a recent study Hung et al. found during a 5-year follow-up period 2.9% complications in non-neonates of which 2.2% were early (within 30 days after circumcision). Non-healing wounds, haemorrhage, wound infection, meatal stenosis, redundant skin and non-satisfying cosmetic appearance as well as cicatrix formation and trapped penis all may occur [49].

3.1.6 Follow-up
Any surgery done on the prepuce requires an early follow-up of four to six weeks after surgery.

3.2 Management of undescended testes

3.2.1 Background
Cryptorchidism or undescended testis is one of the most common congenital malformations of male neonates. Incidence varies and depends on gestational age, affecting 1.0-4.6% of full-term and 1.1-45% of preterm neonates. Following spontaneous descent within the first months of life, nearly 1.0% of all full-term male infants still have undescended testes at one year of age [50]. This congenital malformation may affect both sides in up to 30% of cases [51]. In newborn cases with non-palpable or undescended testes on both sides and any sign of disorders of sex development (DSDs) like concomitant hypospadias, urgent endocrinological and genetic evaluation is required [52].

3.2.2 Classification
The term cryptorchidism is most often used synonymously for undescended testes. The most useful classification of undescended testes is distinguishing into palpable and non-palpable testes, and clinical
management is decided by the location and presence of the testes (see Figure 1). Approximately 80% of all undescended testes are palpable [53]. Acquired undescended testes can be caused by entrapment after herniorrhaphy or spontaneously referred to as ascending testis.

Palpable testes include true undescended testes and ectopic testes. Non-palpable testes include intra-abdominal, inguinal, absent, and sometimes also some ectopic testes. Most importantly, the diagnosis of palpable or non-palpable testis needs to be confirmed once the child is under general anaesthesia, as this is the first step of any surgical procedure for undescended testes.

Figure 1: Classification of undescended testes

3.2.2.1 Palpable testes
Undescended testes

A true undescended testis is on its normal path of descent but is halted on its way down to the scrotum. Depending on the location, the testes may be palpable or not, as in the case of testes arrested in the inguinal canal.

Ectopic testes

If the position of a testis is outside its normal path of descent and outside the scrotum, the testis is considered to be ectopic. The most common aberrant position is in the superficial inguinal pouch. Sometimes an ectopic testis can be identified in a femoral, perineal, pubic, penile or even contralateral position. Usually, there is no possibility for an ectopic testis to descend spontaneously to the correct position; therefore, it requires surgical intervention. In addition, an ectopic testis might not be palpable due to its position.

Retractile testes

Retractile testes have completed their descent into a proper scrotal position but can be found again in a suprascrotal position along the path of their normal descent. This is due to an overactive cremasteric reflex [54]. Retractile testes can be easily manipulated down to the scrotum and remain there at least temporarily.

They are typically normal in size and consistency. However, they may not be normal and should be monitored carefully since up to one-third can ascend and become undescended [55].
3.2.2 Non-palpable testes
Among the 20% of non-palpable testes, 50-60% are intra-abdominal, canalicular or peeping (right inside the internal inguinal ring). The remaining 20% are absent and 30% are atrophic or rudimentary.

Intra-abdominal testes
Intra-abdominal testes can be located in different positions, with most of them being found close to the internal inguinal ring. However, possible locations include the kidney, anterior abdominal wall, and retrovesical space. In the case of an open internal inguinal ring, the testis may be peeping into the inguinal canal.

Absent testes
Monorchidism can be identified in up to 4% of boys with undescended testes, and anorchidism (bilateral absence) in < 1%. Possible pathogenic mechanisms include testicular agenesis and atrophy after intrauterine torsion with the latter one most probably due to an in utero infarction of a normal testis by gonadal vessel torsion. The term “vanishing testis” is commonly used for this condition [56].

3.2.3 Diagnostic evaluation
History taking and physical examination are key in evaluating boys with undescended testes. Localisation studies using different imaging modalities are usually without any additional benefit.

3.2.3.1 History
Caregivers should be asked for maternal and paternal risk factors, including hormonal exposure and genetic or hormonal disorders. If the child has a history of previously descended testes this might be suggestive of testicular ascent [57]. Prior inguinal surgery is indicative of secondary undescended testes due to entrapment.

3.2.3.2 Physical examination
An undescended testis is pursued by carefully advancing the examining fingers along the inguinal canal towards the pubis region, perhaps with the help of lubricant. A possible inguinal testis can be felt to bounce under the fingers [58]. A non-palpable testis in the supine position may become palpable once the child is in a sitting or squatting position. If no testis can be identified along the normal path of descent, possible ectopic locations must be considered.

In the event of unilateral non-palpable testis, the contralateral testis needs to be examined. Its size and location can have important prognostic implications. Any compensatory hypertrophy suggests testicular absence or atrophy [59]. Nevertheless, this does not preclude surgical exploration since the sign of compensatory hypertrophy is not specific enough [60, 61].

In the event of bilateral undescended testes and any evidence or sign of DSDs, such as genital ambiguity, or scrotal hyperpigmentation, further evaluation including endocrinological and genetic assessment becomes mandatory [62].

3.2.3.3 Imaging studies
Imaging studies cannot determine with certainty that a testis is present or not [63]. Ultrasound (US) lacks the diagnostic sensitivity to detect the testis confidently or establish the absence of an intra-abdominal testis [64]. Consequently, the use of different imaging modalities, such as US or Magnetic resonance imaging (MRI) [65], for undescended testes is limited and only recommended in specific and selected clinical scenarios (e.g. identification of Müllerian structures in cases with suspicion of DSDs) [64].

3.2.4 Management
Treatment should be started at the age of six months. After that age, undescended testes rarely descend [66]. Any kind of treatment leading to a scrotally positioned testis should be finished by twelve months, or eighteen months at the latest, because histological examination of undescended testes at that age has already revealed a progressive loss of germ cells and Leydig cells [67]. The early timing of treatment is also driven by the final adult results on spermatogenesis and hormone production, as well as on the risk of tumour development [68].

3.2.4.1 Medical therapy
Unfortunately, most of the studies on hormonal treatment have been of poor quality, with heterogeneous and mixed patient populations, testis location, schedules and dosages of hormonal administration. Additionally, long-term data are almost completely lacking.

Short-term side effects of hormonal treatment include increased scrotal erythema and pigmentation, and induction of pubic hair and penile growth. Some boys experience pain after intramuscular injection of human chorionic gonadotropin (hCG). All of these tend to regress after treatment cessation [69, 70].
3.2.4.1.1 Medical therapy for testicular descent
Hormonal therapy using hCG or gonadotropin-releasing hormone (GnRH) is based on the hormonal dependence of testicular descent, but has a limited success rate of only 20% [71]. However, it must be taken into account that almost 20% of these descended testes have the risk of re-ascending later [72]. In general, success rates depend on testicular location. The higher the testis is located prior to therapy, the lower the success rate, suggesting that testicular position is an important determinant of success [69]. Some authors recommend combined hCG-GnRH treatment. Unfortunately, it is poorly documented and the treatment groups were diverse. Some studies reported successful descent in up to 38% of non-responders to monotherapy [73]. The Panel consensus is that endocrine treatment to achieve testicular descent is not recommended (LE: 4).

Human chorionic gonadotropin
Human chorionic gonadotropin (hCG) stimulates endogenous testosterone production and is administered by intramuscular injection. Several dose and administration schedules are reported. There is no proven difference between 1.5 IU and weight-based doses up to 3.0 IU every other day for fourteen days [74]. Similar response rates were achieved with 500 IU once weekly and 1.50 IU three times weekly [75]. However, there is evidence that dosing frequency might affect testicular descent rates. Fewer lower dose injections per week for five weeks seem to be superior to one higher dose every seven to ten days for three weeks with regard to testicular descent [76].

Gonadotropin-releasing hormone
Gonadotropin-releasing hormone (GnRH) analogues (e.g., buserelin and gonadorelin) are available as nasal sprays, thus avoiding painful intramuscular injections. A typical dosage regimen consists of 1.2 mg per day in three divided doses, for four weeks. Success rates are wide ranging, from 9 to 60%, due to multiple treatment strategies and heterogeneous patient populations [77].

3.2.4.1.2 Medical therapy for fertility potential
Hormonal treatment may improve fertility indices [77, 78] and therefore serve as an additional tool to orchidopexy. There is no difference in treatment with GnRH before (neo-adjuvant) or after (adjuvant) surgical orchidolysis and orchidopexy in terms of increasing fertility index, which may be a predictor for fertility later in life [79]. It is still unknown whether this effect on testicular histology persists into adulthood but it has been shown that men who were treated in childhood with buserelin had better semen analyses compared with men who had childhood orchidopexy alone or placebo treatment [77].

It is reported that hCG treatment may be harmful to future spermatogenesis through increased apoptosis of germ cells, including acute inflammatory changes in the testes and reduced testicular volume in adulthood [80].

Identification of specific subgroups of boys with undescended testes who would benefit from such an approach using hormones is difficult. Since these important data on specific groups as well as additional support on the long-term effects are still lacking, the Nordic consensus does not recommend hormonal therapy [81]. The consensus of the Panel is to recommend endocrine treatment with GnRH analogues in a dosage described above for boys with bilateral undescended testes to preserve the fertility potential (LE: 4).

3.2.4.2 Surgical therapy
If a testis has not concluded its descent at the age of six months (corrected for gestational age), and since spontaneous testicular descent is unlikely to occur after that age, surgery should be performed within the subsequent year, and by age eighteen months at the latest [68]. In addition, early orchidopexy can be followed by partial catch-up testicular growth, which is not the case in delayed surgery [79]. All these findings recommend performing early orchidopexy between the ages of six and twelve months [66]. But despite early and successful orchidopexy within the first year of life up to 25% of boys with non-syndromic undescended testes may be at risk for infertility based on hormonal and histological data, as a recently published series on 333 boys showed. This is especially true for bilateral cases, but in addition in about 5% of unilateral cases reduced numbers of germ cells were detected in testicular biopsies as well [82].

3.2.4.2.1 Palpable testes
Surgery for palpable testes includes orchidofunicolysis and orchidopexy, either via an inguinal or scrotal approach. The latter approach is mainly reserved for low-positioned, undescended testes, with the pros and cons of each method being weighed against each other [83].

3.2.4.2.1.1 Inguinal orchidopexy
Inguinal orchidopexy is a widely used technique with a high success rate of up to 92% [84]. Important steps include mobilisation of the testis and spermatic cord to the level of the internal inguinal ring, with dissection and division of all cremasteric fibres, to prevent secondary retraction and detachment of the gubernaculum...
testis. The patent processus vaginalis needs to be ligated proximally at the level of the internal ring, because an unidentified or inadequately repaired patent processus vaginalis is an important factor leading to failure of orchidopexy [85]. Any additional pathology has to be taken care of, such as removal of an appendix testis (hydatid of Morgagni). At this moment the size of the testis can be measured and the connection of the epididimis to the testis can be judged and described in the protocol. Some boys have a significant dissociation between testis and epididymis which is prognostically bad for fertility. Finally, the mobilised testicle needs to be placed in a sub-dartos pouch within the hemi-scrotum without any tension. If the length achieved using the above-mentioned technique is still inadequate, the Prentiss manoeuvre, which consists of dividing the inferior epigastric vessels and transposing the spermatic cord medially, in order to provide a straight course to the scrotum, might be an option [86]. With regard to fixation sutures, if required, they should be made between the tunica vaginalis and the dartos musculature [87]. Lymph drainage of a testis that has undergone surgery for orchidopexy may have changed from high retroperitoneal drainage to iliac and inguinal drainage, which might become important in the event of later malignancy [88].

3.2.4.2.1 Scrotal orchidopexy

Low-positioned, palpable undescended testes can be fixed through a scrotal incision including division of the gubernaculum, and the processus vaginalis needs to be probed to check for patency [89]. Otherwise, fixation in the scrotum is carried out correspondingly to the inguinal approach. In up to 20% of cases, an inguinal incision will be compulsory to correct an associated inguinal hernia [90]. Any testicular or epididymal appendages can be easily identified and removed. A systematic review shows that the overall success rates ranged from 88 to 100%, with rates of recurrence and post-operative testicular atrophy or hypotrophy < 1% [83]. Another recently published systematic review and meta-analysis revealed similar outcome data regarding post-operative complications, including wound infection, testicular atrophy, testicular reascent, and hernia for palpable low-positioned undescended testes. The only significant difference was the shorter operative time [91].

3.2.4.2.2 Non-palpable testes

For non-palpable testes, surgery must clearly determine whether a testis is present or not [92]. If a testis is found, the decision has to be made to remove it or bring it down to the scrotum. An important step in surgery is a thorough re-examination once the boy is under general anaesthesia, since a previously non-palpable testis might be identifiable and subsequently change the surgical approach to standard inguinal orchidopexy, as described above. Otherwise, the easiest and most accurate way to locate an intra-abdominal testis is diagnostic laparoscopy [93]. Subsequent removal or orchidolysis and orchidopexy can be carried out using the same approach to achieve the therapeutic aims [94]. Some tend to start with inguinal surgical exploration, with possible laparoscopy during the procedure [95]. If an ipsilateral scrotal nubbin is suspected, and contralateral compensatory testicular hypertrophy is present, a scrotal incision with removal of the nubbin, thus confirming the vanishing testis, is an option avoiding the need for laparoscopy [96].

During laparoscopy for non-palpable testes, possible anatomical findings include spermatic vessels entering the inguinal canal (40%), an intra-abdominal (40%) or peeping (10%) testis, or blind-ending spermatic vessels confirming vanishing testis (10%) [97].

If there is a vanishing testis, the procedure is finished once blind-ending spermatic vessels are clearly identified. If the vessels enter the inguinal canal, an atrophic testis may be found upon inguinal exploration or a healthy testis that needs to undergo standard orchidopexy [98]. A peeping testis can be placed down in the scrotum laparoscopically or via an inguinal incision [99]. Placement of an intra-abdominal testis can sometimes be a surgical challenge. Usually, testes lying > 2 cm above the internal inguinal ring may not reach the scrotum without division of the testicular vessels [100]. Under such circumstances, a Fowler-Stephens orchidopexy may be an option [101] (see Figure 2).

Proximal cutting and transection of the testicular vessels, with conservation of the collateral arterial blood supply, via the deferential artery and cremasteric vessels comprise the key features of the Fowler-Stephens procedure. Recently, a modification with low spermatic vessel ligation has gained popularity, allowing blood supply from the testicular artery to the deferential artery. An additional advantage is the position of the peritoneal incision, leading to a longer structure, to ease later scrotal placement [102]. Due to the nature of these approaches the testis is at risk of hypotrophy or atrophy if the collateral blood supply is insufficient [103]. The testicular survival rate in the one-stage Fowler-Stephens technique varies between 50 and 65% based on post-operative Doppler-ultrasound findings [104]. For two-stage procedures success rates increase up to 90% [105]. The advantages of two-stage orchidopexy, with the second part done usually six months after the first, are to allow for development of collateral blood supply and to create greater testicular mobility [106]. In addition, preservation of the gubernaculum may also decrease the chance of testicular atrophy [107]. An alternative might be microsurgical auto-transplantation, which has a success rate of up to 90%. However, this approach requires skilled and experienced surgeons and is performed in a limited number of centres [108].
3.2.4.2.3 Complications of surgical therapy
Surgical complications are usually uncommon, with testicular atrophy being the most serious. A systematic review revealed an overall atrophy rate for primary orchidopexy of 1.83%, 28.1% for one-stage Fowler-Stephens procedure, and 8.2% for the two-stage approach [109]. Other rare complications comprise testicular ascent and vas deferens injury besides local wound infection, dehiscence, and haematoma.

3.2.4.2.4 Surgical therapy for undescended testes after puberty
A study on 51 men diagnosed with inguinal unilateral undescended testis and a normal contralateral one, with no history of any previous therapy, demonstrated a wide range of changes upon histological evaluation. Nearly half of the study population still had significant germ cell activity at different maturation levels. Importantly, the incidence of intratubular germ cell neoplasia was 2% [110].

The Panel consensus recommends orchiectomy in post-pubertal boys with an undescended testis and a normal contralateral one in a scrotal position.

Figure 2: Treatment of unilateral non-palpable undescended testes

3.2.5 Undescended testes and fertility
The association of undescended testes with compromised fertility [111] is extensively discussed in the literature and seems to be a result of multiple factors, including germ cell loss, impaired germ cell maturation [112], Leydig cell diminution and testicular fibrosis [113].

Although boys with one undescended testis have a lower fertility rate, they have the same paternity rate as those with bilateral descended testes. Boys with bilateral undescended testes suffer both lower fertility and paternity rates. Fertility rate is the number of offspring born per mating pair, individual or population whereas paternity reflects the actual potential of fatherhood [114]. The age at which surgical intervention for an undescended testis occurs seems to be an important predictive factor for fertility later in life. Endocrinological studies revealed higher inhibin-B and lower follicle-stimulating hormone (FSH) levels in men who underwent orchidopexy at two years of age compared to individuals who had surgery later, which is indicative of a benefit of earlier orchidopexy [115]. In addition, others demonstrated a relation between undescended testes
and increased loss of germ cells and Leydig cells, which is also suggestive of prompt orchidopexy being a significant factor for fertility preservation [116]. Outcome studies for untreated bilateral undescended testes revealed that 100% are oligospermic and 75% azoospermic. Among those successfully treated for bilateral undescended testes, 75% still remain oligospermic and 42% azoospermic [113].

In summary, early surgical correction of undescended testes is highly recommended before twelve months of age, and by eighteen months at the latest for preservation of fertility potential [67].

3.2.6 Undescended testes and malignancy

Boys who are treated for an undescended testis have an increased risk of developing testicular malignancy. Screening and self-examination both during and after puberty is therefore recommended [117]. A Swedish study, with a cohort of almost 17,000 men (56 developed a testicular tumour) who were treated surgically for undescended testes and followed for 210,000 person-years, showed that management of undescended testes before the onset of puberty decreased the risk of testicular cancer. The relative risk of testicular cancer among those who underwent orchidopexy before thirteen years of age was 2.2 compared to the Swedish general population; this increased to 5.4 for those treated after thirteen years of age [118].

A systematic review and meta-analysis of the literature have also concluded that pre-pubertal orchidopexy may reduce the risk of testicular cancer and that early surgical intervention is indicated in boys with undescended testes [119].

3.3 Testicular Tumours in prepubertal boys

3.3.1 Introduction

Testicular tumours account for approximately 1-2% of all paediatric solid tumours [120]. Testicular tumours in prepubertal boys differ in several aspects to testicular tumours in adolescent and adult men: they have a lower incidence, they have a different histologic distribution (teratomas and yolk sac tumours are more common and germ cell tumours are less common) and they are more often benign. A recent epidemiological study showed that in children under the age of 15 years the incidence is highest in Asia (4.2 per million) and South America (5 per million) and lowest in Europe (2.1 per million) and North America (2.5 per million). This is in contrast to the incidence in adolescent and young adults where the highest incidence is in Europe (137.4 per million), and North America (94.9 per million), while a lower incidence was observed in South and Central America (66.5 per million) and Asia (27.1 per million) [121]. For age distribution in prepubertal boys, there is a small peak around
the age of two years [122]. Some recent studies demonstrated that up to 60-75% of the tumours are benign [120, 123-127]. Intratubular neoplasia (TIN) is practically non-existent in children [128-131]. Testicular tumours can generally be classified as germ cell or stromal tumours. One specific tumour type is the gonadoblastoma, which contains germ cell and stromal cell tumour types and will occur almost exclusively in the setting of disorders of sexual differentiation [132].

In the past 30 years, it has clearly been shown, that there is a fundamental difference between testicular tumours in childhood and those in adulthood - not only in terms of the difference and incidence [121] but also in terms of histology [128]. In prepubertal boys, most intratesticular tumours are benign, whereas post puberty the tumours are most likely malignant.

3.3.2 Clinical presentation

Clinical presentation is a painless scrotal mass in more than 90% of the patients, detected by the caregiver, physician or the patient himself. A history of a trauma, pain or hernia is rare. A hydrocele can be found in 15 – 50% [124, 133]. In boys with early onset of puberty (e.g. early penile and prepubic hair growth) as well as high testosterone and low gonadotropin levels, a Leydig cell tumour should be excluded [134].

In patients presenting with a scrotal mass, paratesticular tumours should also be taken into account as a differential diagnosis. However, these are even less common compared to intratesticular tumours. The spectrum of paratesticular tumours includes benign tumours such as leiomyoma, fibroma, lipoma, haemangioma, cystic lymphangioma and lipoblastoma as well as malignant tumours such as the paratesticular rhabdomyosarcoma with an excellent prognosis and the rare melanotic neuroectodermal tumour of infancy with a high recurrence rate [135-138]. As most of them are benign, intra-operative frozen section should be available during surgery. An organ sparing surgical approach is preferred in benign tumours, whereas in malignant tumour standard orchiectomy is carried out.

3.3.3 Evaluation

To confirm the diagnosis, a high-resolution ultrasound (US) examination (7.5 – 12.5 MHz), preferably a doppler ultrasound, is required. The detection rate is almost 100% [139-142]. With high-resolution US, microlithiasis - small hyperdense areas without sound shadows - is increasingly seen in prepubertal boys. A recent meta-analysis showed that only 4 out of 296 boys (<19 years of age diagnosed with microlithiasis) developed a testicular tumour of whom two previously had a testicular tumour on the opposite or ipsilateral site [143]. If microlithiasis shows up in patients with additional risk factors for testicular tumour, then the caregivers/patients should be informed about the increased risk and encouraged to carry out regular self-examinations - similar to patients treated for undescended testis [144]. There is no evidence, that regular sonographic follow-up is useful [143]. The risk for infertility may be higher in patients with microlithiasis and if these patients have any sign of infertility later, the risk of developing a tumour seems to be higher compared to patients without microlithiasis and infertility [145]. Due to the low incidence of a contralateral tumour, even in cases of testicular microlithiasis, there is no indication for contralateral testicular biopsy in prepubertal boys.

Age should be taken into account, when tumour markers are used. Human chorionic gonadotropin (ß-hCG) is derived from chorion carcinoma, embryonal carcinoma or seminoma. However, these tumours are extremely rare in prepubertal boys and therefore ß-hCG is not useful in prepubertal boys. Alpha-fetoprotein (AFP) has a clear limitation of its sensitivity and specificity in the first months of life [133] and sometimes takes up to twelve months before the serum concentration reaches the known standard values (< 10 ng/mL) [127, 146]. It is produced by > 90% of yolk sac tumours. Teratomas can also produce AFP, but not to that extent of yolk sac tumours [147]. Alpha-fetoprotein should be measured before any therapeutic intervention (tumour enucleation/orchiectomy) and ideally should be available at the time of the procedure. Alpha-fetoprotein has a serum biological half-life of five days and should be measured five days after tumour resection/orchiectomy in those with an elevated AFP. There is no urgent need for pre-operative staging, as this has no consequence before the definitive histology is available.

3.3.4 Treatment/Management

If a testicular tumour is suspected, surgery with the option of intra-operative frozen section should be performed. It is not necessary to do this as an emergency procedure. However, in order to confirm the diagnosis and to avoid familial anxiety, the operation should be scheduled as soon as possible, preferably within the next few days. Organ-preserving surgery should be performed, whenever possible. A recent published review article showed that out of 227 patients with organ-sparing surgery only two cases (one in a patient with an epidermoid cyst and one in a patient with a mature teratoma) had a recurrence [148-150].
Orchiectomy could be considered only if normal testicular parenchyma is no longer detectable in the pre-operatively high-resolution ultrasound and/or the AFP is > 100 ng/mL in a > 12-month-old boy: highly suspicious of a yolk sac tumour.

For surgical technique, the Panel is in favour of an inguinal approach. Furthermore, clamping of the vessels has the advantage of a better view, when organ sparing surgery is performed. However, there is no evidence in the literature, that tumour-spread is prevented by clamping the vessels. Whenever possible, testis sparing surgery should be performed along with frozen sections during surgery to confirm the diagnosis (begin vs. malignant tumour) and to confirm if a microscopically margin-negative resection is performed, in which no gross or microscopic tumour remains in the primary tumour bed (R0 resection). In cases of an R0 resection, the tunica is closed and the testis is replaced in the scrotum. In case of R1 resection (removal of all macroscopic disease, but microscopic margins are positive for tumour) confirmed by frozen section in a malignant or potential malignant tumour, an orchiectomy should be performed at the same time of surgery. If the final pathology later demonstrates a R1 resection in a malignant tumour despite intra-operative negative margins on frozen section, an inguinal orchiectomy can safely be performed.

In patients with a malignant tumour (yolk sac tumour, immature teratoma) staging should be performed including an MRI of the abdomen and a CT-scan from the chest. If there is any suspicion of a non-organ confined tumour, the patient should be referred to a paediatric oncologist. In patients with the rare diagnosis of a Granulosa cell tumour, imaging of the abdomen to exclude enlarged lymph nodes is reasonable as this may be a potentially malignant tumour; in those with Sertoli or a Leydig cell tumour, an MRI is recommended, as 10% are malignant and the metastases do not respond very well to chemotherapy or radiation in the adult literature [151, 152]. The TNM classification from 2015 for adult testicular tumours can be used in patients with a malignant tumour [153]. In benign tumours (mature teratoma, epidermoid cysts) no further staging is required.

### 3.3.5 Tumour entities in prepubertal boys

**Teratomas** are usually benign in prepubertal children and represent the greatest proportion of intratesticular tumours (around 40%) [120, 154]. They present at a median age of 13 months (0-18 months). Only in adolescent and adults, they should be considered as malignant tumours. Histologically they can consist of a combination of the three primitive embryological germ-cell layers (ectoderm, mesoderm and endoderm). Most of these elements shows microscopically mature elements [155]; however, some immature teratomas in this age group have also been reported [156]. To exclude any malignant potential, like focal areas of a yolk-sac tumour, the entire specimen should be investigated. On US examination a heterogenous picture with some calcification is seen [157] and AFP should be less than 100 ng/mL in an infant. After organ-sparing surgery only one recurrence was reported in the literature [150].

**Epidermoid cysts** are of ectodermal origin and seem to be related to well-differentiated teratomas; they are always benign [155]. Keratin-producing epithelium is responsible for the keratinised-squamous-epithelial deposits, which appear hyperechogenic in an US [157]. Organ-sparing surgery should be performed and if confirmed by histology, there is no need for surveillance despite the fact that one “recurrence” has been reported thirteen years after diagnosis [149].

**Juvenile granulosa cell tumours** occur usually in the first year of life, typically within the first six months [158]. They are well circumscribed and have a typical yellow-tan appearance; 2/3 have cystic elements, 1/3 solid [158]. The stroma can be fibrous or fibromyxoid. So far, no recurrence has been reported after organ-sparing surgery [158, 159].

**Leydig cell tumours** arising from the testosterone producing Leydig cells should be suspected in boys with early onset of puberty with high testosterone and low gonadotropin levels [134]. Patients are usually between six and ten years of age; the tumours are well circumscribed with yellow-brown nodules. In children there are no reports of malignant Leydig cell tumours and after organ sparing surgery, there are no reported recurrences to date [160, 161]. In the adult literature, there is a malignancy rate of 10% reported and primary retroperitoneal lymphadenectomy should be discussed in cases with enlarged lymph nodes, as these metastases do not respond very well to chemotherapy or radiation [162].

Around 1/5 of the Sertoli-cell tumours occur in children; usually within the first year of life [163]. In the paediatric age group, the large-cell calcifying Sertoli cell tumours (LCCSCT) are the most common tumour variant [164, 165]. They can occur in patients with complex dysplastic syndromes, such as the Carney or Peutz-Jeghers syndrome [165-167]. Except one case report with the histological diagnosis of a malignant LCCSCT [164], all other reported tumours are benign, therefore organ-sparing surgery should be performed.
Yolk sac tumours are the predominant prepubertal malignant germ cell tumours and may represent around 15% of the prepubertal tumours in boys [120]. They also have a number of other names: endodermal sinus tumours, juvenile embryonal carcinoma, clear cell carcinoma, orchioblastoma, vitellineum, archenteronoma and sometimes extraembryonal mesoblastoma [168]. They are histologically mostly solid, yellow-grey tumours. They occur usually within the first two years of life [169]. Up to 80-85% of the tumours are organ confined (Stage I) [170]. The tumour usually spreads haematogenously (chest). Twenty percent of those with Stage I disease may develop visible metastasis in 20% within the next two years. In a German study, 14 out of 91 patients with Stage I had a recurrence after observation – all were cured by chemotherapy alone. Four out of five with metastatic disease initially, were cured by chemotherapy after radical orchiectomy [171]. In a recent published series from China, 21 out of 90 paediatric patients with a Stage I yolk sac tumour received primary chemotherapy. One of the 21 had a recurrence, whereas 29 out of 69 who underwent surveillance after initial orchiectomy had a recurrence. The overall four-year survival rate was 97.8% [169], almost the same recurrence rate has also been reported by American oncology groups [172, 173]. Therefore in patients with Stage I disease (no metastatic disease in the MRI-abdomen and CT scan of the chest as well as normal age-adapted AFP values) close follow-up together with the paediatric oncologists including AFP every two to three months and MRI of the abdomen is recommended, at least for the first two to three years [133]. This is especially recommended in those with invasions of the lymphatic vessels, as this has been shown to be a prognostic factor in one of the recent series [169]. In cases of recurrence, chemotherapy should be performed by paediatric oncologists according to national study protocols.

3.3.6 Follow-up

Regular US examination is recommended in the follow-up period to detect any recurrence and/or other abnormalities. As there are only a few studies with recurrence after testicular sparing surgery or orchiectomy, no clear recommendation can be made concerning the interval and the duration of follow-up. However, doing an US examination every three to six months within the first year seems reasonable, as few recurrences have been detected at this time and the rate of atrophy is extremely low after organ-sparing surgery [148]. Only in patients with a malignant tumour, regular follow-up examination after the first year of surgery seems reasonable (see above). The follow-up in patients with a Leydig cell tumour should include endocrinological examinations. Using the SEER data base, the five-year relative survival for testicular malignancies for patients < 14 years of age diagnosed with localised testicular cancer was 97.4%, and for those with distant disease 72.6% [174].

3.3.7 Congenital Adrenal Hyperplasia

Boys with a congenital adrenal hyperplasia (CAH) represent a special group. Up to a third of the patients have so-called testicular adrenal rest tumours (TARTs). This proportion increase with age [175, 176]. It is most likely to be ectopic adrenal cells, which are growing under pathological stimulation from Adrenocorticotropic Hormone (ACTH) [177]. They have no malignant potential, but they can have a lasting impact on fertility by displacing the normal testicular parenchyma [177, 178]. These patients should be offered US screening and advice on fertility with the option of cryopreservation [178]. As far as is known, no malignant tumour has been described in patients with a typical TART. As a result, the indication for surgical intervention in these patients to rule out a malignant tumour should be offered very cautiously.

### Summary of evidence LE

| Testicular tumours in prepubertal boys have a lower incidence and a different histologic distribution compared to the adolescent and adult patients. | 2a |
| In prepubertal boys up to 60-75% of testicular tumours are benign. | 3 |

### Recommendations LE Strength rating

| High-resolution ultrasound (7.5 – 12.5 MHz), preferably a doppler ultrasound, should be performed to confirm the diagnosis. | 3 | Strong |
| Alpha-fetoprotein (AFP) should be determined in prepubertal boys with a testicular tumour before surgery. | 2b | Strong |
| Surgical exploration should be done with the option for frozen section, but not as an emergency operation. | 3 | Strong |
| Organ-preserving surgery should be performed in all benign tumours. | 3 | Strong |
| Staging (MRI abdomen / CT chest) should only be performed in patients with a malignant tumour to exclude metastases. | 3 | Strong |
Magnetic resonance imaging should only be performed in patients with the potential malignant Leydig or Sertoli-cell-tumours to rule out lymph node enlargement.  4  Weak
Patients with a non-organ confined tumour should be referred to paediatric oncologists post-operatively.  4  Weak

3.4  Hydrocele

3.4.1  Epidemiology, aetiology and pathophysiology
Hydrocele is defined as a collection of fluid between the parietal and visceral layers of the tunica vaginalis [179]. Pathogenesis of primary hydrocele is based on patency of the processus vaginalis in contrast with secondary hydrocele. Incomplete obliteration of the processus vaginalis peritonei results in formation of various types of communicating hydrocele; a large open processus vaginalis allowing passage of abdominal viscera results in clinical hernia [180]. The exact time of spontaneous closure of the processus vaginalis is not known. It persists in approximately 80-94% of newborns and in 20% of adults [181]. If complete obliteration of the processus vaginalis occurs with patency of mid-portion, a hydrocele of the cord occurs. Scrotal hydroceles without associated patency of the processus vaginalis are also encountered in newborns [182]. Non-communicating hydroceles, based on an imbalance between the secretion and re-absorption of this fluid, are found secondary to minor trauma, testicular torsion, epididymitis, varicocele operation (due to ligation of the lymphatics) or may appear as a recurrence after primary repair of a communicating or non-communicating hydrocele.

3.4.2  Diagnostic evaluation
The classic description of a communicating hydrocele is that of a hydrocele that fluctuates in size, and is usually related to ambulation. It may be diagnosed by history-taking and physical investigation. Transillumination of the scrotum provides the diagnosis in the majority of cases, keeping in mind that fluid filled intestine and some pre-pubertal tumours may transilluminate as well [183, 184]. If the diagnosis is that of a hydrocele, there will be no history of reducibility and no associated symptoms; the swelling is translucent, smooth and usually not tender. If there are any doubts about the character of an intrascrotal mass, scrotal US should be performed and has nearly 100% sensitivity in detecting intrascrotal lesions. Doppler US studies help to distinguish hydroceles from varicocele and testicular torsion, although these conditions may also be accompanied by a hydrocele.

3.4.3  Management
In the majority of infants, surgical treatment of hydrocele is not indicated within the first twelve months because of the tendency for spontaneous resolution [185] (LE: 2). Little risk is taken by initial observation as progression to hernia is rare and does not result in incarceration [185]. Early surgery is indicated if there is suspicion of a concomitant inguinal hernia or underlying testicular pathology [186, 187] (LE: 2). Persistence of a simple scrotal hydrocele beyond twelve months of age may be an indication for surgical correction. There is no evidence that this type of hydrocele risks testicular damage. The natural history of hydrocele is poorly documented beyond the age of two years and according to a systematic review there is no good evidence to support current practice. Delaying surgery may reduce the number of procedures necessary without increasing morbidity [188].

The question of contralateral disease should be addressed by both history-taking and physical examination at the time of initial consultation [189] (LE: 2). In late-onset hydrocele, suggestive of a non-communicating hydrocele, there is a reasonable chance of spontaneous resolution (75%) and expectant management of six to nine months is recommended [190]. In the paediatric age group, the operation consists of ligation of the patent processus vaginalis or scrotal via inguinal incision and the distal stump is left open, whereas in hydrocele of the cord the cystic mass is excised or unroofed [184, 186, 191, 192] (LE: 4). In expert hands, the incidence of testicular damage during hydrocele or inguinal hernia repair is very low (0.3%) (LE: 3). Laparoscopic hernia repair with percutaneous ligation of the patent processus vaginalis is a minimally invasive alternative to open inguinal herniorrhaphy [193, 194]. Sclerosing agents should not be used because of the risk of chemical peritonitis in communicating processus vaginalis peritonei [184, 186] (LE: 4). The scrotal approach (Lord or Jaboulay technique) is used in the treatment of a secondary non-communicating hydrocele.

### 3.5 Acute scrotum

#### 3.5.1 Epidemiology, aetiology and pathophysiology

Acute scrotum is a paediatric urological emergency, most commonly caused by torsion of the testis or appendix testis, or epididymitis/epididymo-orchitis [195-200]. Other causes of acute scrotal pain are idiopathic scrotal oedema, mumps orchitis, varicocele, scrotal haematoma, incarcerated hernia, appendicitis or systemic disease (e.g. Henoch-Schönlein purpura) [201-213]. Trauma can also be a cause of acute scrotum due to post-traumatic haematomas, testicular contusion, rupture, dislocation or torsion [214-219]. Scrotal fat necrosis has also been reported to be an uncommon cause of mild-to-moderate scrotal pain in pre-pubertal overweight boys after exposure to cold [220].

In this chapter testicular torsion and epididymitis are discussed, while recurrent epididymitis is discussed in the chapter dealing with infections. Torsion of the testis occurs most often in the neonatal period and around puberty, whereas torsion of the appendix testis occurs over a wider age range [221]. Epididymitis affects two age groups: less than one year and twelve to fifteen years [222, 223]. One study predicted the annual incidence of epididymitis around 1.2 per 1,000 children [224].

Perinatal torsion of the testis most often occurs prenatally. Bilateral torsion comprises 11-21% of all perinatal cases [225]. Most cases of perinatal torsion are extravaginal, in contrast to the usual intravaginal torsion which occurs during puberty.

#### 3.5.2 Diagnostic evaluation

Patients usually present with scrotal pain, except in neonatal torsion. The sudden onset of invalidating pain in combination with vomiting is typical for torsion of the testis or appendix testis [226, 227].

In general, the duration of symptoms at presentation is shorter in testicular torsion (69% present within twelve hours) and torsion of the appendix testis (62%) compared to epididymitis (31%) [197, 198, 223]. Prepubertal males are more likely to present with atypical symptoms and delayed presentation and diagnosis, leading to delayed surgical intervention and a higher rate of orchiectomy, compared to postpubertal boys [228].

In the early phase, location of the pain can lead to diagnosis. Patients with acute epididymitis experience a tender epididymis, whereas patients with testicular torsion are more likely to have a tender testicle, in case of torsion of the appendix testis there may be isolated tenderness of the superior pole of the testis [223]. An abnormal (horizontal) position of the testis is more frequent in testicular torsion than epididymitis [197]. Looking for absence of the cremasteric reflex is a simple method with 100% sensitivity and 66% specificity for testicular torsion [222, 227] (LE: 3). Elevation of the scrotum may reduce complaints in epididymitis, but not in testicular torsion.

Fever occurs more often in epididymitis (11-19%). The classical sign of a “blue dot” was found only in 10-23% of patients with torsion of the appendix testis [196, 197, 222, 229]. In many cases, it is not easy to determine the cause of acute scrotum based on history and physical examination alone [195-200, 222, 229]. A positive urine culture is only found in a few patients with epididymitis [199, 222, 229, 230]. It should be remembered that a normal urinalysis does not exclude epididymitis. Similarly, an abnormal urinalysis does not exclude testicular torsion.

Doppler US is useful to evaluate acute scrotum, with 63.6-100% sensitivity and 97-100% specificity, a positive predictive value of 100% and negative predictive value of 97.5% [231-236] (LE: 3). The use of Doppler US may reduce the number of patients with acute scrotum undergoing scrotal exploration, but it is operator-dependent and can be difficult to perform in pre-pubertal patients [233, 237]. It may also show a misleading arterial flow in the early phases of torsion and in partial or intermittent torsion. Of key importance, persistent arterial flow does not exclude testicular torsion. Doppler US is useful to evaluate acute scrotum, with 63.6-100% sensitivity and 97-100% specificity, a positive predictive value of 100% and negative predictive value of 97.5% [231-236] (LE: 3). The use of Doppler US may reduce the number of patients with acute scrotum undergoing scrotal exploration, but it is operator-dependent and can be difficult to perform in pre-pubertal patients [233, 237]. It may also show a misleading arterial flow in the early phases of torsion and in partial or intermittent torsion. Of key importance, persistent arterial flow does not exclude testicular torsion. In a multicentre study of 208 boys with torsion of the testis, 24% had normal or increased testicular vascularity [233]. A comparison with the other side should always be done.

Better results were reported using high-resolution US (HRUS) for direct visualisation of the spermatic cord twist with a sensitivity of 97.3% and specificity of 99% [233, 238] (LE: 2). A so-called positive whirlpool sign (the presence of a spiral-like pattern), has a pooled sensitivity and specificity of 0.73 (95% CI; 0.65-0.79) and 0.99 (95% CI; 0.92-0.99), respectively, and may be viewed as a definitive sign for testicular torsion. But its role in neonates is limited [239].
Scintigraphy and, more recently, dynamic contrast-enhanced subtraction MRI of the scrotum also provide a comparable sensitivity and specificity to US [240-243]. These investigations may be used when diagnosis is less likely and if torsion of the testis still cannot be excluded from history and physical examination. This should be done without inordinate delays for emergency intervention [229].

The diagnosis of acute epididymitis in boys is mainly based on clinical judgement and adjunctive investigation. However, it should be remembered that findings of secondary inflammatory changes in the absence of evidence of an extra-testicular nodule by Doppler US might suggest an erroneous diagnosis of epididymitis in children with torsion of the appendix testes [244]. Pre-pubertal boys with acute epididymitis have an incidence of underlying urogenital anomalies of 25-27.6%. Complete urological evaluation in all children with acute epididymitis is still debatable [199, 222, 224].

3.5.3 Management
3.5.3.1 Epididymitis

In pre-pubertal boys, the aetiology is usually unclear, with an underlying pathology in about 25%. A urine culture is usually negative, and unlike in older boys, a sexually transmitted disease is very rare.

Antibiotic treatment, although often started, is not indicated in most cases unless urinalysis and urine culture show a bacterial infection [224, 245]. Epididymitis is usually self-limiting and with supportive therapy (i.e. minimal physical activity and analgesics) heals without any sequelae (LE: 3). However, bacterial epididymitis can be complicated by abscess or necrotic testis and surgical exploration is required [246].

3.5.3.2 Testicular torsion

Manual detorsion of the testis is done without anaesthesia, and should be attempted in all patients if possible, because it is associated with improved surgical salvage rates [247]. It should initially be done by outward rotation of the testis - like opening a book -, unless the pain increases or if there is obvious resistance. Success is defined as the immediate relief of all symptoms and normal findings at physical examination [248] (LE: 3). Doppler US may be used for guidance [249]. Bilateral orchiopexy is still required after successful detorsion. This should not be done as an elective procedure, but rather immediately following detorsion. One study reported residual torsion during exploration in 17 out of 53 patients, including eleven patients who had reported pain relief after manual detorsion [248, 250].

External cooling before exploration may be effective in reducing ischaemia reperfusion injury and preserving the viability of the torsed and the contralateral testis [251]. Medical treatments aimed at limiting such injury remain experimental [252-255].

Torsion of the appendix testis can be managed non-operatively with the use of anti-inflammatory analgesics (LE: 4). During the six-week follow-up, clinically and with US, no testicular atrophy was revealed. Surgical exploration is done in equivocal cases and in patients with persistent pain [236]. Although metachronous torsion of the appendix testis may occur in up to 8.5%, it is not necessary to explore the contralateral side, given the benign nature of the problem. Besides it has been demonstrated that the NNT is 24 [256].

3.5.3.3 Surgical treatment

Testicular torsion is an urgent condition which requires prompt surgical treatment. The two most important determinants of early salvage rate of the testis are the time between onset of symptoms and detorsion, and the degree of cord twisting [257]. Severe testicular atrophy occurred after torsion for as little as four hours when the turn was > 360°. In cases of incomplete torsion (180-360°), with symptom duration up to twelve hours, no atrophy was observed. However, a necrotic or severely atrophied testis was found in all cases of torsion > 360° and symptom duration > 24 hours [258].

Early surgical intervention with detorsion (mean torsion time less than thirteen hours) was found to preserve fertility [259]. Urgent surgical exploration is mandatory in all cases of testicular torsion within 24 hours of symptom onset. In patients with testicular torsion > 24 hours, exploration may be performed as a semi-elective exploration procedure [257, 258] (LE: 3), unless there is a clear history of torsion-detorsion in which urgent exploration should still be considered. In case of prolonged torsion (> 24 hours) it is still subject to debate whether the surgically detorsed testis should be preserved. An alternative to detorsion and fixation may be to perform orchiectomy. A study found that sperm quality was preserved after both orchiectomy and orchidopexy in comparison to normal control men, although orchiectomy resulted in better sperm morphology [260] Incision of the tunica albuginea with tunica vaginalis graft to prevent or treat compartment syndrome has also been suggested [261].

In neonates with signs of testicular torsion at birth the duration of symptoms will not be clear. The decision to perform surgical exploration should be weighed against the general condition of the child. In this age group the operation can safely be done under spinal anesthesia. New onset of symptoms of testicular torsion in neonates should be considered a surgical emergency similar to older boys.
During exploration, fixation of the contralateral testis is also performed. It is good clinical practice to also perform fixation of the contralateral testis in prenatal and neonatal torsion, although there is no literature to support this, and to remove an atrophied testicle [262]. Recurrence after orchidopexy is rare (4.5%) and may occur several years later. There is no consensus recommendation about the preferred type of fixation and suture material [263].

3.5.4 Follow-up
Patients require follow-up mainly for fertility issues and hormonal consequences. Despite timely and adequate detorsion and fixation of the testicle, up to half of the patients may develop testicular atrophy, even when intraoperatively assessed as viable, and should be counselled accordingly [264, 265].

3.5.4.1 Fertility
The results vary and are conflicting. In one study, unilateral torsion of the testis seriously intervened with subsequent spermatogenesis in about 50% of the patients and produced borderline impairment in another 20% [242]. Although, 30% of affected testicles with mumps orchitis show a degree of atrophy, long-term outcome in terms of fertility is not conclusive [266].

A recent study showed a normal pregnancy rate after unilateral testicular torsion, with no difference between the patients undergoing orchidopexy and those after orchidectomy [267].

3.5.4.2 Subfertility
Subfertility is found in 36-39% of patients after torsion. Semen analysis may be normal in only 5-50% in long-term follow-up [257]. Early surgical intervention (mean torsion time less than thirteen hours) with detorsion was found to preserve fertility, but a prolonged torsion period (mean 70 hours) followed by orchiectomy jeopardised fertility [259].

Subfertility and infertility are consequences of direct injury to the testis after the torsion. This is caused by the cut-off of blood supply, but also by post-ischaemia-reperfusion injury that is caused after the detorsion when oxygen-derived free radicals are rapidly circulated within the testicular parenchyma [257].

3.5.4.3 Androgen levels
Even though the levels of FSH, luteinising hormone (LH) and testosterone are higher in patients after testicular torsion compared to normal controls, endocrine testicular function remains in the normal range after testicular torsion [260].

3.5.4.4 Unanswered questions
Although testicular torsion is a common problem, the mechanism of neonatal and prenatal torsion is still not exactly known, as well as whether fixation of the contralateral testicle in these cases is really necessary. The influence of an atrophied testicle on fertility is also unclear.

Recommendations

| Testicular torsion is a paediatric urological emergency and requires immediate treatment. | Strength rating | Strong |
| In neonates with testicular torsion perform orchidopexy of the contralateral testicle. In prenatal torsion the timing of surgery is usually dictated by clinical findings. | Weak |
| Base the clinical decision on physical examination. The use of Doppler ultrasound to evaluate acute scrotum is useful, but this should not delay the intervention. | Strong |
| Manage torsion of the appendix testis conservatively. Perform surgical exploration in equivocal cases and in patients with persistent pain. | Strong |
| Perform urgent surgical exploration in all cases of testicular torsion within 24 hours of symptom onset. In prenatal torsion the timing of surgery is usually dictated by clinical findings. | Strong |
3.6 Hypospadias
3.6.1 Epidemiology, aetiology and pathophysiology

3.6.1.1 Epidemiology
The total prevalence of hypospadias in Europe is 18.6 new cases per 10,000 births (5.1-36.8) according to the recent EUROCAT registry-based study. This incidence was stable over the period of 2001 to 2010 [268, 269]. The mean worldwide prevalence of hypospadias according to an extended systematic literature review varies: Europe 19.9 (range: 1-646), North America 34.2 (6-129.8), South America 5.2 (2.8-110), Asia 0.6-69, Africa 5.9 (1.9-110), and Australia 17.1-34.8. There are conflicting data on the recent trends of prevalence – different trends in Europe and an increasing trend in the USA [270, 271].

3.6.2 Risk factors
Risk factors associated with hypospadias are likely to be genetic, placental and/or environmental [268, 269] (LE: 2b). Interactions between genetic and environmental factors may help explain non-replication in genetic studies of hypospadias. Single nucleotide polymorphisms seemed to influence hypospadias risk only in exposed cases [269, 272] (LE: 2b).

- An additional family member with hypospadias is found in 7% of families, but this is more predominant in anterior and middle forms [272-275].
- Endocrine disorders can be detected in rare cases.
- Babies with a low birth weight have a higher risk of hypospadias [272-275].
- Over the last 25 years, a significant increase in the incidence of hypospadias has been found.
- Endocrines disruptors are one component of a multi-factorial model for hypospadias.
- The use of oral contraceptives prior to pregnancy has not been associated with an increased risk of hypospadias in offspring, but their use after conception increased the risk of middle and posterior hypospadias [273-276] (LE: 2a).

3.6.3 Classification systems
Hypospadias are usually classified based on the anatomical location of the proximally displaced urethral orifice:

- distal-anterior hypospadias (located on the glans or distal shaft of the penis and the most common type of hypospadias);
- intermediate-middle (penile);
- proximal-posterior (penoscrotal, scrotal, perineal).

The pathology may be different after skin release and should be reclassified accordingly. Anatomical location of the meatus may not always be enough to explain the severity and the complex nature of this pathology. Therefore, a simple classification related to severity of the problem, which considers penile length, glans size, shape, urethral plate quality and penile curvature is commonly used. In that classification there are two types: mild hypospadias (glanular or penile isolated hypospadias without associated chordee, micropenis or scrotal anomaly); and severe hypospadias (penoscrotal, perineal hypospadias with associated chordee and scrotal anomalies).

3.6.4 Diagnostic evaluation
Most hypospadias patients are easily diagnosed at birth (except for the megameatus intact prepuce variant which can only be seen after retraction of foreskin). Diagnosis includes a description of the local findings:

- position, shape and width of the orifice;
- presence of atretic urethra and division of corpus spongiosum;
- appearance of the preputial hood and scrotum;
- size of the penis;
- curvature of the penis on erection.

The diagnostic evaluation also includes an assessment of associated anomalies, which are:

- cryptorchidism (in up to 10% of cases of hypospadias);
- open processus vaginalis or inguinal hernia (in 9-15%).

Severe hypospadias with unilaterally or bilaterally impalpable testis, or with ambiguous genitalia, requires a complete genetic and endocrine work-up immediately after birth to exclude DSD, especially congenital adrenal hyperplasia. Urine trickling and ballooning of the urethra requires exclusion of meatal stenosis. The relationship between the severity of the hypospadias and associated anomalies of the upper or lower urinary tract were not confirmed [277] (LE: 3).
3.6.5  **Management**  
3.6.5.1  **Indication for reconstruction and therapeutic objectives**  
Differentiation between functionally necessary and aesthetically feasible operative procedures is important for therapeutic decision making.

The indications for surgery are:
- proximally located (ectopic) meatus causing ventrally deflected or spraying urinary stream;
- meatal stenosis;
- anterior curvature of the penis;
- cleft glans;
- rotated penis with abnormal cutaneous raphe;
- preputial hood;
- penoscrotal transposition;
- split scrotum.

Physical examination should check all anatomic components of the penis and evaluate the degree and nature of abnormality in each component. The examination should evaluate location of the meatus, the degree of proximal spongiosal hypoplasia, presence and degree of penile curvature, width and depth of the urethral plate, size of the glans, degree of ventral skin deficiency, availability of the foreskin and scrotal abnormalities like penoscrotal transposition and bifid scrotum.

As all surgical procedures carry the risk of complications, thorough pre-operative counselling of the caregiver is crucial.

To achieve an overall acceptable functional and cosmetic outcome, the penile curvature must be corrected and a neo-urethra of an adequate size with opening on the glans formed with proper skin coverage of the penile shaft [278] (LE: 4) (Figure 3). The use of magnifying spectacles and fine synthetic absorbable suture materials (6.0-7.0) are required. As in any penile surgery, exceptional prudence should be adopted with the use of cautery. Bipolar cautery is recommended. Knowledge of a variety of surgical reconstructive techniques, wound care and post-operative treatment are essential for a satisfactory outcome.

3.6.5.2  **Pre-operative hormonal treatment**  
There is a lack of high-quality evidence to support that pre-operative hormonal treatment with androgen stimulation improves surgical outcomes. Yet, this treatment in the form of systemic testosterone, topical testosterone, and derivatives like dihydrotestosterone (DHT) and hCG are commonly being used to increase glans size pre-operatively to allow better tubularisation of the urethral plate and decrease the incidence of glans dehiscence. This treatment is usually limited to patients with proximal hypospadias, a small appearing penis, reduced glans circumference or reduced urethral plate [276, 279, 280]. Studies have shown that it leads to significant enlargement of the glans and shaft of the penis (LE: 1b) [281, 282].

Moderate quality evidence from three randomised studies demonstrate significantly lower rates of urethracutaneous fistulae and re-operation rates in patients who received pre-operative hormonal treatment [283].

Pre-operative testosterone administration is most often well tolerated. Transient side effects on child’s behaviour, increased genital pigmentation, appearance of pubic hair, penile skin irritation and redness, increased erections and peri-operative bleeding have been reported, but no persistent side effects related to hormonal stimulation have been reported in the literature. There is also no evidence about possible effects on bone maturation [280, 283, 284].

There are concerns regarding the negative impacts of testosterone on wound-healing and increased bleeding during surgery. Cessation of therapy is recommended one or two months prior to surgery to avoid adverse effects during or after surgery [285].

3.6.5.3  **Age at surgery**  
The age at surgery for primary hypospadias repair is usually 6-18 (24) months [278, 286, 287] (LE: 3). Age at surgery is not a risk factor for urethroplasty complication in pre-pubertal tubularised incised plate urethroplasty (TIP) repair [286] (LE: 2b). Complication rate after primary TIP repair was 2.5 times higher in adults than in the paediatric group according to a recent prospective controlled study [288] (LE: 2a).
3.6.5.4  **Penile curvature**

If present, penile curvature is often released by degloving the penis (skin chordee) and by excision of the connective tissue of the genuine chordee on the ventral aspect of the penis in up to 70% [289]. The urethral plate has well vascularised connective tissue and does not cause curvature in most cases [290, 291]. The residual curvature is caused by corporeal disproportion and requires straightening of the penis, mostly using dorsal midline plication or orthoplasty (modification of the Nesbit plication with or without elevation of the neurovascular bundle). In more severe curvature (> 45°), which is often combined with a short urethral plate requiring transection, ventral penile lengthening is recommended to prevent shortening of the penis. This consists of a ventral transverse incision of the tunica albuginea extending from the 3 to 9 o’clock position patched with tunica vaginalis flap or graft, or in several short ventral corporotomies without grafting (LE: 2b) [292]. After the ventral lengthening, a shorter dorsal midline plication is usually added.

According to a retrospective study, dorsal plication remained significantly associated with recurrent ventral curvature independently of the other factors. Ventral corporeal grafting for severe penile curvature gives good long-term results and safety profiles for erectile function [293] (LE: 2b).

3.6.5.5  **Urethral reconstruction**

The mainstay of hypospadias repair is preservation of the well-vascularised urethral plate and its use for urethral reconstruction has become standard practice in hypospadias repair [291]. Mobilisation of the corpus spongiosum/urethral plate and the bulbar urethra decreases the need for urethral plate transection [292] (LE: 2b). If the urethral plate is wide, it can be tubularised following the Thiersch-Duplay technique. If the plate is too narrow to be simply tubularised, it is recommended relaxing the plate by a midline incision and its subsequent tubularisation according to the Snodgrass-Orkiszewski TIP technique. This technique has become the treatment of choice in distal- and mid-penile hypospadias [294-297]. If the incision of the plate is deep, it is recommended to cover the raw surface with inner preputial (or buccal) inlay graft in primary and secondary repairs [298]. This also enables extension of the incision beyond the end of the plate to prevent meatal stenosis [299, 300] (LE: 2a).

For distal forms of hypospadias, a range of other techniques is available (e.g. Mathieu, urethral advancement) [301] (LE: 2b). The TIP technique has become an option for proximal hypospadias as well [294-297, 302]. However, urethral plate elevation and urethral mobilisation should not be combined with TIP repair because it results in focal devascularisation of the neo-urethra with symptomatic stricture development [303] (LE: 2b). The onlay technique using a preputial island flap is a standard repair, preferred in proximal hypospadias, if a plate is unhealthy or too narrow [289]. An onlay preputial graft is an option for single-stage repair [304] (LE: 2b).

If the continuity of the urethral plate cannot be preserved, single or two-stage repairs are used. For the former, a modification of the tubularised flap (Duckett tube), such as a tube-onlay or an inlay-onlay flap, or onlay flap on albuginea are used to prevent urethral stricture [305-307] (LE: 3); alternatively the Koyanagi-Hayashi technique is used [308-311]. The two-stage procedure has become preferable over the past few years because of lower recurrence of ventral curvature and more favourable results with variable long-term complication rates [300, 305, 312-316].

3.6.5.6  **Re-do hypospadias repairs**

For re-do hypospadias repairs, no definitive guidelines can be given. All the above-mentioned procedures are used in different ways and are often modified according to the individual findings and needs of the patient.
3.6.5.7 Penile reconstruction following formation of the neo-urethra
Following formation of the neo-urethra, the procedure is completed by glansplasty and by reconstruction of the penile skin. If there is a shortage of skin covering, the preputial double-face technique or placement of the suture line into the scrotum according to Cecil-Michalowski is used. In countries where circumcision is not routinely performed, preputial reconstruction can be considered. Preputial reconstruction carries a risk of specific complications but does not seem to increase the risk of urethroplasty complications [317]. In TIP repair, the use of a preputial dartos flap reduces the fistula rate [294, 295] (LE: 2b).

3.6.5.8 Urine drainage and wound dressing
Urine is drained transurethrally (e.g. dripping stent) or with a suprapubic tube. No drainage after distal hypospadias repair is another option [318, 319]. Circular dressing with slight compression, as well as prophylactic antibiotics during surgery, are established procedures [319] (LE: 4). Post-operative prophylaxis after hypospadias repair has limited benefit and it only reduces the risk of asymptomatic bacteriuria [320-322] (LE: 2b). There is no consensus on duration of stenting and dressing.

3.6.5.9 Outcome
Some studies have tried to determine risk factors for complications after hypospadias repair. An analysis of prospectively collected data found glans size (width < 14 mm), proximal meatal location and re-operation as independent risk factors for urethral complication [319, 323]. Low surgeon volume independently increases the risk of fistula, stricture or diverticulum repair [319, 324] (LE: 3).
A meta-analysis of complication rates of TIP repair found lower complication rates and incidence of re-operations in primary distal repairs (in 4.5%) than in primary proximal repairs (in 12.2%) and in secondary repair (in 23.3%) [294-297, 301, 319]. One should expect a predictable outcome with complication rates below 10% in distal hypospadias (fistula, meatal stenosis, dehiscence, recurrent ventral curvature, and haematoma) [324, 325]. A similar incidence of fistula (3.4-3.6%) can be expected after the Mathieu and TIP repairs of distal hypospadias [302, 326-328].

The complication rates of TIP and onlay repairs of primary severe hypospadias are similar, 24% and 27%, respectively. It is higher in free graft and in preputial island tube urethroplasty [289]. There is no strong evidence to suggest that the use of inlay grafts in TIP repair improves the outcome [329].

The complication rates of single-stage Koyanagi and Hayashi modification repairs go up 61%, according to a comparative study [308, 319]. Staged buccal mucosa graft requires a redo grafting in 13% of patients, after the second stage more than one third of patients have complications, mostly with some degree of graft fibrosis [327, 330]. A recent long-term study on two-stage flap repair showed a complication rate of 68% [319]; another study showed a re-operation rate of 28% [300, 319].

3.6.6 Follow-up

Long-term follow-up is necessary up to adolescence to detect urethral stricture, voiding dysfunctions and recurrent penile curvature, diverticula, glanular dehiscence [331]. Up to half of complications requiring re-operation present after the first year post-operatively [332] (LE: 2b).

Obstructive flow curve is common after hypospadias repair and while most are not clinically significant, long-term follow-up is required [333-336] (LE: 2a). Urine flow is significantly lower in patients after hypospadias surgery, especially in those who had corrected chordee, but without significant association with lower urinary tract symptoms (LUTS) [337] (LE: 2a).

Objective scoring systems have been developed in order to evaluate the results of hypospadias surgery (HOSE) [338] (LE: 2b) and cosmetic appearance (HOPE-Hypospadias Objective Penile Evaluation) [339] (LE: 2a). The Pediatric Penile Perception Score (PPPS) is a reliable instrument to assess penile self-perception in children after hypospadias repair and for appraisal of the surgical result by caregivers and uninvolved urologists [340] (LE: 2a). Cosmetic results were judged more optimistically by surgeons as compared to caregivers using validated tools [341]. Current scoring systems have deficiencies in terms of patient reported outcomes, the long term outcomes and sexual function [342].

Adolescents and adults, who have undergone hypospadias repair in childhood, have a slightly higher rate of dissatisfaction with penile size, especially proximal hypospadias patients, but their sexual behaviour is not different from that of control groups [343, 344] (LE: 2a-b). Another long-term follow-up of men born with hypospadias revealed, in a controlled study, that these patients are less satisfied with penile cosmetic outcome according to all parameters of the PPPS; there was a difference in penile length (8.7 vs. 11.6 cm) and more patients had lower maximum urinary flow. More prominent results were found in proximal hypospadias vs. controls [319, 345].

According to a systematic review of long-term patient satisfaction with cosmetic outcomes [346]:

- patient perception of penile size does not differ greatly from the norm;
- patients approaching puberty have a more negative perception and are more critical about the cosmetic outcomes of surgery;
- patients report high levels of perception of deformity and social embarrassment.

There is a wide range of parameters that are measured to assess outcome after hypospadias surgery in the literature. There is a need for age-specific core outcome set [347].

The majority of identified instruments focused on post-operative cosmetic satisfaction, with only one instrument considering urinary function, and no instruments evaluating sexual function and psychosocial sequelae [348].

3.7 **Congenital penile curvature**

### 3.7.1 Epidemiology, aetiology and pathophysiology

Congenital penile curvature presents penile bending of a normally formed penis due to corporal disproportion. The incidence at birth is 0.6% and congenital penile curvature is caused by asymmetry of the cavernous bodies and an orthotopic meatus [349] because of developmental arrest during embryogenesis [350]. On the other hand, the incidence of clinically significant congenital penile curvature is much lower, because the extent of the curvature and its associated sexual dysfunction varies widely [351]. Most of the cases are ventral deviations (48%), followed by lateral (24%), dorsal (5%), and a combination of ventral and lateral (23%) [352]. Most ventral curvatures are associated with hypospadias due to chordee or ventral dysplasia of cavernous bodies [353]. Similarly, dorsal curvature is mostly associated with exstrophy/epispadias complex. Congenital penile curvature can decrease sexual quality of life in adults and successful repair can restore patients’ psychosocial and sexual wellbeing [354].

Curvature > 30° is considered clinically significant; curvature > 60° may interfere with satisfactory sexual intercourse in adulthood (LE: 4). Minor penile curvature may be the result of ventral penile skin deficiency only and should be distinguished from corporal anomalies. For penile curvature associated with hypospadias or epispadias refer to the relevant chapters.

### 3.7.2 Diagnostic evaluation

Penile curvature is frequently not documented until later in childhood since the penis only appears abnormal when erect. Patients are usually concerned with the aesthetic and/or functional aspects of their penis [355]. Besides exact history taking to exclude any possibility of acquired penile curvature (e.g. post-traumatic), a thorough clinical examination is mandatory. In addition, photo documentation of the erect penis clearly showing the curvature from different angles serves as a pre-requisite in pre-operative evaluation [356]. The exact degree of curvature is generally determined at the time of surgery using an artificial erection test.
3.7.3 **Management**

The treatment is surgical, starting with an artificial erection to determine the degree of curvature and to check symmetry after the repair [357]. The ultimate goal of any surgical method used to correct the curvature is to achieve corpora of similar size. Various procedures are in use ranging from simple de-gloving and plication procedures, to corporal rotation, use of free dermal or tunica vaginalis grafts, to complete penile disassembly techniques [358, 359]. Reviews comparing the outcome of Nesbit/modified Nesbit procedures [360] to plication procedures [361] were able to demonstrate that while there is a decreased risk of complications and loss of sensation, it remains unclear whether plication techniques can lead to increased risk of recurrence [362, 363]. Altogether these methods include the risk of post-operative shortening of the penis with an average loss of 2.5 cm in stretched penile length depending on the pre-operative degree of curvature and the type of repair used [364-366].

Recently the non-corporotomy technique has been introduced with promising results enabling correction of any degree of ventral curvature with neither shortening of the penis nor the risk of post-operative erectile dysfunction [367].

3.8 **Varicocele in children and adolescents**

3.8.1 **Epidemiology, aetiology and pathophysiology**

Varicocele is defined as an abnormal dilatation of testicular veins in the pampiniformis plexus caused by venous reflux. It is unusual in boys under ten years of age and becomes more frequent at the beginning of puberty. It is found in 14-20% of adolescents, with a similar incidence during adulthood. It appears mostly on the left side (78-93% of cases). Right-sided varicoceles are less common; they are usually noted only when bilateral varicoceles are present and seldom occur as an isolated finding [368-370].

Varicocele develops during accelerated body growth and increased blood flow to the testes, by a mechanism that is not clearly understood. Genetic factors may be present. An anatomic abnormality leading to impaired venous drainage is expressed by the considerable prevalence of the left side condition where the internal spermatic vein drains into the renal vein. Varicocele can induce apoptotic pathways because of heat stress, androgen deprivation and accumulation of toxic materials. Severe damage is found in 20% of adolescents affected, with abnormal findings in 46% of affected adolescents. Histological findings are similar in children or adolescents and in infertile men. In 70% of patients with grade II and III varicocele, left testicular volume loss was found.

Several authors reported on reversal of testicular growth after varicocelectomy in adolescents [371, 372]. An average proportion of catch-up growth of 76.4% (range: 52.6-93.8%) has been found according to a meta-analysis [373] (LE: 2a). However, this may partly be attributable to testicular oedema associated with the division of lymphatic vessels [374] (LE: 2).

In about 20% of adolescents with varicocele, fertility problems will arise [375]. The adverse influence of varicocele increases with time. Improvement in sperm parameters has been demonstrated after adolescent varicocelectomy [376-379] (LE: 1).
3.8.2 **Classification systems**
Varicocele is classified into 3 grades [380]:
- Grade I - Valsalva positive (palpable at Valsalva manoeuvre only);
- Grade II - palpable (palpable without the Valsalva manoeuvre);
- Grade III - visible (visible at distance).

3.8.3 **Diagnostic evaluation**
Varicocele is mostly asymptomatic, rarely causing pain. It may be noticed by the patient or caregivers, or discovered by the paediatrician at a routine visit. The diagnosis depends upon the clinical finding of a collection of dilated and tortuous veins in the upright posture; the veins are more pronounced when the patient performs the Valsalva manoeuvre. The size of both testicles should be evaluated during palpation to detect a smaller testis.

Venous reflux into the plexus pampiniformis is diagnosed using Doppler US colour flow mapping in the supine and upright position [381]. Venous reflux detected on US only is classified as subclinical varicocele. To discriminate testicular hypoplasia, the testicular volume is measured by US examination or by orchidometer. In adolescents, a testis that is smaller by > 2 mL or 20% compared to the other testis is considered to be hypoplastic [382] (LE: 2).

Extension of Wilms tumour into the renal vein and inferior vena cava can cause a secondary varicocele. A renal US should be routinely added in pre-pubertal boys and in isolated right varicocele (LE: 4). In order to assess testicular injury in adolescents with varicocele, suprarenal FSH and LH responses to the luteinising hormone-releasing hormone (LHRH) stimulation test are considered reliable, because histopathological testicular changes have been found in these patients [378, 383].

3.8.4 **Management**
There is no evidence that treatment of varicocele at paediatric age will offer a better andrological outcome than an operation performed later. Beneficial effect of pubertal screening and treatment for varicocele regarding chance of paternity has been questioned according to a corresponding questionnaire in adult patients [384] (LE: 4). The recommended indication criteria for varicocelectomy in children and adolescents are [369]:
- varicocele associated with a small testis;
- additional testicular condition affecting fertility;
- bilateral palpable varicocele;
- pathological sperm quality (in older adolescents);
- symptomatic varicocele [384].

Testicular (left + right) volume loss in comparison with normal testes is a promising indication criterion, once the normal values are available [385]. Repair of a large varicocele, causing physical or psychological discomfort, may also be considered. Other varicoceles should be followed-up until a reliable sperm analysis can be performed (LE: 4).

Surgical intervention is based on ligation or occlusion of the internal spermatic veins. Ligation is performed at different levels:
- inguinal (or subinguinal) microsurgical ligation;
- suprainguinal ligation, using open or laparoscopic techniques [386-389].

The advantage of the former is the lower invasiveness of the procedure, while the advantage of the latter is a considerably lower number of veins to be ligated and safety of the incidental division of the internal spermatic at the suprainguinal level.

For surgical ligation, some form of optical magnification (microscopic or laparoscopic) should be used because the internal spermatic artery is 0.5 mm in diameter at the level of the internal ring [386, 388]. The recurrence rate is usually < 10%.

Lymphatic-sparing varicocelectomy is preferred to prevent hydrocele formation and testicular hypertrophy development and to achieve a better testicular function according to the LHRH stimulation test [374, 386, 387, 390] (LE: 2). The methods of choice are subinguinal or inguinal microsurgical (microscopic) repairs, or suprainguinal open or laparoscopic lymphatic-sparing repairs [386, 388, 391, 392]. Intrascrotal application of isosulphan blue was recommended to visualise the lymphatic vessels [393, 394]. In suprainguinal approach, an artery sparing varicocelectomy may not offer any advantage in regards to catch-up growth and is associated with a higher incidence of recurrent varicocele [395, 396].

Angiographic occlusion of the internal spermatic veins also meets the requirements of lymphatic sparing repair. It is based on retrograde or antegrade sclerotisation of the internal spermatic veins [397, 398]. However, although this method is less invasive and may not require general anaesthesia, it is associated with radiation burden, which is less controllable in the antegrade technique [369, 397, 398] (LE: 2).
There is low to moderate level of evidence that radiological or surgical treatment of adolescent varicocele is associated with improved testicular size/growth and sperm concentration - based on current available RCTs. The ultimate effects on fertility and paternity rates are not known [399].

Microsurgical varicocele repair in adolescents with varicocele significantly increases paternity rates and decreases time to conception post-operatively. Patients with varicocele who underwent microsurgical varicocele repair had increased sperm parameters and 3.63 times greater odds of paternity than controls who did not undergo varicocele surgery [400].

The Panel conducted a systematic review and meta-analysis regarding the treatment of varicocele in children and adolescents [401]. Of 1,550 articles identified, 98 articles including 16,130 patients were eligible for inclusion (12 RCTs, 47 NRSs and 39 case series). The key findings are summarised in the following paragraphs:

The meta-analysis of the twelve RCTs revealed that varicocele treatment improved testicular volume (mean difference 1.52 ml, 95% CI 0.73-2.31) when compared with observation. Lymphatic sparing surgery significantly decreased hydrocele rates (p=0.02) and the OR was 0.08 (95% CI 0.01, 0.67). Due to the lack of RCTs, it was not possible to identify a surgical technique as being superior to the others. It remains unclear whether open surgery or laparoscopy is more successful for varicocele treatment (OR ranged from 0.13 to 2.84).

The success rates of the treatment (disappearance of varicocele) were between 85.1% and 100% whereas the complication rates were between 0% and 29% in the included studies. The most common complication reported was hydrocele. Resolution of pain after treatment was more than 90% in the reported series.

In conclusion, moderate evidence exists on the benefits of varicocele treatment in children and adolescents in terms of testicular volume and sperm concentration. Current evidence does not demonstrate superiority of any of the surgical/interventional techniques regarding treatment success. Lymphatic sparing surgery significantly decreases hydrocele formation. Long-term outcomes, including paternity and fertility, still remain unknown.

3.9 Urinary tract infections in children

3.9.1 Epidemiology, aetiology and pathophysiology

Urinary tract infections (UTIs) represent the most common bacterial infections in children [402-404]. There are several classification systems used to define a UTI. In neonates, the symptoms differ in many aspects from those in infants and children. The prevalence is higher; there is a male predominance; infections caused by other organisms than Escherichia coli are more frequent; and there is a higher risk of urosepsis [405, 406].

In children presenting with urinary symptoms a pooled prevalence of UTI was 7.8% (CI: 6.6-8.9) [405]. The incidence varies depending on age and sex. One meta-analysis showed that in children presenting with fever in the first three months of life UTIs were present in 7.5% of girls, 2.4% (CI: 1.4-3.5) of circumcised boys, and 20.1% (CI: 16.8-23.4) of uncircumcised boys [405]. The incidence for boys is highest during the first six months of life (5.3%) and decreases with age to around 2% for the ages 0-6 years. In girls, UTIs are less common during the first six months of life (2%) and incidence increases with age to around 11% for the ages 0-6 years [407].

Associated risk factors for recurrent UTIs include bladder and bowel dysfunction (BBD), vesicoureteral reflux (VUR) and obesity [408-410]. In older children a delay in treatment is more often seen than in younger infants [411]. These risk factors in combination with delay in treatment have been associated with renal scarring [412]. Recurrent febrile UTIs, especially in combination with high-grade VUR, lead to renal scarring [413, 414]. Each new febrile UTI increases the risk of renal scarring with an incidence of renal scarring after the first UTI, of 2.8% (CI:1.2-5.8), 25.7% (CI:12.5-43.3) after the second infection and up to 28.6% (CI:8.4-58.1) after 3 or more febrile UTIs [414].

The leading causative organism for UTIs has been E. coli, but other bacteriae have been rising in prevalence. In a large European study E. Coli was found in less than 50% of urine cultures. Klebsiella pneumoniae, Enterobacter spp., Enterococcus spp., Pseudomonas spp., Proteus spp. and Candida spp. are more frequent in nosocomial infections than in community-acquired UTIs, even though, their prevalence has increased outside of the hospital setting [415]. Neonatal UTI is frequently complicated by bacteraemia. In a retrospective study, 12.4% of blood cultures from neonates admitted for UTI were positive for bacteraemia [416], however, it is less frequent in community-acquired than in nosocomial UTI [416, 417].

3.9.2 Classification systems

There are five widely used classification systems according to; site, severity, episode, symptoms and complicating factors. For acute treatment, site and severity are most important.

3.9.2.1 Classification according to site

Lower urinary tract infection (cystitis) is an inflammatory condition of the urinary bladder mucosa with general signs and symptoms including infection, dysuria, frequency, urgency, malodorous urine, enuresis, haematuria, and suprapubic pain.

Upper urinary tract infection (pyelonephritis) is a diffuse pyogenic infection of the renal pelvis and parenchyma. The onset of pyelonephritis is generally abrupt. Clinical signs and symptoms include fever (> 38°C), chills, costovertebral angle or flank pain, and tenderness.

3.9.2.2 Classification according to severity

In a lower UTI, children may have only mild pyrexia; are able to take fluids and oral medication; are only slightly or not dehydrated; and have a good expected level of compliance. When a low level of compliance is expected, such children should be managed as those with severe UTI. In severe UTI, infection is related to the presence of fever of > 39°C, the feeling of being ill, persistent vomiting, or moderate or severe dehydration. Most severe UTIs are upper urinary tract infections.

3.9.2.3 Classification according to episode first/persistent/recurrent/breakthrough

The first UTI may be a sign of anatomical anomalies. Anatomical evaluation is recommended (see below). Recurrent infection can be divided into unresolved and persistent infection.

In unresolved infection, initial therapy is inadequate for elimination of bacterial growth in the urinary tract (inadequate therapy, inadequate antimicrobial urinary concentration [poor renal concentration/gastrointestinal malabsorption], and infection involving multiple organisms with differing antimicrobial susceptibilities).

Persistent infection is caused by re-emergence of bacteria from a site within the urinary tract coming from a nidus for persistent infection that cannot be eradicated (e.g. infected stones, non-functioning or poorly functioning kidneys/renal segments, ureteral stumps after nephrectomy, necrotic papillae, urachal...
cyst, urethral diverticulum, peri-urethral gland, vesicointestinal, rectourethral or vesicovaginal fistulas). The same pathogen is identified in recurrent infections, but episodes of sterile urine may occur during and shortly following antimicrobial treatment.

A breakthrough infection in patients under antibacterial prophylaxis is usually caused by resistant bacteria, parental non-compliance and/or severe urogenital anomalies [418, 419].

In re-infection, each episode can be caused by a variety of new infecting organisms, in contrast to bacterial persistence in which the same infecting organism is always isolated. However, the most common general pathogenic species is \textit{E. coli}, which occurs in many different serotypes. Therefore, recurrent \textit{E. coli} UTI does not equate to infection with the same organism.

3.9.2.4 Classification according to symptoms
Children may have typical or atypical symptoms regarding a UTI.

In neonates and infants the most common symptoms are fever, vomiting, lethargy and/or irritability. Infants and children may have non-specific signs such as poor appetite, failure to thrive, lethargy, irritability, vomiting or diarrhea. Toilet trained children may report cystitis symptoms along with fever/flank pain.

Asymptomatic bacteriuria indicates attenuation of uropathogenic bacteria by the host, or colonisation of the bladder by non-virulent bacteria that are incapable of activating a symptomatic response (no leukocyturia, no symptoms). Asymptomatic UTI includes leukocyturia but no other symptoms.

Symptomatic UTI includes irritative voiding symptoms, suprapubic pain (cystitis), fever and malaise (pyelonephritis). Cystitis may represent early recognition of an infection destined to become pyelonephritis, or bacterial growth controlled by a balance of virulence and host response.

3.9.2.5 Classification according to complicating factors
In uncomplicated UTI, infection occurs in a patient with a morphologically and functionally normal upper and lower urinary tract, normal renal function and competent immune system. This category includes mostly isolated or recurrent bacterial cystitis and is usually associated with a narrow spectrum of infecting pathogens that are easily eradicated by a short course of oral antimicrobial agents. Patients can be managed on an outpatient basis, with an emphasis on documenting resolution of bacteriuria, followed by elective evaluation for potential anatomical or functional abnormalities of the urinary tract [420].

A complicated UTI occurs in children with known mechanical or functional pathology of the urinary tract. Mechanical obstruction is commonly due to the presence of posterior urethral valves, strictures or stones, independent of their location. Functional obstruction often results from lower urinary tract dysfunction (LUTD) of either neurogenic or non-neurogenic origin and dilating VUR. Patients with complicated UTI require hospitalisation and parenteral antibiotics. Prompt anatomical evaluation of the urinary tract is critical to exclude the presence of significant abnormalities [421]. If mechanical or functional abnormalities are present, adequate drainage of the infected urinary tract is necessary.

3.9.3 Diagnostic evaluation
3.9.3.1 Medical history
Medical history includes the question of a primary (first) or secondary (recurring) infection; possible malformations of the urinary tract (e.g. pre- or post-natal US screening); prior operation; family history; and, whether there is constipation or presence of lower urinary tract symptoms (LUTS).

3.9.3.2 Clinical signs and symptoms
Neonates with severe UTI can present with non-specific symptoms (failure to thrive, jaundice, hyperexcitability) and without fever. In neonates it is important to rule out a co-existing meningitis [422]. Urinary tract infection is the cause of fever in 4.1-7.5% of children who present to a paediatric clinic [423, 424]. Septic shock is unusual, even with very high fever. Signs of a UTI may be vague and unspecific in small children, but later on, when they are more than two years old, frequent voiding, dysuria and suprapubic, abdominal or lumbar pain can be detected.

3.9.3.3 Physical examination
Physical examination includes a general examination of the throat, lymph nodes, abdomen (constipation, palpable and painful kidney, or palpable bladder), flank, the back (stigmata of spina bifida or sacral agenesis), genitalia (phimosis, labial adhesion, vulvitis, epididymo-orchitis), measurement of body weight and temperature.

3.9.3.4 Urine sampling, analysis and culture
Urine sampling has to be performed before any antimicrobial agent is administered. The technique for obtaining urine for urinalysis as well as culture affects the rate of contamination, which influences interpretation of the results. Especially in early infancy, it can be challenging and depends on the mode of urine sampling [425].
3.9.3.4.1 Urine sampling

Urine must be collected under defined conditions and investigated as soon as possible to confirm or exclude UTI, especially in children with fever. In neonates, infants and non-toilet-trained children, there are four main methods with varying contamination rates and invasiveness to obtain urine:

(1) Plastic bag attached to the cleaned genitalia: Although this technique is most often used in daily practice, contamination rates are high with around 50-60% [426]. It is helpful when the culture results are negative. Also, if the dipstick is negative for both leukocyte esterase and nitrite, or microscopic analysis is negative for both pyuria and bacteriuria, UTI can be excluded without the need for confirmatory culture [427].

(2) Clean-catch urine (CCU) collection: The infant is placed in the lap of a caregiver or member of the nursing staff, who holds a sterile foil bowl underneath the infant’s genitalia. The infant is offered oral fluids and urine collection is awaited [428]. Suprapubic tapping alternated with paravertebral lumbar massage can stimulate spontaneous voiding [426, 429]. There seems to be a good correlation between the results of urine culture obtained by this method and suprapubic aspiration (SPA), with a false-positive rate of 5% and false-negative rate of 12% [428, 430]; however, the contamination rate is higher for CCU with up to 26% compared to catheterisation 10% and SPA 1% [426, 431]. In one prospective cohort study in infants below the age of six months, the success rate was 49% and the contamination rate 16% with some differences in the culture results between those obtained by CCU and those by more invasive methods [432].

(3) Transurethral bladder catheterisation: is the fastest and safest method to obtain a reliable urine sample for microscopic and bacteriological evaluation to rule out or to document a UTI in non-toilet trained infants and children.

(4) Suprapubic bladder aspiration: This is the most invasive but also the most sensitive method to obtain an uncontaminated urine sample in this age group [433, 434]. For suprapubic puncture ultrasound imaging should be performed to assess bladder filling.

A two-step procedure where the CCU is screened and a catheter or SPA confirmation of the positive screens is used can lead to a reduction in invasive procedures [426, 431].

In older, toilet-trained children who can void on command, after carefully retracting the foreskin and cleaning the glans penis in boys and spreading the labia and cleaning the peri-urethral area in girls, the use of clean catch, especially midstream urine, could be an acceptable technique for obtaining urine. After cleaning the urethral meatus and perineum with gauze and liquid soap twice, the risk of contamination was reduced from 23.9% (41/171) to 7.8% (14/171) in a randomised trial [435].

3.9.3.4.2 Urinalysis

There are three methods that are commonly used for urinalysis:

(1) Dipsticks: These are appealing because they provide rapid results, do not require microscopy, and are ready to use. Leukocyte esterase (as a surrogate marker for pyuria) and nitrite (which is converted from dietary nitrates by most Gram-negative enteric bacteria in the urine) are the most frequent markers, and are usually combined in a dipstick test. The conversion of dietary nitrates to nitrites by bacteria takes approximately four hours in the bladder [430, 436]. Using only nitrate sticks to screen febrile children < 2 years of age has a too low sensitivity and relevant UTIs can be missed. However, the specificity is high for children at any age [437, 438]. In febrile infants < 90 days old urine dipstick tests using CCU samples can be used for screening for a UTI when nitrites and leukocyte esterase combined are used with a sensitivity of 86% and a specificity of 80% [439].

(2) Microscopy: This is the standard method of assessing pyuria after centrifugation of the urine with a threshold of five white blood cells (WBCs) per high-power field (25 WBC/μL) [440]. In uncentrifuged urine, > 10 WBC/μL has been demonstrated to be sensitive for UTI [441] and this could perform well in clinical situations [442]. However, this is rarely done in an outpatient setting. No significant differences was found between dipsticks and microscopy testing for UTI [438]. A meta-analysis showed, that only microscopy with Gram staining has a higher sensitivity compared to dipsticks [443].

(3) Flow imaging analysis technology: This is being used increasingly to classify particles in uncentrifuged urine specimens [444]. The numbers of WBCs, squamous epithelial cells and red cells correlate well with those found by manual methods [430]. Flow cytometry-based bacterial and leukocyte count analysis when using a cut-off value of 250 bacteria/μL in the presence of leukocyturia has a sensitivity of 0.97 and specificity of 0.91 for diagnosing UTI [445].
3.9.3.4.3 Urine culture

After negative results for dipstick, microscopic or automated urinalysis, urine culture is generally not necessary, especially if there is an alternative source of fever. If the dipstick result is positive, confirmation by urine culture is strongly recommended.

It is unclear what represents a significant UTI. In patients with a severe UTI, $\geq 10^5$ cfu/mL can be expected. However, the count can vary and be related to the method of specimen collection, diuresis, and time and temperature of storage until cultivation occurs [406]. Clean-catch urine, midstream and catheterisation urine cultures can be considered positive as $10^3 - 10^4$ cfu/mL in a monoculture, and any counts obtained after SPA should be considered as significant. Mixed cultures are indicative of contamination. In febrile children < 4 months of age a cut-off value of $10^3$ cfu/mL can be used when clinical and laboratory findings match and a correct sampling method has been used [446].

A negative culture with the presence of pyuria may be due to incomplete antibiotic treatment, urolithiasis, or foreign bodies in the urinary tract, and infections caused by Mycobacterium tuberculosis or Chlamydia trachomatis.

A flowchart was developed as guidance during the basic diagnostic evaluation and subsequent management of febrile children with clinical symptoms of UTI, Figure 4.

**Figure 4: Diagnostic evaluation and subsequent management of a febrile child with clinical symptoms of UTI**

![Flowchart](image)

CRP = C-reactive protein; AB = antibiotic.

3.9.3.5 Imaging

3.9.3.5.1 Ultrasound

Renal and bladder US within 24 hours is advised in infants with febrile UTI to exclude obstruction of the upper and lower urinary tract. Abnormal results are found in 15% of cases, and 1-2% have abnormalities that require prompt action (e.g., additional evaluation, referral or surgery) [427]. When a renal US is performed in all children presenting with a UTI, 7% will have an abnormal US warranting further investigations [447]. The sensitivity to detect high-grade VUR with US was found to be 0.59 (CI: 0.45-0.72) with a specificity of 0.79 (CI: 0.65-0.87) [448]. Renal US should be performed before and after voiding. Post-void residual (PVR) urine should be measured in toilet-trained children to exclude voiding abnormalities as a cause of UTI. Elevated PVR urine volume predicts recurrence of UTIs in toilet-trained children [449]. When peri-renal or psoas abcesses or renal masses are seen on US, it is important to consider xanthogranulomatous pyelonephritis, and subsequent CT imaging is proposed [450].
3.9.3.5.2 Radionuclide scanning/MRI
Changes in dimercaptosuccinic acid (DMSA) clearance during acute UTI indicate pyelonephritis or parenchymal damage, correlated with the presence of dilating reflux and the risk of further pyelonephritis episodes, breakthrough infections [451] and future renal scarring. In the acute phase of a febrile UTI (up to four to six weeks), DMSA-scan can demonstrate pyelonephritis by perfusion defects. Renal scars can be detected after three to six months [452]. Diffusion-weighted MRI has shown to accurately diagnose acute pyelonephritis and reveal late renal scars and could be an alternative to DMSA; therefore, avoiding radion burden [453]. The average effective radiation dose of a single DMSA scan was 2.84 (1-12) mSv in one study [454]. These findings are different in neonates. After the first symptomatic, community-acquired UTI, the majority of renal units with VUR grade III or higher had normal early DMSA scanning [455]. The sensitivity of the DMSA scan to detect VUR is 0.75 (CI: 0.67-0.81) with a specificity of 0.48 (CI: 0.38-0.57), and a negative DMSA scan resulting in a very low probability of high-grade VUR [456].

3.9.3.5.3 Voiding cystourethrography/urosonography
The optimum method to exclude or confirm VUR is VCUG. The timing of VCUG does not influence the presence or severity of VUR [457]. Performance of early VCUG in patients with proven sterile urine does not cause any significant morbidity [458]. Using harmonic voiding urosonography may be an alternative to the standard VCUG avoiding radiation [459]. Visualisation of the urethra may be difficult with this technique.

It is important to diagnose high-grade VUR after the first UTI since this is an important risk for renal scarring. On the other hand, physicians want to avoid unnecessary VCUG investigations at the same time, given its invasive character and radiation burden [447, 460]. Various studies have investigated the risk factors for high-grade VUR and a top down approach is feasible. The most important risk factors for high-grade VUR and subsequent renal scarring are: abnormal renal US, high fever UTI and non-E. Coli infections. Different top down strategies with selective VCUG investigations have been proposed [461-465]. Based on these studies we recommend the following updated diagnostic strategy (see Figure 5).

**Figure 5: Diagnosis strategy for first febrile UTI**

UTI = urinary tract infection; VUR = vesicoureteral reflux; i.v. = intravenous.
3.9.4 Management

3.9.4.1 Administration route of antibacterial therapy

The choice between oral and parenteral therapy should be based on patient age; clinical suspicion of urosepsis; illness severity; refusal of fluids, food and/or oral medication; vomiting; diarrhoea; non-compliance; and complicated pyelonephritis (e.g. urinary obstruction). As a result of the increased incidence of urosepsis and severe pyelonephritis in newborns and infants aged less than two months, parenteral antibiotic therapy is recommended. Electrolyte disorders with life-threatening hyponatraemia and hyperkalaemia based on pseudohypoaldosteronism can occur in these cases [466, 467].

The choice of agent is also based on local antimicrobial sensitivity patterns, and should later be adjusted according to sensitivity-testing of the isolated uropathogen [430]. Not all available antibiotics are approved by national health authorities, especially in infancy. When recent urinary cultures are available use these sensitivity patterns in the choice for treatment. In children who require intravenous treatment tobramycin or gentamicin is recommended if there is normal kidney function. When abnormal kidney function is suspected, ceftriaxone or cefotaxime are alternative treatment options. In children who can receive oral treatment without any known resistant urinary cultures, cefixime or amoxicillin-clavulanate are the empirical treatment options [468]. Some studies have demonstrated that once daily parenteral administration of gentamicin or ceftriaxone in a day treatment centre is safe, effective and cost-effective in children with UTI [469-471]. Delaying treatment in children with a febrile UTI for more than 48-72 hours increases the risk of renal scars [412, 472].

3.9.4.2 Duration of therapy

Prompt adequate treatment of UTI can prevent the spread of infection and renal scarring. In newborns and young infants with a febrile UTI, up to 20% may have a positive blood culture [416, 421]. Children with bacteremia did not show significant clinical differences with non-bacteremic infants, but did receive longer parental treatment [473]. In late infancy, there are no differences between strategies regarding the incidence of parenchymal scars, as diagnosed with DMSA scan [474]. Outcomes of short courses (one to three days) are inferior to seven to fourteen-day courses [430]. However, a simple cystitis can be treated with three to five days of antibiotics [468]. No significant difference in recurrent UTIs and rehospitalisation was found between seven day parental treatment and longer regimens for bacteremic UTI in younger infants [475]. In young infants a short course of parental treatment with early conversion to oral antibiotics may be considered. The use of exclusively oral therapy with a third-generation cephalosporin (e.g. cefixime or cefetibuten) has been demonstrated to be equivalent to the usual two to four days intravenous therapy followed by oral treatment [476-479]. Similar data have been shown for amoxicillin-clavulanate [480]. If ambulatory therapy is chosen, adequate surveillance, medical supervision and, if necessary, adjustment of therapy must be guaranteed. In the initial phase of therapy, a close ambulant contact to the family is advised [481].

In complicated UTI, uropathogens other than E. coli, such as Proteus mirabilis, Klebsiella spp., Pseudomonas aeruginosa, enterococci and staphylococci are more often the causative pathogens [421]. A temporary urinary diversion (transurethral catheter, suprapubic cystostomy, percutaneous nephrostomy or ureteral stenting) might be required in case of failure of conservative treatment in obstructive uropathy. Children with acute focal bacterial nephritis often present without pyuria and significant bacteruria. For the majority of children, the pathogenesis is related to ascending infection due to pre-existing uropathy, especially VUR or urinary obstruction. Initial management consists of broad-spectrum antibiotics with good tissue penetration. A treatment regimen of a total of three weeks with initial intravenous and subsequently oral therapy tailored to the pathogen identified in culture is recommended [482].

3.9.4.3 Antimicrobial agents

There is a great difference in the prevalence of antibiotic resistance of uropathogenic E. coli in different countries, with increased high resistance patterns in countries outside of the Organisation for Economic Co-operation and Development (OECD) [483]. There are upcoming reports of UTIs caused by extended spectrum ß-lactamase-producing enterobacteriaes (ESBL) in children, with pooled numbers of UTI caused by ESBL producing bacteria of around 14% [484]. Within OECD countries the prevalence of resistance was 53% for ampicillin, 24% for trimethoprim, 8% for co-amoxiclav, 2% for ciproxin and 1% for nitrofurantoin [483]. Several risk factors and determinants for UTIs caused by ESBL and non-E. Coli bacteriae have been identified: history of infection, recent hospitalisation, short-term exposure to antibiotics, and prophylaxis [483, 485, 486]. Overall, oral nitrofurantoin seems to be a good empirical choice in the treatment of cystitis [487].

The choice of antibiotics should be guided by good antibiotic stewardship. It is important to be aware of the local resistance patterns. These are variable between countries and moreover between hospitals. Local antibiotic protocols and web-based recommendations can guide the choice for type of antibiotic therapy. The individual patient’s previous urine cultures should also be taken into account in this decision. The daily dosage of antibiotics is depended on the age, weight of the child as well as on renal and liver function.
3.9.4.4 Preventative measures

Recurrent UTIs are problematic because the symptoms are bothersome to children and recurrent febrile UTIs will also result in renal scarring [414]. Therefore, it is important to prevent the incidence of recurrent UTIs.

3.9.4.4.1 Chemoprophylaxis

Chemoprophylaxis is commonly used to prevent UTIs in children. However, with the increasing bacterial resistance numbers, it should be carefully considered which patients should receive antibacterial prophylaxis. The evidence for the use of antibacterial prophylaxis has been conflicting. Its use causes a reduction of the number of recurrent symptomatic UTIs, but long-term use of antibacterial prophylaxis has also been associated with increased microbial resistance [418, 488]. Its use did not reduce newly acquired renal damage in children with first or second UTI [488]. However, when used in patients with anatomic abnormalities of the urinary system a reduction in UTIs and subsequent renal scarring was shown [418, 488]. In children with BBD and VUR, a benefit was seen in the reduction of recurrent UTI with the use of antimicrobial prophylaxis [489, 490] (see also Chapter 3.14 on VUR). For the specific group of patients with incomplete bladder emptying with properly performed clean intermittent catheterisation but still suffering from recurrent UTIs the intravesical application of gentamycin has proven to be effective [491].

** Substances of first choice are nitrofurantoin and trimethoprim. In exceptional cases, oral cephalosporin can be used.

3.9.4.4.2 Dietary supplements

Cranberry, mostly as juice, has been shown to prevent UTIs in healthy children, while in children with urogenital abnormalities, cranberries appear to be just as effective as antibiotic prophylaxis [493]. The results for probiotics are somewhat more conflicting, with one systematic review not ruling out any effect [298] and a RCT showing promising results in children with normal urogenital anatomy [494]. A meta-analysis could not demonstrate a beneficial effect, only as an adjuvant to antibiotic prophylaxis [495].

Other supplements of interest were Vitamin A, which showed promising results in preventing renal scarring in children with acute pyelonephritis [496, 497]. The use of Vitamin E could possibly improve the symptoms of UTI [498]. More studies into these supplements are warranted.

3.9.4.4.3 Preputium

A risk reduction of recurrent UTI regarding the preputium has been shown in two studies. When a physiologic phimosis is present in boys with a UTI the use of steroid cream significantly reduced recurrent UTIs [499]. In boys with recurrent UTIs and hydronephrosis present, ten boys would need to be circumcised to prevent one UTI [34].

3.9.4.4.4 Bladder and bowel dysfunction

Bladder and bowel dysfunction is a risk factor for which each child with UTI should be screened upon presentation [409]. Normalisation of micturition disorders or bladder overactivity is important to lower the rate of UTI recurrence. If there are signs of BBD at infection-free intervals, further diagnosis and effective treatment are strongly recommended [490]. Treatment of constipation leads to a decrease in UTI recurrence and a multidisciplinary approach is recommended [409, 489, 490]. Therefore, exclusion of BBD is strongly recommended in any toilet-trained child with febrile and/or recurrent UTI, and it should be treated (For treatment see chapter 3.10 on LUTS).

3.9.4.5 Monitoring of UTI

With successful treatment, urine usually becomes sterile after 24 hours, and leukocyturia normally disappears within three to four days. Normalisation of body temperature can be expected within 24-48 hours after the
start of therapy in 90% of cases. In patients with prolonged fever and failing recovery, treatment-resistant uropathogens or the presence of congenital uropathy or acute urinary obstruction should be considered. Repeated US examination is recommended in these cases.

Procalcitonin (among other laboratory inflammatory parameters such as C-reactive protein and leukocyte count) can be used as reliable serum marker for early prediction of renal parenchymal inflammation [500]. A cut-off value of serum procalcitonin of 1.0 ng/mL has been shown to be predictive of acute pyelonephritis in young children [501]. In patients with febrile UTI, serum electrolytes and blood cell counts should be followed up.

### 3.10 Day-time lower urinary tract conditions

#### 3.10.1 Terminology, classification, epidemiology and pathophysiology

Urinary incontinence in children may be caused by congenital anatomical or neurologic abnormalities such as ectopic ureter, bladder exstrophy or myelomeningocele (MMC). In many children, however, there is no such obvious cause for the incontinence, and they are referred as having functional bladder problems. The most
recent International Children’s Continence Society (ICCS) document suggests using the term day-time lower urinary tract (LUT) conditions to group together all functional bladder problems in children.

Normal storage and emptying of the bladder at a socially accepted place and time is mostly achieved by age three to four. Children with LUT conditions would present with failure to achieve continence (being still wet after the age of four), urgency, weak stream, hesitancy, frequency and accompanied UTIs. Isolated night-time wetting without any day-time symptoms is known as ‘enuresis’ and considered as a different entity (see chapter 3.11) [502].

As different studies have used varying definitions and criteria, it is difficult to give reliable percentages regarding the incidence of this problem. Reported prevalence ranges widely from 1% to 20% [503-511]. Due to increasing awareness and better access to specialised health care, the prevalence seems to be increasing [512, 513].

Lower urinary tract conditions in children may be due to disturbances of the filling phase, the voiding phase or a combination of both in varying severity. Mainly the conditions are divided into either overactive bladder (OAB) or dysfunctional voiding. They can, of course, coincide and one may even be causative of the other. Dysfunctional bowel emptying may also be part of the clinical problems and BBD is the term used to cover concomitant bladder and bowel disturbances.

Lower urinary tract conditions are considered to be the result of incomplete or delayed maturation of the bladder sphincter complex. The pons is considered to be responsible for detrusor sphincter co-ordination while the cortical area is responsible for inhibition of the micturition reflex and voluntary initiation of micturition. Therefore overactivity would be the result of delayed maturation of cortical control, while dysfunctional voiding would be the result of non-maturation of the co-ordination. Detrusor overactivity should not be considered as a sole bladder based problem but more a symptom of a centrally located dysfunction affecting bladder, bowel and even mood and behaviour [514].

A link between LUT and behavioural disorders such as ADHD (attention deficit/ hyperactivity disorder) has also been shown [515-517].

3.10.1.1 Filling-phase (storage) dysfunctions
In filling-phase dysfunctions, the detrusor can be overactive, as in OAB, or underactive, as in underactive bladder (UAB). Overactivity of the bladder is the most common problem, seen mostly around five to seven years of age. This may lead to disturbances characterised by urgency, frequency and at times urgency incontinence. Some children habitually postpone micturition leading to voiding postponement. Therefore, holding manoeuvres such as leg crossing and squatting can often be seen in this group. Recurrent UTIs are common and high-pressure state of the bladder can be a cause of VUR. Constipation can be an additional aetiological factor, which needs to be assessed. In children with an underactive detrusor, voiding occurs with reduced or minimal detrusor contractions with post-void residuals. Urinary tract infections, straining to void, constipation and incontinence is common. Incontinence often occurs when the bladder is over-distended in the form of overflow incontinence.

3.10.1.2 Voiding-phase (emptying) dysfunctions
In voiding-phase (emptying), incomplete relaxation or tightening of the sphincteric mechanism and pelvic floor muscles results in staccato voiding pattern (continuous urine flow with periodic reductions in flow rate precipitated by bursts of pelvic floor activity) or an interrupted voiding pattern (unsustained detrusor contractions resulting in infrequent and incomplete voiding, with micturition in fractions). The general term for this condition is dysfunctional voiding and is associated with elevated bladder pressures and PVRs. Symptoms will vary depending on the severity of inco-ordination between bladder and the sphincter. Staccato voiding is in less severe forms and interrupted voiding and straining is in more severe forms. The co-existence of constipation and LUTD and recurrent UTI is well described [518]. There is no evidence to conclude if bladder problems or bowel problems are the leading cause. The prevalence of constipation in older children varies from 5 to 27%. Approximately 90% of them being functional constipation without an organic cause In children with functional constipation the prevalence of bladder symptoms have been shown to be as high as 64% [519, 520].

In incomplete emptying, high voiding pressures generated by bladder working against a functional obstruction caused by non-relaxing sphincter may induce not only UTIs but also VUR. It is been shown that LUTD is more significant for the occurrence of UTI than VUR itself [521]. In the majority of children with dysfunctional voiding the recurrent infections disappear following successful treatment, which confirms the hypothesis that
dysfunctional voiding is the main factor responsible for the infections. Spontaneous resolution of VUR may also be seen after successful treatment of dysfunctional voiding.

### 3.10.2 Diagnostic evaluation

The evaluation of LUT conditions includes medical and voiding history (bladder diaries and structured questionnaires), a physical examination, a urinalysis, and uroflowmetry with PVR. The upper urinary tract (UUT) needs to be evaluated in children with recurrent infections and dysfunctional voiding. Uroflowmetry can be combined with pelvic floor electromyography to demonstrate overactivity of the pelvic floor muscles during voiding. Urodynamic studies are usually reserved for patients with therapy-resistant dysfunctional voiding and those not responding to treatment who are being considered for invasive treatment [517, 522-525].

In addition to a comprehensive medical history a detailed voiding diary provides documentation of voiding and defecation habits, frequency of micturition, voided volumes, night-time urine output, number and timing of incontinence episodes, and fluid intake. A voiding diary should at least be done for two days, although longer observation periods are preferred. A voiding diary provides information about storage function and incontinence frequency, while a pad test can help to quantify the urine loss. In the paediatric age group, where the history is taken from both the caregivers and child together, a structured approach is recommended using a questionnaire. Many signs and symptoms related to voiding and wetting will be unknown to the caregivers and should be specifically requested, using the questionnaire as a checklist. Some symptom scorings have been developed and validated [526, 527]. Although the reliability of questionnaires are limited they are practical in a clinical setting to check the presence of symptoms and have also been shown to be reliable to monitor the response to treatment. History taking should also include assessment of bowel function. For evaluation of bowel function in children, the Bristol Stool Scale is an easy-to-use tool [528, 529].

Urinalysis and urinary culture are essential to evaluate for UTI. Since transient voiding symptoms are common in the presence of UTI, exclusion of UTI is essential before further management of symptoms. During clinical examination, genital inspection and observation of the lumbosacral spine and the lower extremities are necessary to exclude obvious uropathy and neuropathy.

Uroflowmetry with PVR evaluates the emptying ability, while an UUT US screens for (secondary) anatomical changes. A flow rate which reaches its maximum quickly and levels off ('tower shape') may be indicative of over-active bladder whereas interrupted or staccato voiding patterns may be seen in dysfunctional voiding. Plateau uroflowmetry patterns are usually seen in anatomic obstruction of flow. A single uroflowmetry test may not always be representative of the clinical situation and multiple uroflowmetry tests, which all give a similar result, are more reliable. Uroflowmetry examination should be done when there is desire to empty the bladder and the voided volume should at least be 50% of the age-expected capacity [(age in years) + 1] x 30 mL for the children. While testing the child in a clinical environment, the impact of stress and mood changes on bladder function should also be taken into account [530, 531].

In the case of treatment failure re-evaluation is warranted and (video)-urodynamic (VUD) studies and neurological evaluation may be considered. Sometimes, there are minor, underlying, urological or neurological problems, which can only be suspected using VUD. In these cases, structured psychological interviews to assess social stress should be added [532] (LE: 1b).

Video-urodynamics may also be used as initial investigational tool in patients with suspicion of reflux. In this case reflux may be observed along with bladder dynamics. In the case of anatomical problems, such as posterior urethral valve (PUV) problems, syringoceles, congenital obstructive posterior urethral membrane (COPUM) or Moormann’s ring, it may be necessary to perform cystoscopy with treatment. If neuropathic disease is suspected, MRI of the lumbosacral spine and medulla can help to exclude tethered cord, lipoma or other rare conditions.

### 3.10.3 Management

The treatment of LUTD involves a multimodal approach, involving strategies such as behavioural modification, and anticholinergic medication along with underlying and potentially complicating conditions such as constipation and UTIs.

Behavioural modification, mostly referred to as urotherapy, is a term which covers all non-pharmacological and non-surgical treatment modalities. It includes standardisation of fluid intake, bowel management; timed voiding and basic relaxed voiding education. The child and family are educated about normal bladder function and responses to urgency. Voiding regimens are instituted and UTIs and any constipation are treated. Treatment is aimed at optimising bladder emptying and inducing full relaxation of the urinary sphincter or pelvic floor prior to and during voiding.
Strategies to achieve these goals include:

1. Information and demystification, which includes explanation about normal LUT function and how a particular child deviates from normal function.
2. Instructions about what to do about the problem:
   - Regular voiding habits, sound voiding posture, pelvic floor awareness and training to relax pelvic floor and avoiding holding manoeuvres.
   - Lifestyle advice, regarding fluid intake, prevention of constipation, etc.
   - Registration of symptoms and voiding habits using bladder diaries or frequency-volume charts.
   - Support and encouragement via regular follow-up by the caregiver.

Recurrent UTIs and constipation should also be treated and prevented during the treatment period. In case of combined BBD it is advised to treat the bowel dysfunction first [512] as LUTS may disappear after successful management of bowel dysfunction.

Addition of other strategies, as below, may be needed:

- Pelvic floor muscle awareness practices with repeated sessions of biofeedback visualisation of uroflow curves and/or pelvic floor activity and relaxation.
- Clean intermittent self-catheterisation for large PVR volumes of urine.
- Antimuscarinic drug therapy if detrusor overactivity is present.
- If the bladder neck is associated with increased resistance to voiding, α-blocker drugs may be introduced.

Treatment efficacy can be evaluated by improvement in bladder emptying and resolution of associated symptoms. Controlled studies of the various interventions are needed. As with detrusor overactivity, the natural history of untreated dysfunctional voiding is not well delineated and optimum duration of therapy is poorly described. A high success rate has been described for urotherapy programmes, independent of the components of the programme. However, the evidence level is low as most studies of urotherapy programmes are retrospective and non-controlled [533]. A recent Cochrane analysis found very little evidence that can help to make evidence-based treatment decisions [534].

3.10.3.1 Specific interventions

As well as urotherapy, there are some specific interventions, including physiotherapy (e.g. pelvic floor exercises), biofeedback, alarm therapy and neuromodulation. Although good results with these treatment modalities have been reported, the level of evidence remains low, since only a few RCTs were published [535-541].

A systematic review reports that biofeedback is an effective, non-invasive method of treating dysfunctional voiding, and approximately 80% of children benefited from this treatment. However, most reports were of low level of evidence and studies of more solid design such as RCTs should be conducted [542]. A more recently published multicentre controlled trial of cognitive treatment, placebo, oxybutynin and bladder and pelvic floor training did not report better results with oxybutynin and pelvic floor training compared to standard urotherapy [532] (LE: 1b).

Two RCTs on underactive bladder without neurophatic disease have recently been published. Transcutaneous interferential electrical stimulation and animated biofeedback with pelvic floor exercise have been shown to be effective [543, 544]. In some cases, pharmacotherapy may be added. Some studies on orthosympathicomimetics have been published with a low level of evidence [545].

Overactive bladder is common in the paediatric population. Although a stepwise approach starting with behavioural therapy is advised, antimuscarinic agents remain the mainstay of medical treatment for OAB. Oxybutynin is the most commonly used antimuscarinic in the paediatric population. The response to antimuscarinics varies and many children experience serious side effects. Although there have been reports about the use of tolterodine, fesoterodine, trospium, propiverine, and solifenacin in children, to date, most of them are off-label depending on age and national regulations. A few RCTs have been published, one on tolterodine showed safety but not efficacy [546], while another on propiverine showed both safety and efficacy [547] (LE:1). The recent study on solifenacin showed its efficacy with side effects like constipation and electrocardiogram changes [548].

The difference in results is probably due to study design. Despite the low level of evidence for the use of anticholinergics and antimuscarinics, their use is recommended because of the large number of studies reporting a positive effect on OAB symptoms. Although α-blocking agents are used occasionally, an RCT showed no benefit [549]. Botulinum toxin injection seems promising, but can only be used off-label [550].
A meta-analysis reports that neuromodulation therapy may lead to better partial improvement of nonneurogenic OAB; however, it may not render a definitive complete response. Office-based neuromodulation seems more efficacious than self-administered neuromodulation [551]. These new treatment modalities can only be recommended for standard therapy-resistant cases [552]. Despite early successful treatment, there is evidence that there is a high recurrence rate of symptoms in the long term which necessitates long-term follow-up [553]. In addition, many patients may present later in adulthood with different forms of LUTD [554].

3.11 Monosymptomatic nocturnal enuresis - bedwetting

3.11.1 Epidemiology, aetiology and pathophysiology

Monosymptomatic nocturnal enuresis (NE), also known as bedwetting, is defined as an intermittent nocturnal incontinence. It is a relatively frequent symptom in children, 5-10% at seven years of age and 1-2% in adolescents. There is a gender difference in the incidence: two boys to one girl at any age [555]. With a spontaneous yearly resolution rate of 15% (at any age), it is considered as a relatively benign condition [530, 556]. Seven out of 100 seven-year-old bedwetting children will continue to wet their bed into adulthood. Nocturnal enuresis is considered primary when a child has not yet had a prolonged period of being dry (six months). The term “secondary NE” is used when a child or adult begins wetting again after having stayed dry.

Non-monosymptomatic NE is defined as the condition of NE in association with day-time lower urinary tracts symptoms (LUTS, recurrent UTIs and/or bowel dysfunction) [556, 557]. The presence of constipation has a negative association with bladder capacity [558].

Nocturnal enuresis has significant secondary stressful, emotional and social consequences for the child and their caregivers. A lower quality of life has been reported for children with NE compared to controls and NE can influence relationships with friends and family [559-562]. Therefore, treatment is advised from the age of six to seven years onwards considering mental status, family expectations, social issues, and cultural background.

There is a clear hereditary factor in NE. If none of the parents or their immediate relatives has suffered from bedwetting, the child has a 15% chance of wetting its bed. If one of the parents, or their immediate relatives have suffered from bedwetting, the chance of bedwetting increases to 44%, and if both parents have a positive history the chance increases to 77%. However, from a genetic point of view, enuresis is a complex and heterogeneous disorder. Loci have been described on chromosomes 12, 13 and 22 [557].

Children with NE are considered deep but poor sleepers due to high arousal thresholds and frequently disturbed sleep. High arousal threshold is the most important pathophysiological factor in the aetiology of NE: the child does not wake up when the bladder is full. Full night polysomnographic recordings support this hypothesis by demonstrating the disruption of children’s sleep microstructure [563]. In addition to the high arousal threshold, there needs to be an imbalance between night-time urine output and night-time bladder
capacity [530, 556, 557]. Recently, attention has been given to the chronobiology of micturition in which the existence of a circadian clock in kidney, brain and bladder is postulated [564].

A high incidence of comorbidity and correlation between nocturnal urine production and sleep disordered breathing, such as obstructive sleep apnoea, has been found and investigated [565, 566]. Symptoms such as habitual snoring, apnoeas, excessive sweating at night and mouth breathing in the patient history or via sleep questionnaires, such as the BEARS questionnaire [567], can lead to the detection of sleep disorders and/or adenotonsillar hypertrophy. When present, a consultation with the ENT specialist can be considered [568].

Obesity is associated with a higher incidence of NE and a lower efficacy for treatment [569]. The presence of allergic diseases has been recognised as a risk factor of NE and with a greater risk for more allergic episodes [570-572].

It is important to consider the child’s and family’s psychological status as primary NE has been associated with psychopathology, such as Attention Deficit Hyperactivity Disorder (ADHD) and depressive symptoms [573, 574]. In children with ADHD symptoms of NE are more severe and it is important to inform the child and the parents about a delayed success rate and higher relapse rate compared to children without ADHD [575].

3.11.2 Diagnostic evaluation

The diagnosis is mainly obtained by history-taking. Focused questions to differentiate monosymptomatic vs. non-monosymptomatic, primary vs. secondary, comorbid factors such as behavioural or psychological problems and sleep disorder breathing, should be asked. In addition, a two-day complete micturition and drinking diary, which records day-time bladder function and drinking habits will further exclude comorbid factors such as LUTS and polydipsia.

Specific attention should be made regarding bowel movements as irregular bowel movements can change the diagnosis from monosymptomatic NE to non-monosymptomatic NE. If constipation or faecal incontinence is found (it is reported in up to 20% of children with NE), it should be treated simultaneously, and the family should be informed that constipation can negatively influence treatment outcomes [576, 577].

The night-time urine production should be registered by weighing the night-time diapers in the morning and adding the first morning voided volume [578]. The night-time urine production should be recorded over (at least) a two-week period to diagnose an eventual differentiation between a high night-time production (more than 130% of the age expected bladder capacity) vs. a night-time OAB.

A physical examination should be performed with special attention to the back of the child (to exclude any neurological problem), the external genitalia and surrounding skin, as well as to the condition of the clothes (wet underwear or encopresis).

Urine analysis is indicated if there is a sudden onset of bedwetting, a suspicion or history of UTIs, or inexplicable polydipsia.

A uroflowmetry and US is indicated only if there is a history of previous urethral or bladder surgery and presence of daytime urinary symptoms. For further evaluation, see Section 3.10 on Day-time LUT conditions.

There is no clinical indication nor use for a functional MRI (fMRI) in the diagnostic of NE. Research is ongoing, however one of the main issues is the fact that the MRI is performed in an awake state, whereas the NE is a solely event during sleep. The use of fMRI in the elucidation of the NE’s neuropathological mechanisms has not yet been fruitful [579, 580].

3.11.3 Management

Before introducing any form of possible treatment, it is of utmost importance to explain the bedwetting condition to the child and the caregivers in order to demystify the problem. Parents should be encouraged to seek medical attention for their bedwetting children and be informed that it is known that the quality of life of parents with a child with NE is negatively impaired. Medical providers assisting families with a child must be aware of this fact and therefore guide parents, by explaining that the key role for treating a child with NE is the ability to understand and the co-operation of the child itself [581].

Since the COVID-19 pandemic situation and promotion of virtual contacts between doctors and patients, it has been shown that telemedicine is a good method of closely follow-up and can be used for follow-up after treatment [582].

3.11.3.1 Supportive treatment measures

Initially, supportive measures including normal and regular eating and drinking habits should be reviewed, stressing normal fluid intake during the day and reducing fluid intake in the hours before sleep. Keeping a chart depicting wet and dry nights, also called as basic bladder advice, has not been shown to be successful
in the early treatment of NE [583]. To assure good sleep quality, specifically in children with NE, it is also recommended to limit the use of electronic devices before bedtime [584].

Referral for psychological support should be advised and followed-up for patients with NE and their families, especially if the NE comorbid factor is developmental, attention or learning difficulties, family problems, parental distress and possible punishment of the child are observed. Parental stress levels are higher compared to parents of non-NE children [585] and anger is found to be the most common parental reaction towards NE children [586], this would explain why childhood traumas such as neglect and abuse are more often seen in children with NE [587]. Psychological interventions with parents of NE children were shown to significantly improve their coping mechanisms [588].

3.11.3.2 Wetting alarm treatment
The nocturnal alarm treatment relies on the use of a device that is activated by getting wet. The goal of this therapeutic approach is that the child wakes up by the alarm, which can be acoustic or tactile, either by itself or with the help of a caregiver. Their method of action is to repeat the awakening and therefore change the high arousal to a low arousal threshold, specifically when a status of full bladder is reached. In the most recent Cochrane review (even though the quality of the included studies was low), several studies have shown that alarm treatment will reduce the number of wet nights a week. An alarm treatment has a higher complete response rate and a low relapse rate compared to no treatment at all [589]. In the event of relapse after initial success, one should actively investigate for OAB [590]. The recommended length of therapy with the alarm treatment continues to be uncertain, varying from 8-12 weeks (ICCS) to 16-20 weeks [591].

Regular follow-up will improve the success. It is of utmost importance that the child plays an active role in the alarm treatment, is willing to continue and understand the purpose of the treatment modality.

3.11.3.3 Medical treatment
If the child and the family would like to act on the high night-time urine production and eventual night-time OAB, they should be able and willing to adjust their drinking habits and take either desmopressin or a combination of desmopressin and an anticholinergic drug.

Success rates of 70% can be obtained with Desmopressin, either as tablets (200-400 μg), or as sublingual Desmopressin oral lyophilisate (120-240 μg). A rare side-effect is water intoxication which can be prevented by adequate water intake. The dosage of 120 ug has been shown to be effective and safe [592, 593]. A structured titration increase up to 240 ug has been shown to be effective [594]. Predictive factors for success with Desmopressin have been identified: older children, in children with fewer wet nights and high night-time urine production [595]. Children that show a good response on low-dose Desmopressin are more likely to show a complete response during the maintenance period [596]. When poor responses are seen on Desmopressin be aware of low compliance [597]. Relapse rates can be high after Desmopressin discontinuation [530], it is unclear if structured withdrawal will result in lower relapse rates [598, 599]. A nasal spray is no longer recommended due to the increased risk of overdose [600].

In the event of Desmopressin-resistant treatment for NE or if a suspicion exists for night-time OAB, combination of Desmopressin with anticholinergics is safe and efficient, even after cessation of treatment [601-604]. With night-time OAB a treatment failure to Desmopressin can be explained because of the bladder reservoir dysfunction [605]. There is no indication for monotherapy with an anticholinergic drug [606].

Alarm and Desmopressin treatment have comparable efficacy in achieving >50% reduction in wet nights. Alarms offer superior treatment response (OR: 2.89, 95% CI 1.38 to 6.04) and lower relapse rates (OR: 0.25, 95% CI 0.12 to 0.50) in children [607]. Multimodal treatment can achieve a partial or full response in 80% of children. However, side effects are seen in up to 30% of children [608].

3.11.3.4 Electrical neuromodulation
Several systematic reviews and randomized trials have documented potential benefits of electrical neural stimulation for NE. However, the quality of the included studies was low and different types of electrical neural stimulation, such as intra-anal stimulation and interferential current stimulation have been included [609-612]. The one RCT that compares transcutaneous electrical nerve stimulation to placebo demonstrates no anti-enuretic effect [613].

3.11.3.5 Complementary treatments:
A Cochrane review showed no benefit for treatments such as hypnosis, psychotherapy, acupuncture, chiropractic and medicinal herbs for the treatment of NE [614].

3.11.3.6 Conservative “wait and see” approach
If the child and its family is unable to comply with a treatment, if the treatment options are not possible for the
family situation, and if there is no social pressure, a “wait and see” approach can be chosen. However, in this approach, it is important to emphasise the fact that the child should wear diapers at night to ensure a normal quality of sleep [615]. The success rate of wait and see is 15% per year, independent of age. Figure 6 presents stepwise assessment and management options for NE.

Perform a urine test to exclude the presence of infection or potential causes such as diabetes insipidus. 2 Strong

Offer supportive measures in conjunction with other treatment modalities, of which pharmacological and alarm treatment are the two most important. 1 Strong

Offer desmopressin in proven night-time polyuria. 1 Strong

Offer alarm treatment in motivated and compliant families. 1 Strong

### 3.12 Management of neurogenic bladder

#### 3.12.1 Epidemiology, aetiology and pathophysiology

Neurogenic detrusor-sphincter dysfunction (NDSD) can develop as a result of a lesion at any level in the nervous system. This condition contributes to various forms of LUTD, which may lead to incontinence, UTIs, VUR, and ultimately to renal scarring and renal failure requiring dialysis and/or transplantation. Conservative treatment starting in the first year of life is the first choice, however, surgery may be required at a later stage to establish adequate bladder storage, continence and drainage later on [616]. The main goals of treatment concerning the urinary tract are prevention of UTI’s, urinary tract deterioration, achievement of continence at an appropriate age and promoting a good as possible QoL [4, 5]. With regard to the associated bowel dysfunction, stool continence, with evacuation at a social acceptable moment, is another goal as well as education and treatment of disturbance in sexual function. Due to the increased risk of development of latex allergy, latex-free products (e.g., gloves, catheters etc.) should be used from the very beginning whenever possible [617].

Neurogenic bladder in children with myelodysplasia presents with various patterns of Detrusor-Sphincter-Dyssynergia with a wide range of severity [618]. About 12% of neonates with myelodysplasia have no signs of neuro-urological dysfunction at birth [619]. Newborns with myelodysplasia who initially have normal urodynamic studies are at risk for neurological deterioration secondary to spinal cord tethering, especially during the first six years of life. Close follow-up of these children is important for the early diagnosis and timely surgical correction of tethered spinal cord, and for the prevention of progressive urinary tract deterioration [619]. At birth, the majority of patients have normal UUTs, but up to 60% develop upper tract deterioration due to bladder changes, UTI and /or VUR, if not treated properly [620-623]. Even today in a contemporary series around 50% of the patients are incontinent and 15% have an impaired renal function at the age of 29 years [624]. A systematic review concerning the outcome of adult meningomyelocele patients demonstrated that around 37% (8-85%) are continent, 25% have some degree of renal damage and 1.3% end stage renal failure [625]. The term “continence” is used differently in the reports, and the definition of “always dry” was used in only a quarter of the reports [626]. A recent nationwide survey in USA showed, that less than 50% of the adult spina population reported being continent [627], which demonstrates the need for better consulting and lifelong support.

The most common presentation at birth is myelodysplasia. The incidence of neural tube defects in Europe is 9.1 per 10,000 births and has not decreased in recent years, despite longstanding recommendations concerning folic acid supplementations [628]. The term myelodysplasia includes a group of developmental anomalies that result from defects in neural tube closure. Lesions include spina bifida aperta and occulta, meningocele, lipomyelomeningocele, or myelomeningocele. Myelomeningocele is by far the most common defect seen and the most detrimental.

With antenatal screening spina bifida can be diagnosed before birth with the possibility of intrauterine closure of the defect [629, 630]. Traumatic and neoplastic spinal lesions of the cord are less frequent in children but can also cause severe urological problems. Other congenital malformations or acquired diseases can cause a neurogenic bladder, such as total or partial sacral agenesis which can be part of the caudal regression syndrome [631]. In any child presenting with anorectal malformation (ARM) and cloacal malformations, the development of a neurogenic bladder is possible [632]. Patients with cerebral palsy may also present with varying degrees of voiding dysfunction, usually in the form of uninhibited bladder contractions (often due to spasticity of the pelvic floor and sphincter complex) and wetting. Finally, “non-neurogenic neurogenic” bladder dysfunction, such as Hinman or Ochoa syndrome, have been described, in which no neurogenic anomaly can be found, but severe bladder dysfunction as seen in neurogenic bladders is present [633, 634].

#### 3.12.2 Classification systems

As bladder sphincter dysfunction is poorly correlated with the type and spinal level of the neurological lesion, urodynamic and functional classifications are much more practical for defining LUT pathology and planning treatment in children.
The bladder and sphincter are two units working in harmony to act as a single functional unit. In patients with a neurogenic disorder, the storage and emptying phase of the bladder function can be disturbed. The bladder and sphincter may be either overactive or underactive and present in four different combinations. This classification system is based on urodynamic findings [635-637]:

- Overactive sphincter and overactive bladder.
- Overactive sphincter and underactive bladder.
- Underactive sphincter and overactive bladder.
- Underactive sphincter and underactive bladder.

3.12.3 Diagnostic evaluation

Today several guidelines and timetables are used [638-640]. The Panel advocate proactive management in children with spinal dysraphism. In those with a safe bladder during the first urodynamic investigation, the next urodynamic investigation can be delayed until one year of age [4].

3.12.3.1 History and clinical evaluation

History should include questions on clean intermittent catheterisation (CIC) frequency, urine leakage, bladder capacity, UTI, medication, bowel function as well as changes in neurological status. A thorough clinical evaluation is mandatory including the external genitalia and the back. A two-day diary, recording drinking volume and times as well as CIC intervals, bladder volume and leakage can provide additional information about the efficacy of the treatment.

3.12.3.2 Laboratory and urinalysis

After the first week of life, plasma creatinine level should be obtained, later in life; cystatin level is more accurate [641, 642]. If there is any sign of decreased renal function, physicians should be encouraged to optimize the treatment as much as possible. The criteria for urine analysis are the same as for UTI (refer to Chapter 3.9). However, it is much easier for caregivers or patients to obtain catheter urine in patients who are on CIC. They can also perform a dip stick analysis to screen for UTI at home. (For relevance see Section 3.12.4.5). Albuminuria is an early marker of renal disease also in children with neurogenic bladder [643].

3.12.3.3 Ultrasound

At birth, US of the kidneys and bladder should be performed and then repeated at least annually. If there are any clinical changes in between, another US should be performed. Dilatation of the UUT should be reported according to the classification system of the Society of Foetal Urology [644], including the measurement of caliceal dilatation and anterior posterior diameter of the renal pelvis. Residual urine and bladder wall thickness should also be noted. A dilated ureter behind the bladder should be recorded. Bladder wall thickness has been shown not to be predictive of high pressures in the bladder during voiding and storage and cannot be used as a non-invasive tool to judge the risk for the UUT [645].

3.12.3.4 Urodynamic studies/videourodynamic

Urodynamic studies (UD) are one of the most important diagnostic tools in patients with neurogenic bladders. In newborns with spina bifida aperta), the first UD should be performed after the phase of spinal shock after closure, usually between the second and third months of life [646]. Especilly in newborns, performing and interpretation of UD may be difficult, as no normal values exist. After that it should be repeated annually, depending on the clinical situation. During and after puberty bladder capacity, maximum detrusor pressure and detrusor leak point pressure increase significantly [647]. Therefore, during this time, a careful follow-up is mandatory.

3.12.3.4.1 Preparation before urodynamic studies

Before any UD a urine analysis should be undertaken. The first assessment should be done under antibiotic prophylaxis. A Cochrane analysis of nine randomised controlled trials showed, that the administration of prophylactic antibiotics compared to placebo reduced the risk of significant bacteriuria from 12% to 4% after UD studies. However, this was without significant difference for symptomatic UTI (20% vs. 28%), fever or discomfort [648]. If there is significant bacteriuria, antibacterial treatment should be discussed; especially in older patients a single dose may be sufficient [649].

Generally, UD-parameters should include:

- the cystometric capacity;
- the intravesical filling pressure;
- detrusor compliance;
- the intravesical pressure at the moment of voiding or leakage;
• the presence or absence of detrusor overactivity;
• the competence of the internal and external sphincter;
• the degree of synergy of the detrusor and sphincter during voiding;
• the PVR volume.

In infants, information on detrusor filling pressure and the pressure and bladder volume at which the child voids or leaks can be obtained [646]. Detrusor leak point pressure is more accurate than abdominal leak point pressure but keeping the rectal probe in an infant in place can be challenging [646]. Addition of fluoroscopy (video-urodynamic study) will provide information about presence of VUR, at what pressures VUR occurs and the configuration of the bladder neck during filling and leakage or voiding.

3.12.3.4 Uroflowmetry
Unlike in children with non-neurogenic voiding dysfunction, uroflowmetry can rarely be used since most affected patients do not void spontaneously. In those with cerebral palsy, non-neurogenic-neurogenic bladder or other neurological conditions allowing active voiding it may be a practical tool. It provides an objective way of assessing the efficiency of voiding, while recording of pelvic floor activity with electromyography (EMG) can be used to evaluate synergy between detrusor and the sphincter. PVR urine volume is measured by US. The main limitation of uroflowmetry is the compliance of the child to follow instructions [650-653].

3.12.3.5 Urodynamic studies
The standards of the ICCS should be applied to UDs in patients with neurogenic bladders and accordingly reported [522, 636]. Natural fill UD in children with neurogenic bladder detects more overactivity compared with diagnoses delivered by conventional UD [654, 655]. It may be an option in patients where the findings in the conventional UD are inconsistent with clinical symptoms and other clinical findings [655].

3.12.3.6 Voiding cystourethrogram
If video-urodynamic equipment is not available, a VCUG with UD is an alternative to confirm or exclude VUR and visualise the LUT including the urethra.

3.12.3.7 Renal scan
DMSA (Technetium Dimercapto-Succinic Acid) Renal scan is the gold standard to evaluate renal parenchyma. In contemporary series, renal scars can be detected in up to 46% as patients get older [656-658]. In a recent study 4 out of 68 children had renal scarring, 3 had a history of febrile UTI and one a vesicoureteral reflux [608]. A positive DMSA-Scan correlates well with hypertension in adulthood, whereas US has a poor correlation with renal scars [658]. Therefore, a DMSA scan as a baseline evaluation in the first year of life is recommended.

3.12.4 Management
The medical care of children with neurogenic bladder requires an on-going multidisciplinary approach. There is some controversy about optimal timing of the management; proactive vs. expectant management [659-661]. Even with a close expectant management e.g. in one series 11 out of 60 need augmentation within a follow-up of 16 years and 7 out of 58 had a decrease in total renal function, which was severe in two [662]. During the treatment it should also be taken into account in spina bifida patients, that QoL is related to urinary incontinence independent of the type and level of spinal dysraphism and the presence or absence of a liquor shunt [663].

Foetal open and endoscopic surgery for meningomyelocele are performed to close the defect as early as possible in order to reduce neurological, orthopaedic and urological problems [664]. In the MOMS-Trial, Brooks et al. found no difference between those closed in utero vs. those closed after birth concerning the need for CIC [630], but less bladder trabeculation was found in the prenatal surgery group. Mean gestation age (28.3 vs. 35.2) seems to have no initial impact on bladder function in the first few years of life [665]. Two European series showed, that there is a possible benefit of open intrauterine closure on urinary continence showing normal bladder function in up to 33% at least in the first 2-3 years of life [666] [667]. Despite these promising reports [665, 668-670], caregivers need to be aware of the high risk of developing a neurogenic bladder as demonstrated by a Brazilian group [671]. Regular and close follow-up examinations including UD are indicated in all these patients.

3.12.4.1 Early management with intermittent catheterisation
Starting intermittent catheterisation (IC) soon after birth and closure of the defect by the neurosurgeon in all infants has shown to decrease renal complications and the need for later augmentation [672-675]. In infants without any clear sign of outlet obstruction, this may be delayed but only in very selected cases. These infants
should be monitored very closely for UTIs and changes of the urinary tract with US and UD. The early initiation of CIC in the new-born period makes it easier for caregivers to master the procedure and for children to accept it, as they grow older [676, 677]. Up to 90% of patients will perform CIC [678].

A Cochrane review as well as a recent study showed, that there is a lack of evidence to state that the incidence of UTI is affected by use of sterile or clean technique, coated or uncoated catheters, single (sterile) or multiple use (clean) catheters, self-catherisation or catherisation by others, or by any other strategy [679-683]. Looking at the microbiological milieu of the catheter, there was a trend for reduced recovery of potentially pathogenic bacteria with the use of hydrophlic catheters. Also, a trend for a higher patient satisfaction with the use of hydrophilic catheters was seen [684]. Based on the current data, it is not possible to state that one catheter type, technique or strategy is better than any other.

### 3.12.4.2 Medical therapy

**Antimuscarinic/anticholinergic medication** reduces/prevents detrusor overactivity and lowers intravesical pressure [685, 686]. Effects and side effects depend on the distribution of the M1-M5 receptors [687]. In the bladder, the subtype M2 and M3 are present [686, 688]. Oxybutynin is the most frequently used in children with neurogenic bladder with a success rate of up to 93% [689, 690]. Dose-dependent side-effects (such as dry mouth, facial flushing, blurred vision heat intolerance etc.) limit its use. Intravesical administration gives a significant higher bioavailability due to the circumvention of the intestinal first pass metabolism, as well as possible local influence on C-fiber-related activity and can be responsible for different clinical effect [691, 692].

Intravesical administration should be considered in patients with severe side-effects, as long-term results demonstrated that it was well-tolerated and effective [693, 694]. Transdermal administration also leads to a substantially lower ratio of N-desethyloxybutyn in to oxybutynin plasma levels, however, there are treatment-related skin reactions in 12 out of 41 patients [695]. There are some concerns about central anticholinergic adverse effects associated with oxybutynin [696, 697]. A double blinded cross-over trial, as well as a case control study, showed no deleterious effect on children's attention and memory [658, 698]. Tolterodine, solifenacine, fesoterodin, trospium chloride and propiverine and their combinations can also be used in children [699-707].

The oral dosage for oxybutynin is up to 0.2 mg/kg [686] given three times daily. The intravesical dosage can be up to 0.7 mg/kg/daily and transdermal 1.3-3.9 mg/daily. The dosage of the other drugs is: Tolterodine 0.5 – 4 mg/day divided in two doses, Solifenacin 1.25 up to 10 mg per day (single dose), fesoterodine 4-8 mg per day (single dose) Propiverin 0.8 mg/kg/day divided in two dosages and trospium chloride up to 3 times 15 mg starting with 3 times 5 mg. Except for oxybutynin, all other anticholinergic drugs are off-label use, which should be explained to the caregivers.

Early prophylactic treatment with anticholinergics showed a lower rate of renal deterioration as well as a lower rate of progression to bladder augmentation [672, 708]. Beta-3 agonists like mirabegron as an adjuvant treatment has been shown to be effective and safe in some recent studies of children (> 5 years) and adolescents [709-712].

**Alpha-adrenergic antagonists** may facilitate emptying in children with neurogenic bladder [713]. Doxazosin with an initial dose of 0.5 to 1.0 mg or tamsulosin hydrochloride in a medium (0.0002-0.0004 mg/kg/day) or high dose (0.0004-0.0008 mg/kg/day) has been given to children with neurogenic bladders [713-715]. It was well tolerated but not effective at least in one study [714].

Botulinum toxin A injections: In neurogenic bladders that are refractory to anticholinergics, the off-label use of suburothelial or intramuscular injection of onabotulinum toxin A into the detrusor muscle is a treatment option [653, 654]. In children, continence could be achieved in 32-100% of patients, a decrease in maximum detrusor pressure of 32% to 54%, an increase of maximum cystometric capacity from 27% to 162%, and an improvement in bladder compliance of 28%-176% [653]. Onabotulinum toxin A seems to be more effective in bladders with obvious detrusor muscle over-activity, whereas non-compliant bladders without obvious contractions are unlikely to respond [716, 717]. Also, the injections into the trigone seems to be save in regard of reflux and upper tract damage; if it has some benefit is not further investigated [657]. Of the patients with failed augmentation cystoplasty, 43% responded well to intra-detrusor onabotulinum toxin A injections in a recent series of 30 patients [718].

The most used dose of onabotulinum toxin A is 10 to 12 U/kg with a maximum dose between 200 U and 360 U [719]. A recent randomized trail demonstrated, that 200IE have greater efficacy in reducing bladder pressure...
and increasing bladder capacity compared to 50 or 100IE [720]. Onabotulinum toxin A can be effective between three to twelve (0-25) months and repeated injections are effective up to ten years in one study [721-723].

Urethral sphincter onabotulinum toxin A injection has been shown to be effective in decreasing urethral resistance and improve voiding. The evidence is still too low to recommend its routine use in decreasing outlet resistance, but it could be considered as an alternative in refractory cases [724, 725].

Neuromodulation
Intravesical electrical stimulation of the bladder [726-728], sacral nerve stimulation [729, 730] and transcutaneous neuromodulation [668] are still experimental and cannot be recommended outside of clinical trials. The same is true for the intradural somatic-to-autonomic nerve anastomosis [731, 732].

Urethral Dilatation
The aim is to lower the pop-off pressure by lowering the detrusor leak-point pressure by dilatation of the external sphincter under general anaesthesia up to 36 Charr. Some studies showed, that especially in females, the procedure is safe and in selected patients, effective [733-735].

Vesicostomy
Vesicostomy - preferably a Blocksom stoma [736] - is an option to reduce bladder pressure in children/new-borns, if the caregivers are compliant with IC and/or IC through the urethra is extremely difficult or impossible [737]. Especially in the young infant with severe upper tract dilatation or infections, a vesicostomy should be considered. In some patients it may be also a good long-term solution to prevent infection and renal deterioration [738]. Drawbacks are the difficulty fitting and maintaining a collecting appliance in older patients. A cystostomy button may be an alternative, with a complication rate (mostly UTI) of up to 34% within a mean follow-up of 37 months [739].

3.12.4.3 Management of faecal incontinence
Children with neurogenic bladder usually have also a neurogenic bowel function. Faecal incontinence may have an even greater impact on QoL, as the odour can be a reason for social isolation. The aim of each treatment is to obtain a smooth, regular bowel emptying and to achieve continence and impendence. The regime should be tailored to the patient’s need, which may change over time. Beside a diet with small portioned fibre food and adequate fluid intake to keep a good fluid balance [686], follow-up options should be offered to the patients and caregivers.

In the beginning, faecal incontinence is managed most commonly with mild laxatives, such as mineral oil, combined with enemas to facilitate removal of bowel contents. To enable the child to defecate once a day at a given time, rectal suppositories as well as digital stimulation by parents or caregivers can be used. Today, transanal irrigation is one of the most important treatments for patients with neurogenic bowel incontinence. Regular irrigations significantly reduce the risk for faecal incontinence also in the long run in up to 90% of the patients [740]. The risk of irrigation induced perforation of the bowel is estimated as one per 50,000 [678]. During childhood, most children depend on the help of the caregivers. Later in some patients, transanal irrigation becomes difficult or impossible due to anatomic or social circumstances. In these patients antegrade irrigation using a MACE-stoma (Malone Antegrade Continence Enema) is an option, which can also be placed in the left abdomen [741, 742]. In a long-term study of 105 patients with a MACE stoma, 69% had successful bowel management. They were started on normal saline, but some switched to GoLYTELY (PEG-3350 and electrolyte solution). Additives (biscodyl, glycerin etc.) were needed in 34% of patients. Stomal complications occurred in 63% (infection, leakage, and stenosis) of patients, 33% required surgical revision and 6% eventually required diverting ostomies [743]. In addition, patients need to be informed, that the antegrade irrigation is also time consuming taking at least 20-60 minutes.

3.12.4.4 Urinary tract infection
Urinary tract infections are common in children with neurogenic bladders. However, there is no consensus in most European centres, for prevention, diagnosing and treating UTIs in children with neurogenic bladders performing CIC [744]. Although bacteriuria is seen in more than half of children on CIC, patients who are asymptomatic do not need treatment [745, 746]. Continuous antibiotic prophylaxis (CAP) creates more bacterial resistance as demonstrated by a randomized study. Those that stopped the prophylaxis had reduced bacterial resistance, however, 38 out of 88 started antibiotic prophylaxis again due to recurrent UTIs or the caregivers request [747]. A cohort study with 20 patients confirmed these findings. Continuous antibiotic prophylaxis was not protective against the development of symptomatic UTIs and new renal scarring but increased the risk of bacterial resistance [748]. A randomized study in 20 children showed that
cranberry capsules significantly reduced the UTI-rate as well as the rate of bacteriuria [749]. If VUR is present, prophylactic antibiotics should be started when patients experience recurrent UTIs [750, 751].

3.12.4.4.1 Urinary tract infection and clean intermittent catheterisation
The incidence of asymptomatic bacteriuria ranges between 42%-76% [676, 686, 752]. A cross-over study in 40 children with neurogenic bladder demonstrated, that the reuse of CIC-catheters for up to three weeks compared to one week increased the prevalence of bacteriuria from 34% to 74% (it was 60% at the start of the study). During the study-period of eighteen weeks, none of the patients developed a febrile UTI [753]. There is no medical benefit in performing CAP in children with neurogenic bladder, who perform CIC [686]. In those with recurrent UTI, intravesical instillation of gentamycin or neomycin/polymyxin may be an option [754, 755].

Reflux
Secondary reflux in patients with neurogenic bladder increases the risk for pyelonephritis. The treatment is primary related to bladder function including anticholinergic therapy, CIC and may be later augmentation [756]. Those with early and post-therapy persistent reflux during videourodynamic studies at low pressure have a higher risk of pyelonephritis [757]. Patients with a high-grade reflux before augmentation have a higher risk of persistent symptomatic reflux after the enterocystoplasty [758]. Therefore simultaneous ureteral re-implantation in high-grade symptomatic reflux especially in those with low-pressure high-grade reflux should be discussed with the patient/caregivers. Endoscopic treatment has a failure rate of up to 75% after a median follow-up of 4.5 years [759] which is in contrast to the open techniques with a higher success rate but may have an increased risk of inducing obstruction [760].

3.12.4.5 Sexuality
Sexuality, while not an issue in childhood, becomes progressively more important as the patient gets older. This issue has historically been overlooked in individuals with myelodysplasia. However, patients with myelodysplasia do have sexual encounters [761]. The prevalence of precocious puberty is higher in girls with meningomyelocele [762]. Studies indicate that at least 15-20% of males are capable of fathering children and 70% of females can conceive and carry a pregnancy to term. It is therefore important to counsel patients about sexual development in early adolescence.

Women seem to be more sexually active than men in some studies from the Netherlands and the USA [761, 763]. The level of the lesion was the main predictor to be sexually active [764, 765]. Erectile function can be improved by sildenafil in up to 80% of the male patients [766, 767]. Neurosurgical anastomosis between the inguinal nerve and the dorsal penile nerve in patients with a lesion below L3 and disturbed sensation is still to be considered as an experimental treatment [763, 768]. Only 17% to one third of the patients talk to their doctors about sexuality, 25–68% were informed by their doctors about reproductive function [761]. Continence seems to play an important role too. Nine out eleven females without sexual dysfunction reported continence, whereas 50 out of 59 with sexual dysfunction have some urinary incontinence in a recent study [769]. Therefore, early discussion about sexuality in the adolescent is recommended and should be promoted by the paediatric urologist taking care of these patients.

3.12.4.6 Bladder augmentation
In patients where conservative treatment including onabotulinum toxin A (for indication see 3.12.4.3) fails to keep a low-pressure reservoir with a good capacity and compliance, bladder augmentation should be offered. For augmentation, ileal and colonic segments can be used [770]. Gastric segments are rarely used due to its associated complications like the haematuria-dysuria syndrome as well as secondary malignancies, which arise earlier than with other intestinal segments [771-774]. Enterocystoplasty increases bladder capacity, reduces storage pressure and can improve UUT drainage [775]. A good socially acceptable continence rate can be achieved with or without additional bladder outlet procedures [776]. In those, who are not able to perform CIC through the urethra, a continent cutaneous channel should be offered. One recent study in 10 patients showed that thoracic epidural analgesia appears to be a safe and effective opioid sparing option to assist with postoperative pain management following lower urinary tract reconstruction [777]. Surgical complications and revision rate in this group of patients is high. The 30-day all over event rate in the American College of Surgeons’ National Surgical Quality Database is approximately 30% (23-33%) with a re-operation rate in this short time period of 13% [778, 779]. In these patients with long-life expectancy the complication rate clearly increases with the follow-up period [780]. The ten-year cumulative complication incidence from the Paediatric Health Information System showed a rate of bladder rupture in up to 6.4%, small bowel obstruction in up to 10.3%, bladder stones in 36%, pyelonephritis in more than a third of the patients and a re-augmentation rate of up to 13% [781]. Bladder perforation, as one of the worst complications, occurs in 3-13% [782]. The rate of VP-shunt infections after gastrointestinal and urological procedures ranges between
0-22%. In a recent study, bowel preparation seems not to have a significant influence on the infection rate (10.5% vs. 8.3%) [783]. Not only surgical complications must be considered; also metabolic complications and consequences after incorporating bowel segments have to be taken into account, such as imbalance of the acid base balance, decrease in vitamin B12 levels and loss of bone density. Stool frequency can increase as well as diarrhoea after exclusion of bowel segments [784] and last, but not least, these patients have a lifelong increased risk to develop secondary malignancies [785, 786]. Therefore, a lifelong follow-up of these patients is required including physical examination, US, blood gas analysis, (pH and base excess), renal function and vitamin B12 if ileum is used. Endoscopic evaluation starting ten years after augmentation is not cost-effective [787, 788], but may prevent some advanced cancer. Woodhouse et al. do not recommend cystoscopy within the first fifteen years after surgery [789]. The real value of annual cystoscopic evaluation has not been proven by any study. Urodynamic studies after bladder augmentation are only indicated, if upper tract dilatation and/or incontinence after the operation has not improved [790].

Adverse effects of intestinal cystoplasties can be avoided by the use of ureterocystoplasty. The combination of a small contracted bladder, associated with a severe dilation of the ureter of a non-functioning kidney is quite rare. The technique was first described in 1973 by Eckstein [791]; the success rate depends on patient selection and the re-augmentation rate can reach 73% [792, 793].

Auto-augmentation with partial detrusorectomy or detrusoromyotomy creating a diverticulum avoids metabolic complications with the use of intestinal segments. The reports are conflicting, therefore, it may be used in selected cases [794-797]. For a successful outcome, a pre-operative bladder capacity of 75-80% of the expected volume seems necessary [795, 798]. Seromuscular cystoplasty has also not proven to be as successful as standard augmentation with intestine [799]. Tissue engineering, even if successful in vitro and some animal models, does not reach the results by using intestinal segments with a higher complication rate [800, 801]. Therefore, these alternatives for bladder augmentation should be considered as experimental and should be used only in controlled trials.

3.12.4.7 Bladder outlet procedures

No available medical treatment has been validated to increase bladder outlet resistance. Alpha-adrenergic receptor stimulation of the bladder neck has not been effective [713]. Using fascial slings with autologous fascial strip or artificial material a continence rate between 40-100% can be achieved. In most cases this is achieved in combination with bladder augmentation [802-807]. Catheterising through a reconstructed bladder neck or a urethra compressed by a sling may not be easy; many surgeons prefer to combine this approach with a catheterisable channel [659]. In contrast to the autologous slings, artificial slings in girls with CIC through the urethra have a high complication rate [808]. In males, it may be an option [809], however as long as long-term results are missing, this method has to be classified as experimental and should only be carried out in studies. Artificial urinary sphincters were introduced by Scott in 1973 [810]. The continence rates in the literature in selected patients can be up to 83% [811, 812]. Post-pubertal patients, who can void voluntary are good candidates, if they are manually dexterous. In very selected patients, CIC through the sphincter in an augmented bladder is possible [812]. The erosion rate can be up to 29% and the revision rate up to 100% depending on the follow-up time [806].

Patients, who underwent a bladder neck procedure only, have a chance of > 30% for an augmentation and/or onabotulinum toxin A injections > 30% later on; half of them developed new upper tract damage in that time [813-815]. In patients with a good bladder capacity and bladder compliance without an indication for bladder augmentation, up to 40% will need augmentation later on [814]. Therefore, close follow-up of these patients with UD is required to avoid upper tract damage and chronic renal failure.

Bladder neck reconstruction is used mostly in exstrophy patients with acceptable results. However, in children with a neurogenic bladder the results are less favourable [816]. In most patients, the creation of a continent catheterisable stoma is necessary due to difficulties in performing the CIC via the urethra. In one series, 10% to a third still performed CIC via the urethra with a re-operation rates between 67% and 79% after a median follow-up between seven and ten years [817]. In patients who are still incontinent after a bladder outlet procedure, bladder neck closure with a continent catheterisable stoma is an option. The combination of a sling procedure together with a urethral lengthening procedure may improve the continence rates [818].

Bulking agents have a low success rate (10-40%), which is in most cases only temporary [819-821]. However, it does not adversely affect the outcome of further definite surgical procedures [819].
Bladder neck closure is often seen as the last resort to gain urinary continence in those patients with persistent urinary incontinence through the urethra. In girls, the transection is done between bladder neck and urethra and in boys above the prostate with preservation of the neurovascular bundle. It is an effective method to achieve continence together with a catheterisable cutaneous channel +/- augmentation as a primary or secondary procedure [822, 823]. A complication rate of up to a third and a vesicourethral/vesicovaginal fistula in up to 15% should be considered [824], together with a higher risk for bladder stones, bladder perforation and deterioration of the upper tract function, if the patient is not compliant with CIC and bladder irrigations [824, 825].

3.12.4.8 Catheterisable cutaneous channel.
In most patients with a neurogenic bladder CIC is required. If this is not possible, or very time and/or resource consuming via the urethra, a continent cutaneous catheterisable channel should be offered as well as in those with bladder outlet procedures. It is especially beneficial to wheelchair-bound patients who often have difficulty with urethral catheterisation or are dependent on others to catheterise the bladder. In long-term studies the revision rate due to stenosis or incontinence can be as high as 50-60% depending on the type of channel [826, 827].

The stoma can be placed at the umbilicus or in the lower right abdominal wall using a VQZ plasty [828]. It should be carefully evaluated pre-operatively: it is extremely important that the patient can reach the stoma easily. Sometimes it has to be placed in the upper abdominal wall due to severe scoliosis mostly associated with obesity.

3.12.4.9 Continent and incontinent cutaneous urinary diversion
Incontinent urinary diversion should be considered in patients who are not willing or able to perform a CIC and who need urinary diversion because of upper tract deterioration or gain urinary continence due to social reasons. In children and adolescents, the colonic conduit has shown to have less complications compared to the ileal conduit [829-832]. Total bladder replacement is extremely rare in children and adolescents, but may be necessary in some adults due to secondary malignancies or complications with urinary diversions. Any type of major bladder and bladder outlet construction should be performed in centres with sufficient experience in the surgical technique, and with experienced healthcare personnel to carry out post-operative follow-up [776, 833, 834].

Algorithms can be used for management of these patients (Figures 7 and 8).

3.12.5 Follow-up
Neurogenic bladder patients require lifelong follow-up including not only urological aspects but also neurological and orthopaedic aspects. Regular investigation of upper and lower urinary tract is mandatory. In patients with changes of the function of the upper and/or lower urinary tract, a complete neurological re-investigation should be recommended including a total spine MRI to exclude a secondary tethered cord or worsening of the hydrocephalus. In addition, if some neurological changes are observed a complete investigation of the urinary tract should be undertaken.

A recent study of this guideline panel revealed that the priorities of patients for future expectations were as following in decreasing order: QoL, surgical techniques, development of new medications and sexuality/fertility issues. Male spina bifida patients preferred new medications and sex/fertility issues more, whereas females favoured QoL issues improvement more. These factors should be considered during long-term management [2].

In those patients with urinary tract reconstruction using bowel segments, regular investigations concerning renal function, acid base balance and vitamin B12 status are mandatory to avoid metabolic complications. There is an increased risk for secondary malignancies in patients with a neurogenic bladder either with or without enteric bladder augmentations [835-839]. Therefore, patients need to be informed of this risk and possible signs like haematuria. Although there are insufficient data on follow-up schemes to discover secondary malignancies, after a reasonable follow-up time (e.g. ten to fifteen years), an annual cystoscopy can be considered.

3.12.6 Self-organisation of patients
As patients’ self-organisations can support the parents, caregivers and the patients in all aspects of their daily life, patients should be encouraged to join these organisations.
**Figure 7a: Management of children with myelodysplasia with a neurogenic bladder**

**Flowchart - First year of life**

3.13 Dilatation of the upper urinary tract (UPJ and UVJ obstruction)

3.13.1 Epidemiology, aetiology and pathophysiology
Dilatation of the upper urinary tract (UUT) remains a significant clinical challenge in deciding which patient will benefit from treatment. Ureteropelvic junction (UPJ) obstruction is defined as impaired urine flow from the pelvis into the proximal ureter with subsequent dilatation of the collecting system and the potential to damage the kidney. It is the most common pathological cause of neonatal hydronephrosis [840]. It has an overall incidence of 1:1,500 and a ratio of males to females of 2:1 in newborns.

Ureterovesical junction (UVJ) obstruction is an obstructive condition of the distal ureter as it enters the bladder, commonly called a primary obstructive megaureter. Megaureters are the second most likely cause of pathological neonatal hydronephrosis. They occur more often in males and are more likely to occur on the left side [841]. It can be very difficult to define ‘obstruction’ as there is no clear division between ‘obstructed’ and ‘non-obstructed’ urinary tracts. Currently, the most popular definition is that an obstruction represents any restriction to urinary outflow that, if left untreated, will cause progressive renal deterioration [842].

3.13.2 Diagnostic evaluation
The widespread use of US during pregnancy has resulted in a higher detection rate for antenatal hydronephrosis [843]. The challenge in the management of dilated UUT is to decide which child should be observed, which should be managed medically, and which requires surgical intervention. Despite the wide range of diagnostic tests, there is no single test that can accurately distinguish obstructive from non-obstructive cases (see Figure 9).

3.13.2.1 Antenatal ultrasound
Usually between the 16th and 18th weeks of pregnancy, the kidneys are visualised routinely, when almost all amniotic fluid consists of urine. The most sensitive time for foetal urinary tract evaluation is the 28th week. If dilatation is detected, US should focus on:
- laterality, severity of dilatation, and echogenicity of the kidneys;
- hydronephrosis or hydro-ureteronephrosis;
- bladder volume and bladder emptying;
- sex of the child;
- amniotic fluid volume [844].

3.13.2.2 Postnatal ultrasound
Since transitory neonatal dehydration lasts about 48 hours after birth, imaging should be performed following this period of postnatal oliguria. However, in severe cases (bilateral dilatation, solitary kidney, oligohydramnios), immediate postnatal sonography is recommended [845]. Ultrasound should assess the anteroposterior diameter of the renal pelvis, calyceal dilatation, kidney size, thickness of the parenchyma, cortical echogenicity, ureters, bladder wall and residual urine.

3.13.2.3 Voiding cystourethrogram
In newborns with identified UUT dilatation, the primary or important associated factors that must be detected include:
- vesicoureteral reflux (found in up to 25% of affected children) [846];
- urethral valves;
- ureteroceles;
- diverticula;
- neurogenic bladder.

Conventional VCUG is the method of choice for primary diagnostic procedures [847].

3.13.2.4 Diuretic renography
Diuretic renography is the most commonly used diagnostic tool to detect the severity and functional significance of problems with urine transport. Technetium-99m (99mTc) mercaptoacetyltriglycine (MAG3) is the radionuclide of choice. It is important to perform the study under standardised circumstances (hydration, transurethral catheter) after the fourth and sixth weeks of life [848]. Oral fluid intake is encouraged prior to the examination. At fifteen minutes before the injection of the radionuclide, it is mandatory to administer normal saline intravenous infusion at a rate of 15 mL/kg over 30 minutes, with a subsequent maintenance rate of 4 mL/kg/h throughout the entire time of the investigation [849]. The recommended dose of furosemide is 1 mg/kg for infants during the first year of life, while 0.5 mg/kg should be given to children aged one to sixteen years, up to a maximum dose of 40 mg.
A diagnostic work-up including VCUG must be discussed with the caregivers, as it is possible that, even if reflux is detected, it may have absolutely no clinical impact. However, it should be borne in mind that reflux has been detected in up to 25% of cases of prenatally detected and postnatally confirmed hydrenephrosis [757].

US = ultrasound.

3.13.3 Management

3.13.3.1 Prenatal management

Counselling the caregivers of an affected child is one of the most important aspects of care. The prognosis is hopeful for a hydrenephrotic kidney, even if it is severely affected, as it may still be capable of meaningful renal function, unlike a severely hypoplastic and dysplastic kidney. It is important to be able to tell the caregivers exactly when they will have a definitive diagnosis for their child and what this diagnosis will mean. In some cases, however, it will be immediately obvious that the child is severely affected; there will be evidence of massive bilateral dilatation, bilateral hypoplastic dysplasia, progressive bilateral dilatation with oligohydramnios, and pulmonary hypoplasia.

Intrauterine intervention is rarely indicated and should only be performed in well-experienced centres [850].

3.13.3.1.1 Antibiotic prophylaxis for antenatal hydronephrosis

The benefits and harms of continuous antibiotic prophylaxis (CAP) vs. observation in patients with antenatal hydronephrosis are controversial. Currently, only two RCTs have been published, one of which is a pilot trial [851] and the other publication is only available as a congress abstract [852]. Both publications present incomplete data and outcomes.

The Panel conducted a SR assessing the literature from 1980 onwards [853]. The key findings are summarised below.

Due to the heterogeneity of the published literature it was not possible to draw strong conclusions as to whether CAP is superior to observation alone in children diagnosed with antibiotic prophylaxis for antenatal hydronephrosis (ANH). In the first RCT, a prospective longitudinal study [851], female gender, uncircumcised males, lack of CAP, high-grade hydronephrosis, hydroureteronephrosis and VUR were found to be the independent predictors for the development of UTI. The second RCT included in the SR, was published as an abstract only, presented limited data [852]. This trial seemed to focus mainly on patients with ANH and VUR and did not report any beneficial effect of CAP on UTI rates, but details on the study population were limited.

Key findings of the SR are that CAP may or may not be superior to observation in children with antenatal hydronephrosis in terms of decreasing UTI. Due to the low data quality it was also not possible to establish whether boys or girls are at a greater risk of developing a UTI, or ascertain whether the presence or absence of VUR impacts UTI rates. A correlation between VUR-grade and UTI could not be established either. However, noncircumcised infants, children diagnosed with high-grade hydronephrosis and hydroureteronephrosis were shown to be at higher risk of developing a UTI.

The SR also tried to identify the most effective antibiotic regimen and present data on adverse effects but, due to heterogeneity, the available data could not be statistically compared. The most commonly used antibiotic in infants with antenatal hydronephrosis is trimethoprim, but only one study reported side effects [851].
In conclusion, based on the available evidence, the benefits and harms of CAP in children with antenatal hydronephrosis remain unproven. Uncircumcised infants and infants with hydroureteronephrosis and high-grade hydronephrosis are more likely to develop a UTI. Continuous antibiotic prophylaxis should be reserved for this sub-group of children who are proven to be at high risk.

3.13.3.2 UPJ obstruction
It is most important that management decisions are made on the basis of serial investigations that have used the same technique and have been performed by the same institution under standardised circumstances. According to a Cochrane review, non-surgical management of unilateral UPJ obstruction in infants less than two years old is also an option. However the high risk of bias of the included studies limits the evidence of this systematic review [854].

Symptomatic obstruction (recurrent flank pain, UTI) requires surgical correction using a pyeloplasty, according to the standardised open technique of Hynes and Anderson [855]. In experienced hands, laparoscopic or retroperitoneoscopic techniques and robot-assisted techniques have the same success rates as standard open procedures. In asymptomatic cases, conservative follow-up is the treatment of choice. A recent interventional study suggested that, in operated infants less than six months, inserting a stent (transanastomotic stent) decreases the complication rates compared to stentless approach [856]. However the results should be taken cautiously since there are successful reported stentless procedures in other age groups.

Indications for surgical intervention comprise impaired split renal function (< 40%), a decrease of split renal function of > 10% in subsequent studies, poor drainage function after the administration of furosemide, increased anteroposterior diameter on US, and grade III and IV dilatation as defined by the Society for Fetal Urology [644].

Well-established benefits of conventional laparoscopy over open surgery are the decreased length of hospital stay, better cosmesis, less post-operative pain and early recovery [857, 858]. A recent meta-analysis in children has shown that laparoscopic pyeloplasty (LP) was associated with decreased length of hospital stay and complication rates but prolonged operative time when compared to open pyeloplasty (OP). Additionally, both LP and OP had equal success rates [859]. Laparoscopic pyeloplasty can also be performed for re-do cases with the same advantages of the primary cases [860]. Robotic-assisted laparoscopic pyeloplasty (RALP) has all the same advantages as LP plus better manoeuvrability, improved vision, ease in suturing and increased ergonomics but higher costs [861, 862]. A recent study comparing RALP and LP has shown similar postoperative outcomes with exception of decreased operative time for RALP [863]. There does not seem to be any clear benefit of minimal invasive procedures in a very young child but current data is insufficient to defer a cut-off age.

3.13.3.3 Megaureter
The treatment options of secondary megaureters are reviewed in Chapter 3.14.3.

3.13.3.3.1 Non-operative management
If a functional study reveals and confirms adequate ureteral drainage, conservative management is the best option. Initially, low-dose prophylactic antibiotics within the first year of life are recommended for the prevention of UTIs, although there are no existing prospective randomised trials evaluating the benefit of this regimen [864]. With spontaneous remission rates of up to 85% in primary megaureter cases, surgical management is no longer recommended, except for megaureters with recurrent UTIs, deterioration of split renal function and significant obstruction [865].

3.13.3.3.2 Surgical management
In general, surgery is indicated for symptomatic children, if there is a drop in function in conservative follow-up and hydroureteronephrosis is increasing [866]. Data suggest that children with a ureteric diameter of > 10-15 mm are more likely to require intervention [867].

The initial approach to the ureter can be either intravesical, extravesical or combined. Straightening the ureter is necessary without devascularisation. Ureteral tapering should enhance urinary flow into the bladder. The ureter must be tapered to achieve a diameter for an anti-reflux repair. Several tailoring techniques exist, such as ureteral imbrication or excisional tapering [868]. Some institutions perform endoscopic stenting, but there are still no long-term data and no prospective randomised trials to confirm their outcome. A systematic review assessed the success rates of endoscopic management of primary obstructive megaureters [869]. It was reported that endoscopic managements including; stent placement, balloon dilatation and incision can be an alternative treatment in patients > 1 years of age. One third of those patients required further surgical correction. Furthermore, the long-term outcome of endoscopic management is still unknown. Therefore the EAU Paediatric Urology Guidelines Panel can not recommend endoscopic management routinely since the type of intervention and the management outcomes are unclear.
3.13.4 Conclusion
The use of routine perinatal sonography has resulted in increased detection of hydronephrosis caused by UPJ or UVJ obstruction. Meticulous and repeat postnatal evaluation is mandatory to try to identify obstructive cases at risk of renal deterioration and requiring surgical reconstruction. Surgical methods are standardised and have a good clinical outcome.

3.14 Vesicoureteric reflux
Lack of robust prospective RCTs limits the strength of the established guidelines for the management of VUR. The scientific literature for reflux disease is still limited and the level of evidence is generally low. Most of the studies are retrospective, include different patient groups, and have poor stratification of quality. Also, there is a high risk of presenting misleading results by combining different types of studies when systematically extracting data. Therefore, for reflux disease, it is unfortunately not possible to produce recommendations based on high-quality studies. The Panel have assessed the current literature, but in the absence of conclusive findings, have provided recommendations based on Panel consensus.

These Guidelines aim to provide a practical approach to the treatment of VUR based on risk analysis and selective indications for both diagnostics and intervention. Although the Panel have tried to summarise most of the possible scenarios in one single table, the table itself is still quite busy. The Panel strongly share the view that making simple and practical guidelines would underestimate the complexity of VUR as a sign of a wide range of pathologies [870].

3.14.1 Epidemiology, aetiology and pathophysiology
Vesicoureteric reflux is an anatomical and/or functional disorder with potentially serious consequences, such as renal scarring, hypertension and renal failure. Patients with VUR present with a wide range of severity, and a good proportion of reflux patients do not develop renal scars and probably do not need any intervention [871]. Vesicoureteric reflux is a very common urological anomaly in children, with an incidence of nearly 1%. 
The main management goal is the preservation of kidney function, by minimising the risk of pyelonephritis. By defining and analysing the risk factors for each patient (i.e. age, sex, reflux grade, LUTD, anatomical abnormalities, and kidney status), it is possible to identify those patients with a potential risk of UTIs and renal scarring. Controversy persists over the optimal management of VUR, particularly the choice of diagnostic procedures, treatment (medical, endoscopic or surgical), and the timing of treatment.

Many children present without symptoms of UTI and, because invasive diagnostic procedures are performed only when clinically indicated, the exact prevalence of VUR is unknown. However, the prevalence of VUR in non-symptomatic children has been estimated at 0.4-1.8% [872]. Among infants prenatally identified with hydronephrosis on US, who were screened for VUR, the prevalence was 16.2% (7-35%) [873]. Siblings of children with VUR had a 27.4% (3-51%) risk of also having VUR, whereas the offspring of parents with VUR had a higher incidence of 35.7% (21.2-61.4%) [873].

However, reflux detected by sibling screening is associated with lower grades [781] and significantly earlier resolution [874]. When VUR is discovered in siblings after UTI, it is usually high-grade and associated with a high incidence of reflux nephropathy, particularly if the sibling is male and the grade of reflux was high in the index patient [875].

The incidence of VUR is much higher among children with UTIs (30-50%, depending on age). Urinary tract infections are more common in girls than boys due to anatomical differences. However, among all children with UTIs, boys are more likely to have VUR than girls (29% vs. 14%). Boys also tend to have higher grades of VUR diagnosed at younger ages, although their VUR is more likely to resolve itself [876-879].

There is a clear co-prevalence between LUTD and VUR [880]. Lower urinary tract dysfunction refers to the presence of LUTS, including urge, urge incontinence, weak stream, hesitancy, frequency and UTIs, which reflect the filling and/or emptying dysfunction and may be accompanied with bowel problems [880]. Some studies have described a prevalence of 40-60% for VUR in children with LUTD [881]. A published Swedish reflux trial has demonstrated LUTD in 34% of patients, and subdivision into groups characteristic of children revealed that 9% had isolated overactive bladder and 24% had voiding phase dysfunction [882].

The spontaneous resolution of VUR is dependent on age at presentation, sex, grade, laterality, mode of clinical presentation, and anatomy [874]. Faster resolution of VUR is more likely with age less than one year at presentation, lower grade of reflux (grade 1-3), and asymptomatic presentation with prenatal hydronephrosis or sibling reflux. The overall resolution rate is high in congenital high-grade VUR during the first years of life. In several Scandinavian studies, the complete resolution rate for high-grade VUR has been reported at > 25%, which is higher than the resolution rate for VUR detected after infancy [882-884].

The presence of renal cortical abnormality, bladder dysfunction, and breakthrough febrile UTIs are negative predictive factors for reflux resolution [885-887].

Dilating VUR increases the risk of developing acute pyelonephritis and renal scarring. Untreated recurrent UTIs may have a negative impact on somatic growth and medical status of the child. Evidence of renal scarring is present in 10-40% of children with symptomatic VUR, resulting from either congenital dysplasia and/or acquired post-infectious damage, which may have a negative impact on somatic growth and general well-being [888-890].

Scar rates vary in different patient groups. Patients with higher grades of VUR present with higher rates of renal scars. In those with prenatal hydronephrosis, renal scarring occurs in 10% of patients [891-896], whereas in patients with LUTD, this may increase up to 30% [857, 890, 897]. Renal scarring may adversely affect renal growth and function, with bilateral scarring increasing the risk of insufficiency. Reflux nephropathy (RN) may be the most common cause of childhood hypertension. Follow-up studies have shown that 10-20% of children with RN develop hypertension or end-stage renal disease [898].

### 3.14.2 Diagnostic evaluation

The diagnostic work-up should aim to evaluate the overall health and development of the child, the presence of UTIs, renal status, the presence of VUR, and LUT function. A basic diagnostic work-up comprises a detailed medical history (including family history, and screening for LUTD), physical examination including blood pressure measurement, urinalysis (assessing proteinuria), urine culture, and serum creatinine in patients with bilateral renal parenchymal abnormalities.

The standard imaging tests include renal and bladder US, VCUG and nuclear renal scans. The criterion standard in diagnosis of VUR is VCUG, especially at the initial work-up. This test provides precise anatomical detail and allows grading of VUR [899]. In 1985, the International Reflux Study Committee introduced a uniform system for the classification of VUR [900, 901] (Table 2). The grading system combines two earlier classifications and is based upon the extent of retrograde filling and dilatation of the ureter, renal pelvis and calyces on VCUG [901].

Radionuclide studies for detection of reflux have lower radiation exposure than VCUG, but the anatomical details depicted are inferior [902]. Recent studies on alternative imaging modalities for detection on VUR have yielded good results with voiding US and magnetic resonance VCUG [903-905]. Contrast
enhanced voiding urosonography with intravesical instillation of different ultrasound contrast agents has been shown to be highly sensitive giving comparable results with conventional VCUG while avoiding exposure to ionising radiation [459, 906]. However, despite the concerns about ionising radiation and its invasive nature, conventional VCUG still remains the gold standard because it allows better determination of the grade of VUR (in a single or duplicated kidney) and assessment of the bladder and urethral configuration.

Dimercaptosuccinic acid is the best nuclear agent for visualising the cortical tissue and differential function between both kidneys. Dimercaptosuccinic acid is taken up by proximal renal tubular cells and is a good indicator of renal parenchyma function. In areas of acute inflammation or scarring, DMSA uptake is poor and appears as cold spots. Dimercaptosuccinic acid scans are therefore used to detect and monitor renal scarring. A baseline DMSA scan at the time of diagnosis can be used for comparison with successive scans later during follow-up [908]. Dimercaptosuccinic acid can also be used as a diagnostic tool during suspected episodes of acute pyelonephritis [909]. Children with a normal DMSA scan during acute UTI have a low-risk of renal damage [909, 910].

Video-urodynamic studies are only important in patients in whom secondary reflux is suspected, such as those with spina bifida or boys in whom VCUG is suggestive of PUV. In the case of LUTS, diagnosis and follow-up can be limited to non-invasive tests (e.g. voiding charts, US, or uroflowmetry) [880]. Cystoscopy has a limited role in evaluating reflux, except for infravesical obstruction or ureteral anomalies that might influence therapy.

3.14.2.1 Infants presenting with prenatally diagnosed hydronephrosis

Ultrasound of the kidney and bladder is the first standard evaluation tool for children with prenatally diagnosed hydronephrosis. It is non-invasive and provides reliable information regarding kidney structure, size, parenchymal thickness and collecting system dilatation [911, 912]. Ultrasound should be delayed until the first week after birth because of early oliguria in the neonate. It is essential to evaluate the bladder, as well as the kidneys. The degree of dilatation in the collecting system under US, when the bladder is both full and empty, may provide significant information about the presence of VUR. Bladder wall thickness and configuration may be an indirect sign of LUTD and reflux. The absence of hydronephrosis on postnatal US excludes the presence of significant obstruction; however, it does not exclude VUR.

Monitoring with careful US avoids unnecessary invasive and irradiating examinations. The first two US scans within the first one to two months of life are highly accurate for defining the presence or absence of renal pathology. In infants with two normal, successive scans, VUR is rare, and if present it is likely to be low-grade [891, 913]. The degree of hydronephrosis is not a reliable indicator for the presence of VUR, even though cortical abnormalities are more common in high-grade hydronephrosis [873]. The presence of cortical abnormalities on US (defined as cortical thinning and irregularity, as well as increased echogenicity) warrants the use of VCUG for detecting VUR [873]. Dimercaptosuccinic acid provides more reliable and quantitative measurement of the degree of cortical abnormalities, first detected with US.

The use of VCUG is recommended in patients with US findings of bilateral high-grade hydronephrosis, duplex kidneys with hydronephrosis, ureterocele, ureteric dilatation, and abnormal bladders, because the likelihood of VUR is much higher. In all other conditions, the use of VCUG to detect reflux is optional [873, 893, 914-916].

When infants who are diagnosed with prenatal hydronephrosis become symptomatic with UTIs, further evaluation with VCUG should be considered [915]. Patients with severe hydronephrosis and those whose hydronephrosis is sustained or progressive, need further evaluation to exclude obstruction.
3.14.2.2 Siblings and offspring of reflux patients

The screening of asymptomatic siblings and offspring is controversial. Some authors think that early identification of children with VUR may prevent episodes of UTI and therefore renal scarring, whereas others think that screening asymptomatic individuals is likely to result in significant over-treatment of clinically insignificant VUR. In screened populations the prevalence of VUR is 27.4% in siblings and 35.7% in offspring [907]. The overall estimate for renal cortical abnormalities is 19.3% (11-54%), with 27.8% having renal damage in cohorts of symptomatic and asymptomatic children combined. In asymptomatic siblings only, the rate of renal damage is 14.4% (0-100%). Although early screening and therefore early diagnosis and treatment appears to be more effective than late screening in preventing further renal damage [873, 875, 917, 918], screening in all siblings and offspring cannot be recommended based on the available evidence. The lack of RCTs for screened patients to assess clinical health outcomes makes evidence-based guideline recommendations difficult.

3.14.2.3 Recommendations for paediatric screening of VUR

<tr>
<td>Use voiding cystourethrography if there is evidence of renal scarring on US or a history of urinary tract infection.</td>
<td>Weak</td>
</tr>
<tr>
<td>Do not screen older toilet-trained children since there is no added value in screening for VUR.</td>
<td>Weak</td>
</tr>
</tbody>
</table>

3.14.2.4 Children with febrile urinary tract infections

A routine recommendation of VCUG at zero to two years of age after the first proven febrile UTI is the safest approach as the evidence for the criteria to selecting patients for reflux detection is weak. Children with febrile infections and abnormal renal US findings may have higher risk of developing renal scars and they should all be evaluated for reflux [462]. If reflux is diagnosed, further evaluation has traditionally consisted of a DMSA scan.

An alternative “top-down” approach is also an option, as suggested by several studies in the literature. This approach carries out an initial DMSA scan close to the time of a febrile UTI, to determine the presence of pyelonephritis, which is then followed by VCUG if the DMSA scan reveals kidney involvement. A normal DMSA scan with no subsequent VCUG will fail to identify VUR in 5-27% of cases, with the missed VUR presumably being less significant. In contrast, a normal DMSA scan with no VCUG avoids unnecessary VCUG in > 50% of those screened [452, 919-921].

3.14.2.5 Children with lower urinary tract symptoms and vesicoureteric reflux

Detection of LUTD is essential in treating children with VUR. It is suggested that reflux with LUTD resolves faster after LUTD correction, and that patients with LUTD are at higher risk for developing UTI and renal scarring [879, 922]. The co-existence of both conditions should be explored in any patient who has VUR. If there are symptoms suggestive of LUTD (e.g. urgency, wetting, constipation or holding manoeuvres), an extensive history and examination, including voiding charts, uroflowmetry and residual urine determination, will reliably diagnose underlying LUTD.

Among toilet-trained children, those with both LUTD and VUR are at higher risk of developing recurrent UTIs than children with isolated VUR [490].

In LUTD, VUR is often low-grade and US findings are normal, and there is no indication for performing VCUG in all children with LUTD, but the presence of febrile infections should be meticulously investigated. The co-existence of LUTD and VUR means it would be better to do a test covering both conditions, such as a VUDS. Any patient with LUTD and a history of febrile UTI should be investigated with a VUDS, if available. Furthermore, any child who fails standard therapy for LUTD should undergo urodynamic investigation. At this stage, combining a urodynamic study with VCUG is highly recommended.

3.14.3 Disease management

There are two main treatment approaches: conservative (non-surgical and surgical).

3.14.3.1 Non-surgical therapy

The objective of conservative therapy is prevention of febrile UTI. It is based on the understanding that:

- Vesicoureteric reflux resolves spontaneously, mostly in young patients with low-grade reflux.
- Resolution is nearly 80% in VUR grades I and II and 30-50% in VUR grades III-V within four to five years of follow-up.
• Spontaneous resolution is low for bilateral high-grade reflux [923].
• Vesicoureteric reflux does not damage the kidney when patients are free of infection and have normal LUT function.
• There is no evidence that small scars can cause hypertension, renal insufficiency or problems during pregnancy. Indeed, these are possible only in cases of severe bilateral renal damage.
• The conservative approach includes watchful waiting, intermittent or continuous antibiotic prophylaxis, and bladder rehabilitation in those with LUTD [657, 922, 924-926].
• Circumcision during early infancy may be considered as part of the conservative approach because it is effective in reducing the risk of infection in normal children [927].

3.14.3.1 Follow-up
Regular follow-up with imaging studies (e.g. VCUG, nuclear cystography, or DMSA scan) is part of the conservative management to monitor spontaneous resolution and kidney status. Conservative management should be dismissed in all cases of febrile breakthrough infections, despite prophylaxis, and intervention should be considered.

3.14.3.1.2 Continuous antibiotic prophylaxis
Vesicoureteral reflux increases the risk of UTI and renal scarring especially when in combination with LUTD. Many prospective studies have evaluated the role of continuous antibiotic prophylaxis in the prevention of recurrent UTI and renal scarring.

It is clear that antibiotic prophylaxis may not be needed in every reflux patient [928-930]. Trials show the benefit of CAP is none or minimal in low-grade reflux. Continuous antibiotic prophylaxis is useful in patients with grade III and IV reflux in preventing recurrent infections but its use in preventing further renal damage is not proven. Toilet-trained children and children with LUTD derive better benefit from CAP [930-935]. The RIVUR trial was the largest, randomised, placebo-controlled, double blind, multi-centre study, involving 607 children aged 2-72 months with grade I-IV VUR. The RIVUR study showed that prophylaxis reduced the risk of recurrent UTI by 50% but not renal scarring and its consequences (hypertension and renal failure), at the cost of increased antimicrobial resistance. The benefit of prophylaxis was insignificant in patients with grade III or IV VUR and in the absence of LUTD [936-939]. Additional review of the RIVUR data based on a risk classification system defines a high-risk group (uncircumcised males; presence of BBD and high grade reflux) who would benefit from a antibiotic prophylaxis significantly. Therefore selective prophylaxis for this group is recommended [940].

It may be difficult and risky to select patients who do not need CAP. A safe approach would be to use CAP in most cases. Decision-making may be influenced by the presence of risk factors for UTI, such as young age, high-grade VUR, status of toilet-training/LUTS, female sex, and circumcision status. Although the literature does not provide any reliable information about the duration of CAP in reflux patients, a practical approach would be to use CAP until after children have been toilet-trained and ensuring that there is no LUTD. Continuous antibiotic prophylaxis is mandatory in patients with LUTD and reflux. Active surveillance of UTI is needed after CAP is discontinued. The follow-up scheme and the decision to perform an anti-reflux procedure or discontinuation of CAP may also depend on personal preferences and the attitude of patients and caregivers. It is strongly advised that the advantages and disadvantages should be discussed in detail with the family.

3.14.3.2 Surgical treatment
Surgical treatment can be carried out by endoscopic injection of bulking agents or ureteral re-implantation.

3.14.3.2.1 Subureteric injection of bulking materials
With the availability of biodegradable substances, endoscopic subureteric injection of bulking agents has become an alternative to long-term antibiotic prophylaxis and open surgical intervention in the treatment of VUR in children. Using cystoscopy, a bulking material is injected beneath the intramural part of the ureter in a submucosal location. The injected bulking agent elevates the ureteral orifice and the distal ureter, so that coaptation is increased. This results in narrowing of the lumen, which prevents reflux of urine into the ureter, while still allowing its antegrade flow.

Several bulking agents have been used over the past two decades, including polytetrafluoroethylene (PTFE or Teflon™), collagen, autologous fat, polydimethylsiloxane, silicone, chondrocytes, a solution of dextranomer/hyaluronic acid (Deflux™, Dexell®) and more recently polyacrylatepolyalcohol copolymer hydrogel (Vantris®) [941, 942].

Although the best results have been obtained with PTFE [943], due to concerns about particle migration, PTFE has not been approved for use in children [944]. Although they are all biocompatible, other compounds such as collagen and chondrocytes have failed to provide a good outcome. Deflux™ was
approved by the USA FDA in 2001 for the treatment of VUR in children. Initial clinical trials have demonstrated that this method is effective in treating reflux [945]. Studies with long-term follow-up have shown that there is a high recurrence rate which may reach as high as 20% in two years [930]. In a meta-analysis [946] of 5,527 patients and 8,101 renal units, the reflux resolution rate (by ureter) following one treatment for grades I and II reflux was 78.5%, 72% for grade III, 63% for grade IV, and 51% for grade V. If the first injection was unsuccessful, the second treatment had a success rate of 68% and the third treatment 34%. The aggregate success rate with one or more injections was 85%. The success rate was significantly lower for duplicated (50%) vs. single (73%) systems, and neuropathic (62%) vs. normal (74%) bladders.

Obstruction at UVJ may happen in the long term follow-up after endoscopic correction of reflux. Patients with high-grade reflux and dilated ureters are at risk of late obstruction. It is significantly more common when polyacrylate-polyalcohol copolymer is used as bulking substance [947-949].

Clinical validation of the effectiveness of anti-reflux endoscopy is currently hampered by the lack of methodologically appropriate studies. In the most recent prospective, randomised trials comparing three treatment arms: i) endoscopic injection; ii) antibiotic prophylaxis; iii) surveillance without antibiotic prophylaxis in 203 children aged one to two years with grade III/IV reflux, endoscopic treatment gave the highest resolution rate of 71% compared to 39% and 47% for treatment arms ii and iii, respectively, after two years’ follow-up. The recurrence rate at two years after endoscopic treatment was 20%. The occurrence of febrile UTIs and scar formation was highest in the surveillance group at 57% and 11%, respectively. New scar formation rate was higher with endoscopic injection (7%) compared with antibiotic prophylaxis (0%) [950]. Longer follow-up studies are needed to validate these findings.

3.14.3.2.2 Open surgical techniques
Various intra- and extravesical techniques have been described for the surgical correction of reflux. Although different methods have specific advantages and complications, they all share the basic principle of lengthening the intramural part of the ureter by submucosal embedding of the ureter. All techniques have been shown to be safe with a low rate of complications and excellent success rates (92-98%) [951].

The most popular and reliable open procedure is cross trigonal re-implantation described by Cohen [949]. The main concern with this procedure is the difficulty of accessing the ureters endoscopically, if needed, when the child is older. Alternatives are supravesical re-implantation (Politano-Leadbetter technique) and infravesical re-implantation (Glenn-Anderson technique). If an extravesical procedure (Lich-Gregor) is planned, cystoscopy should be performed pre-operatively to assess the bladder mucosa and the position and configuration of the ureteric orifices. In bilateral reflux, an intravesical anti-reflux procedure may be considered, because simultaneous bilateral extravesical reflux repair carries an increased risk of temporary post-operative urine retention [952]. Overall, all surgical procedures offer very high and similar success rates for correcting VUR.

3.14.3.2.3 Laparoscopy and robot-assisted
There have been a considerable number of case series of transperitoneal, extravesical and pneumovesicoscopic intravesical ureteral re-implantation, which have shown the feasibility of the techniques. Various anti-reflux surgeries have been performed with the robot and the extravesical approach is the most commonly used. Although initial reports give comparable outcomes to their open surgical counterparts in terms of successful resolution of reflux, recent meta-analysis of results of Robotic-Assisted Laparoscopic Ureteral Reimplantation (RALUR) are within a wide range of variation and on average they are poor compared to open surgery. Operative times, costs and post-operative complications leading to secondary interventions are higher with RALUR but post-operative pain and hospital stay is less compared to open surgery [953-956].

Also, laparoscopic- or robotic-assisted approaches are more invasive than endoscopic correction and their advantages over open surgery are still debated. Therefore, at present, a laparoscopic approach cannot be recommended as a routine procedure. It can be offered as an alternative to the caregivers in centres where there is established experience [927, 957-965].
### Summary of evidence and recommendations for the management of vesicoureteric reflux in childhood

<table>

3.15 Urinary stone disease
3.15.1 Epidemiology, aetiology and pathophysiology

Paediatric stone disease is an important clinical problem in paediatric urology practice. Due to its recurrent nature, every effort should be made to discover the underlying metabolic abnormality so that it can be treated appropriately. Obtaining a stone-free state with close follow-up are of the utmost importance, although, it may not be possible in some circumstances (e.g. oxalosis or nephrocalcinosis).

Bladder stones are still common in underdeveloped areas of the world and are usually ammonium acid urate and uric acid stones, strongly implicating dietary factors [966]. Patients with augmented bladder constitute another important group with a risk of up to 15% [967].

The incidence and characteristics of stones show a wide geographical variation in children. Although urinary stone disease is generally considered to be a relatively rare disease, it is quite common in some parts of the world. Paediatric stone disease is endemic in Turkey, Pakistan and in some South Asian, African and South American countries. However, recent epidemiological studies have shown that the incidence of paediatric stone disease is also increasing in the Western world [968-970], especially in girls, Caucasian ethnicity, African Americans and older children [971]. More than 70% of stones in children contain calcium oxalate, while infection stones are found more frequently in younger children [972].

3.15.2 Classification systems

Urinary stone formation is the result of a complex process involving metabolic, anatomical factors and presence of infection.

3.15.2.1 Calcium stones

Calcium stones are usually made from calcium oxalate or calcium phosphate. Super-saturation of calcium (hypercalciuria) and oxalate (hyperoxaluria) or decreased concentration of inhibitors, such as citrate (hypocitraturia) or magnesium (hypomagnesemia) play a major role in the formation of calcium oxalate stones. Higher super-saturations of calcium oxalate was shown to be associated with multiple stone disease [973].

Hypercalciuria: This is defined by a 24-hour urinary calcium excretion of more than 4 mg/kg/day (0.1 mmol/kg/day) in a child weighing < 60 kg. In infants younger than three months, 5 mg/kg/day (0.125 mmol/kg/day) is considered to be the upper limit for normal calcium excretion [974].

Hypercalciuria can be classified as either idiopathic or secondary. Idiopathic hypercalciuria is diagnosed when clinical, laboratory, and radiographic investigations fail to delineate an underlying cause leading to hypercalcaemia. Urinary calcium may increase in patients with high sodium chloride intake.

Secondary hypercalciuria occurs when a known process produces excessive urinary calcium. In secondary hypercalcaemic hypercalciuria, a high serum calcium level may be due to increased bone resorption (hyperparathyroidism, hyperthyroidism, immobilisation, acidosis, metastatic disease) or gastrointestinal hyperabsorption (hypervitaminosis D) [975].

A good screening test for hypercalciuria compares the ratio of urinary calcium to creatinine. The normal calcium-to-creatinine ratio in children is less than 0.2. If the calculated ratio is higher than 0.2, repeat-testing is indicated. Neonates and infants have a higher calcium excretion and lower creatinine excretion than older children [974, 975]. If the follow-up ratios are normal, then no additional testing for hypercalciuria is needed.

However, if the ratio remains elevated, a timed 24-hour urine collection should be obtained and the calcium excretion calculated.

The 24-hour calcium excretion test is the standard criterion for the diagnosis of hypercalciuria. If calcium excretion is higher than 4 mg/kg/day (0.1 mmol/kg/day), the diagnosis of hypercalciuria is confirmed and further evaluation is warranted: levels of serum bicarbonate, creatinine, alkaline phosphatase, calcium, phosphorus, magnesium, pH, and parathyroid hormone. Freshly voided urine should be measured for pH [974-976]. In addition to calcium, the 24-hour urine analysis should also include phosphorus, sodium, magnesium, uric acid, citrate and oxalate.

Initial management is always to increase fluid intake and urinary flow. Dietary modification is a mandatory part of effective therapy. The child should be referred to a dietician to assess accurately the daily intake of calcium, animal protein, and sodium. Dietary sodium restriction is recommended as well as maintenance of calcium intake consistent with the daily needs of the child [977]. A brief trial of a low calcium diet can be carried out to determine if exogenous calcium intake and/or calcium hyperabsorption is contributing to high urinary calcium. Any recommendation to restrict calcium intake below the daily needs of the child should be avoided. Moreover, low calcium intake is a risk factor for stone formation [978] (LE: 3).
Hydrochlorothiazide and other thiazide-type diuretics may be used to treat idiopathic hypercalciuria, especially with calcium renal leak, at a starting dosage of 0.5-1 mg/kg/day [979-982] (LE: 3). In long-term use of thiazide-type diuretics, a decrease in hypocalciuric effect may be seen after the third month and may cause hypokalemia, hypocitraturia, hyperuricaemia and hypomagnesaemia. Therefore, control of blood and serum values should be performed with regular intervals. Citrate therapy is also useful if citrate levels are low or if hypercalciuria persists, despite other therapies [979, 983] (LE: 4).

Hyperoxaluria: Only 10-15% of oxalate comes from diet. The average child excretes less than 50 mg (0.57 mmol)/1.73 m2/day [984-986], while infants excrete four times as much. Hyperoxaluria may result from increased dietary intake, enteric hyperabsorption (as in short bowel syndrome) or an inborn error of metabolism.

In rare primary hyperoxaluria, one of the two liver enzymes that play a role in the metabolism of oxalate may be deficient. With increased deposition of calcium oxalate in the kidneys, renal failure may ensue in resulting deposition of calcium oxalate in other tissues (oxalosis). The diagnosis is made upon laboratory findings of severe hyperoxaluria and clinical symptoms. The definitive diagnosis requires liver biopsy to assay the enzyme activity.

Other forms of hyperoxaluria, as mentioned earlier, may be due to hyperabsorption of oxalate in inflammatory bowel syndrome, pancreatitis and short bowel syndrome. Yet, the majority of children have ‘mild’ (idiopathic) hyperoxaluria, with urine oxalate levels elevated only mildly in these cases. The treatment of hyperoxaluria consists of the promotion of high urine flow, restriction of dietary oxalate and regular calcium intake. Pyridoxine may be useful in reducing urine levels, especially in primary hyperoxaluria. Citrate administration increases inhibitory urine activity [979, 987] (LE: 4).

Hypocitraturia: Citrate is a urinary stone inhibitor. Citrate acts by binding to calcium and by directly inhibiting the growth and aggregation of calcium oxalate as well as calcium phosphate crystals. Thus low urine citrate may be a significant cause of calcium stone disease. In adults, hypocitraturia is the excretion of citrate in urine of less than 320 mg/day (1.5 mmol/day) for adults; this value must be adjusted for children depending on body size [988-990]. Hypocitraturia usually occurs in the absence of any concurrent symptoms or any known metabolic derangements. It may also occur in association with any metabolic acidosis, distal tubular acidosis or diarrhoeal syndromes.

Environmental factors that lower urinary citrate include a high protein intake and excessive salt intake. Many reports emphasise the significance of hypocitraturia in paediatric calcium stone disease. The presence of hypocitraturia ranges from 30% to 60% in children with calcium stone disease [989, 991]. The urine calcium-to-citrate ratios were higher in recurrent calcium stone forming children than solitary formers [988, 992].

The restoration of normal citrate levels is advocated to reduce stone formation, although there are few relevant studies in children. Hypocitraturia is treated by potassium citrate at a starting dose of 1 mEq/kg, given in two divided doses [980] (LE: 3). The side effects of potassium citrate are very rare and most of the time they include non-specific gastrointestinal complaints. Potassium citrate should be used with caution in hyperkalemic and chronic renal failure conditions.

3.15.2.2 Uric acid stones
Uric acid stones are responsible for urinary calculi in 4-8% of children. Uric acid is the end product of purine metabolism. Hyperuricosuria is the main cause of uric acid stone formation in children. A daily output of uric acid of more than 10 mg/kg/day (0.6 mmol/kg/day) is considered to be hyperuricosuria [979].

The formation of uric acid stones is mainly dependent on the presence of acidic urinary composition. Uric acid dissociation and solubility is strongly reduced at pH of < 5.8. As the pH becomes more alkaline, uric acid crystals become more soluble and the risk of uric acid stone formation is reduced.

In the familial or idiopathic form of hyperuricosuria, children usually have normal serum uric acid levels. In other children, it can be caused by uric acid overproduction secondary to inborn errors of metabolism, myeloproliferative disorders or other causes of cell breakdown. Hyperuricosuria is also caused by high purine and protein intake. Although hyperuricosuria is a risk factor for calcium oxalate stone formation in adults, this does not appear to be a significant risk factor in children. Uric acid stones are non-opaque stones. Plain X-rays are insufficient to show uric acid stones, and renal sonography and spiral CT are used for diagnosis. Alkalisation of urine is the mainstay of therapy and prevention for uric acid stones. Citrate preparations are useful as alkalinising agents. Maintaining a urine pH of 6 to 6.5 is sufficient to prevent uric acid stones [979]. In patients who failed with conservative measures with sustaining hyperuricosuria and
hyperuricemia, stone recurrences or myeloproliferative diseases, allopurinol (10 mg/kg) may be used. This medication may cause several drug reactions (rash, diarrhea, eosinophilia) and should be cautiously used in chronic renal failure patients.

3.15.2.3 Cystine stones
Cystinuria is the cause of cystine stone formation and accounts for 2-6% of all urinary stones in children. Cystinuria is an incompletely recessive autosomal disorder characterised by failure of renal tubules to reabsorb four basic amino acids: cystine, ornithine, lysine and arginine.

Of these four amino acids, only cystine has poor solubility in urine, so that only cystine stones may form in the case of excessive excretion in urine. Cystine solubility is pH-dependent, with cystine precipitation beginning at pH levels < 7.0. Other metabolic conditions, such as hypercalciuria, hypocitraturia and hyperuricosuria, may accompany cystinuria, so leading to the formation of mixed-composition stones. Cystine stones are faintly radiopaque and may be difficult to visualise on regular radiograph studies. They are also hard in texture and more difficult to disintegrate by extracorporeal shockwave lithotripsy (SWL). Cystinuric patients present with larger stones at the time of diagnosis, higher new stone formation rates, and are at higher risk of surgery [993].

The medical treatment for cystine stones aims to reduce cystine saturation in urine and increase its solubility. The initial treatment consists of maintaining a high urine flow and the use of alkalinising agents, such as potassium citrate to maintain urine pH at above 7.0 (better above 7.5). If this treatment fails, the use of α-mercaptopropionyl glycine or D-penicillamin may increase cystine solubility and reduce cystine levels in urine and prevent stone formation. Side effects of these drugs are mostly mild and include gastrointestinal complaints (alterations in taste and odour), fever and rash, however they can be associated with severe side effects, such as bone marrow depression, nephrotic syndrome and epidermolysis [994] (LE: 4).

3.15.2.4 Infection stones (struvite stones)
Infection-related stones constitute nearly 5% of urinary stones in children, though incidence increases over 10% in younger ages [995] and in non-endemic regions [972, 996]. Bacteria capable of producing urease enzyme (Proteus, Klebsiella, Pseudomonas) are responsible for the formation of such stones.

Urease converts urea into ammonia and bicarbonate, alkalinising the urine and further converting bicarbonate into carbonate. In the alkaline environment, triple phosphates form, eventually resulting in a supersaturated environment of magnesium ammonium phosphate and carbonate apatite, which in turn leads to stone formation.

In addition to bacterial elimination, stone elimination is essential for treatment, as stones will harbour infection and antibiotic treatment will not be effective. Consideration should be given to investigating any congenital problem that causes stasis and infection. Genitourinary tract anomalies predispose to formation of such stones.

3.15.3 Diagnostic evaluation
Presentation tends to be age-dependent, with symptoms such as flank pain and haematuria being more common in older children. Non-specific symptoms (e.g. irritability, vomiting) are common in very young children. Haematuria, usually visible, occurring with or without pain, is less common in children. However, nonvisible haematuria may be the sole indicator and is more common in children. In some cases, urinary infection may be the only finding leading to radiological imaging in which a stone is identified [997, 998].

3.15.3.1 Imaging
Generally, US should be used as a first approach. Renal US is very effective for identifying stones in the kidney. Many radiopaque stones can be identified with a simple abdominal flat-plate examination. The most sensitive test for identifying stones in the urinary system (especially for ureteric stones) is non-contrast helical CT scanning. It is safe and rapid, with 97% sensitivity and 96% specificity [999-1001] (LE: 2). Despite its high diagnostic accuracy, because of the potential radiation hazards, its use should be reserved for cases with noninformative US and/or plain abdominal roentgenogram. Low dose protocols have also been developed with the goal of reducing radiation dose with adequate image quality [1002]. Intravenous pyelography is rarely used in children, but may be needed to delineate the caliceal anatomy prior to percutaneous or open surgery.

3.15.3.2 Metabolic evaluation
Due to the high incidence of predisposing factors for urolithiasis in children and high stone recurrence rates, every child with a urinary stone should be given a complete metabolic evaluation [966, 994, 1003, 1004]. A limited urinary metabolic evaluation (24-h calcium, citrate, and oxalate and low urinary volume) is able to detect the vast majority of clinically significant metabolic abnormalities [1005]. However collections are most of the time inadequate and should be repeated in this case [1005, 1006].
Metabolic evaluation includes:

- family and patient history of metabolic problems and dietary habits;
- analysis of stone composition (following stone analysis, metabolic evaluation can be modified according to the specific stone type);
- electrolytes, blood/urea/nitrogen (BUN), creatinine, calcium, phosphorus, alkaline phosphatase, uric acid, total protein, carbonate, albumin, and parathyroid hormone (if there is hypercalcaemia);
- spot urinalysis and culture, including ratio of calcium to creatinine;
- urine tests, including a 24-hour urine collection for calcium, phosphorus, magnesium, oxalate, uric acid citrate, protein, and creatinine clearance;
- 24-hour cystine analysis if cystinuria is suspected (positive sodium nitroprusside test, cystine stone, cystine hexagonal crystals in urine).

Figure 10 provides an algorithm of how to perform metabolic investigations in urinary stone disease in children and how to plan medical treatment accordingly.

**Figure 10: Algorithm for metabolic investigations in urinary stone disease in children**

$\text{Ca} = \text{calcium; HCTZ = hydrochlorothiazide; Mg = magnesium; Ox = oxalate; PTH = parathyroid hormone; SWL = extracorporeal shockwave lithotripsy; RTA = renal tubular acidosis; Uric A = uric acid.}$
3.15.4 Management

Adequate fluid intake and restricting the use of salt within daily allowance range are the general recommendations besides the specific medical treatment against the detected metabolic abnormalities. With the advance of technology, stone management has changed from open surgical approaches to endoscopic techniques that are less invasive. Deciding on the type of treatment depends on the number, size, location, stone composition and the anatomy of the urinary tract [1004, 1007, 1008]. Expectant management is the initial management in children with asymptomatic small size stones (< 4-5 mm) with a possibility of spontaneous clearance. There is no consensus on the size of stones for different ages eligible for clearance and the duration of conservative follow-up. Adult literature reveals the benefits of medical expulsive therapy (MET) using α-blockers. Although, experience in children is limited showing different results [1009], a meta-analysis of three randomised and two retrospective studies demonstrate that treatment with MET results in increased odds of spontaneous ureteral stone passage and a low rate of adverse events [1010]. Currently, most paediatric stones can easily be managed by SWL. Endoscopic treatment can be applied for ureteric and bladder stones. Percutaneous removal of stones is also possible for kidney stones in children. Only a small portion of children will require open surgery but all attempts must be made to completely remove all stones since post-operative residual fragments pass spontaneously in only 20-25% of cases [1011, 1012]. A congenital obstructive uropathy should be managed together with stone removal therapy to prevent recurrence.

3.15.4.1 Extracorporeal shockwave lithotripsy

Many reports confirm that SWL can be performed in children with no suspicion of long-term morbidity of the kidney [1013-1020].

The mean number of shockwaves for each treatment is approximately 1,800 and 2,000 (up to 4,000 if needed) and the mean power settings vary between 14 kV and 21 kV. The use of US and digital fluoroscopy has significantly decreased the radiation exposure and it has been shown that children are exposed to significantly lower doses of radiation compared to adults [1007, 1021, 1022]. Concerns about anaesthesia no longer present a problem due to advances in technique and medication, even in the infant age group. The type of anaesthesia should be general or dissociative for children under ten years of age, whereas conventional intravenous sedation or patient-controlled analgesia is an option for older children who are able to co-operate [1023] (LE: 2b).

Stone-free rates are significantly affected by various factors. Regardless of the location, as the stone size increases, the stone-free rates decrease and retreatment rate increases. The stone-free rates for < 1 cm, 1-2 cm, > 2 cm and overall, were reported as nearly 90%, 80%, 60% and 80%, respectively. As the stone size increases, the need for additional sessions increases [1007, 1021, 1022, 1024-1028].

Localisation of the calculi has been described as a significant factor affecting the success rates in different studies. Stones in the renal pelvis and upper ureter seem to respond better to SWL. For these locations, the stone clearance rates are nearly 90%. However, SWL was found to be less effective for caliceal stones; particularly the lower caliceal stones. Several studies reported stone-free rates for isolated lower caliceal stones varying between 50% and 62% [1029-1031].

Shockwave lithotripsy can also be used to treat ureteral calculi. However, this is a more specific issue and controversial. The success rates with SWL are less for distal ureteric stones. There may also be technical problems with localisation and focusing of ureteric stones in children [1030-1033].

The type of machine used significantly influences success rates and complications. First-generation machines can deliver more energy to a larger focal zone, resulting in higher fragmentation rates in a single therapy. However, general anaesthesia is usually required due to the intolerable discomfort associated with a first-generation machine. Later-generation machines have a smaller focal zone and deliver less energy, and have a lower risk of pulmonary trauma, however, additional treatments may be needed. The success rate is higher in younger children [1026].

Although stenting does not affect stone clearance, overall complication rates are higher. Hospital stay is longer in the unstented patient [1026, 1028]. Stenting is essential in solitary kidneys undergoing SWL treatment. Children with a large stone burden have a high risk of developing Steinstrasse and urinary obstruction and should be followed more closely for the risk of prolonged urinary tract obstruction after SWL. Post-SWL stent or nephrostomy tube placement may be needed in prolonged obstruction [994, 1025].

The Hounsfield Unit (HU) of stone on non-contrast tomography has also been shown to be a predictive factor for success in children and SWL was found to be more successful in stones with HU less than 600 [1012] and 1,000 [1034]. Two nomogram studies revealed male gender, younger age, smaller stone size, single stone, non-lower pole localisation and negative history for previous intervention are favourable factors for stone clearance in paediatric SWL [1035, 1036]. A recent comparative study reported that these two nomograms are independent predictors of stone-free rate following SWL in paediatric patients [1037]. Although, the invention of miniaturised endoscopic instruments seems to reduce the importance and popularity of SWL, it has the advantage of not carrying the risk of certain complications related to endoscopic surgeries.
and moreover studies comparing SWL and RIRS showed that besides having similar stone-free rates, SWL was cheaper, had shorter hospital stay [1038], with less post-operative emergency visit, pain and anaesthetic session [1039]. Complications arising from SWL in children are usually self-limiting and transient. The most common are:

- renal colic;
- transient hydronephrosis;
- dermal ecchymosis;
- UTI;
- formation of Steinstrasse;
- sepsis;
- rarely, haemoptysis.

In children with sterile pre-operative urine cultures, antibiotic prophylaxis to decrease infectious complications is not recommended [1040]. However, every effort should be made to sterilise the urine before performing SWL, ureteroscopy (URS), or percutaneous nephrolithotomy (PCNL).

Due to the smaller size of the probes, laser energy is easier to use in smaller instruments and is more useful for paediatric cases [1041-1050].

### 3.15.4.2 Percutaneous nephrolithotomy

Shockwave lithotripsy is the first choice for treating most renal paediatric stones. However, percutaneous renal surgery should be used for larger and complex stones. Pre-operative evaluation, indication and surgical technique are similar in children and adults. In most cases, percutaneous nephrolithotomy (PCNL) is used as monotherapy, but is also used as an adjunctive procedure to other therapies.

The use of adult-sized instruments, in association with an increased number of tracts and sheath size, seems to increase blood loss. However, the development of small-calibre instruments means that PCNL can be used in children. In children (particularly smaller children), PCNL has some advantages, such as smaller skin incision, single-step dilation and sheath placement, good working access for paediatric instruments, variable length, and lower cost [1040, 1051, 1052].

As monotherapy, PCNL is considerably effective and safe. The reported stone-free rates in the recent literature are between 86.9% and 98.5% after a single session. These rates increase with adjunctive measures, such as second-look PCNL, SWL and URS. Even in complete staghorn cases, a clearance rate of 89% has been achieved following a single session [1044, 1053-1057].

The most frequently reported complications of PCNL in children are bleeding, post-operative fever or infection, and persistent urinary leakage. Bleeding requiring transfusion in the modern series is reported in less than 10% [1058-1063] and is closely associated with stone burden, operative time, sheath size and the number of tracts [1062, 1064, 1065]. In recent studies, post-operative infectious complications, such as fever with or without documented UTI, are reported as less than 15% [1058, 1059, 1061-1063, 1066] and the origin of fever is not always found to be the infection. With the availability of smaller size instruments, miniaturised PCNL ('miniperc') through a 13F or 14F sheath [1052, 1066, 1067] as well as ultramini-PCNL (UMP) through 12F sheaths [1068] have become possible, with decreased transfusion rates [1066]. The mini- and supermini-PCNL (SMP) were shown to have higher efficacy with acceptable complication rates which were deemed to be a safe alternative to SWL by some authors [1069, 1070]. The SMP was shown to be advantageous over mini-PCNL in terms of complications with similar stone-free rates [1071, 1072]. This miniaturisation has been further developed into the technique of ‘micro-perc’ using a 4.85F ‘all-seeing needle’. This technique is still experimental and enables the stone to be fragmented by a laser in situ and left for spontaneous passage [1073]. A study revealed that microperc provides a similar stone-free rate with similar complication rates and a lower additional treatment rate compared with SWL in the treatment of kidney stone disease in children [1074] (LE: 3). For stones 10-20 mm, micro-PNL was shown to have comparable results, with less bleeding, compared to mini-PCNL [1075] and similar outcomes with less anaesthetic sessions compared to RIRS [1076] (LE: 3). As experience has accumulated in adult cases, new approaches have started to be applied in children, including tubeless PCNL. This technique has been used in uncomplicated surgery for stones < 2 cm, with patients left either with an indwelling catheter or double J stent in the ureter [1060, 1077] or totally tubeless [1078]. Moreover, use of US for establishment of access is gaining popularity [1079, 1080] and supine approach [1081] was also reported to be feasible in children.

The mean post-operative hospital stay is similar to adults. It is reported as three to four days in all published literature and is much shorter than open surgery. The less invasive nature of this technique has made it a promising alternative to open surgery for treating renal stones in children (LE: 2) [1058, 1060, 1061, 1063-1065, 1067, 1068, 1073-1075, 1077, 1078, 1081, 1082].
3.15.4.3 **Ureterorenoscopy**

The increasing availability of smaller size endourological equipment has made it possible to manage paediatric ureteral stones using endoscopic techniques.

The technique used in children is similar to the one used in adults. It is strongly recommended that guide wires are used and the procedure is performed using direct vision. Routine balloon dilation of the ureterovesical junction and ureteral stenting are controversial. In general, ureteral dilatation is being performed less and only in selected cases. There is a tendency to use hydrodilation more because it is similarly effective [1, 1040, 1042, 1048, 1083-1086] (LE: 3).

Different lithotripsy techniques, including ultrasonic, pneumatic and laser lithotripsy, have all been shown to be safe and effective. Due to the smaller size of the probes, laser energy is easier to use in smaller instruments and is more useful for paediatric cases [1041-1050].

All studies reporting the use of endoscopy for ureteric stones in children have clearly demonstrated that there is no significant risk of ureteric strictures or reflux with this mode of therapy (LE: 1). The risk of post-operative hydronephrosis depends on the presence of impacted stone and ureteral injury during operation [1087]. A multi-institutional study on the use of semi-rigid ureteroscopy for ureteral calculi in children has revealed that the procedure is effective with a 90% stone-free rate and efficacy quotient. The study also focused on the factors affecting the complication rates. The authors found that, although operating time, age, institutional experience, orifice dilation, stenting and stone burden were significant on univariate analysis, multivariate analysis revealed that operating time was the only significant parameter affecting the complication rate [1088]. However, for proximal ureteral stones semi-rigid ureteroscopy is not a good first option because of higher complication and failure rates [1089].

A recent literature review contains a growing number of case series on the use of flexible ureterorenoscopic interventions in children. Both intrarenal and ureteric stones can be treated using this approach [1090-1095]. In these series, the authors generally did not use active orifice dilation, but attempted to use a ureteral sheath where possible. However, an important problem was the inability to obtain retrograde access to the ureter in approximately half of the cases [1091, 1093]. This problem can be overcome by stenting and leaving the stent indwelling for passive dilation of the orifice, and performing the procedure in a second session. The success rates varied between 60 and 100%, with a negligible number of complications [1090, 1092-1094, 1096]. The need for additional procedures was related to stone size [1094]. A comparative study showed that retrograde intra-renal surgery (RIRS) had similar stone-free rate compared to ESWL after three months, with fewer sessions [1097], however for stones larger than 2 cm, RIRS monotherapy has lower stonefree rates than mini-PCNL with the advantages of decreased radiation exposure, fewer complications and shorter hospital stay [1098] (LE: 3). In contrast, for stones between 10-20 mm, RIRS has similar success and complication rates and shorter hospital stay and low radiation exposure when compared to micro-PNL [1099] (LE: 3). A recent systematic review revealed that compared with the other two treatments, PCNL had a longer operative time, fluoroscopy time and hospital stay. Shockwave lithotripsy had a shorter hospital stay, higher retreatment rate and auxiliary rate in comparison with the other two treatments. It was also shown that PCNL presented a higher efficacy quotient than the other two treatments, and RIRS had a lower efficiency than SWL and PCNL. In the subgroup analysis of paediatric patients with stone ≤ 20 mm, the comparative results were similar to those described above, except for the higher complication rate of PCNL than SWL [1100].

3.15.4.4 **Open or laparoscopic stone surgery**

Most stones in children can be managed by SWL and endoscopic techniques. However, in some situations, open surgery is inevitable. Good candidates for open stone surgery include very young children with large stones and/or a congenitally obstructed system, which also require surgical correction. Open surgery is also necessary in children with severe orthopaedic deformities that limit positioning for endoscopic procedures.

In centres with a well-established experience, a laparoscopic approach may be a good alternative for some cases as a last resort before open surgery. Suitable candidates include patients who have a history of previous failed endoscopic procedures, complex renal anatomy (ectopic or retrorenal colon), concomitant UPJ obstruction or caliceal diverticula, mega-ureter, or large impacted stones. Laparoscopic stone surgery via conventional or a robot-assisted transperitoneal or retroperitoneal approach can be attempted. However, there is limited experience with these techniques and they are not routine therapeutic modalities [1101-1104].

Bladder stones in children can usually be managed by endoscopic techniques. Open surgery may also be used for very large bladder stones or for bladder stones caused by an anatomical problem.

In addition to the advantages and disadvantages of each treatment modality for the specific size and location of the stone, consideration has to be given to the availability of the instruments and the experience with each treatment modality before the choice of technique is made. Recommendations for interventional management are given in Table 4.

3.16 Obstructive pathology of renal duplication: ureterocele and ectopic ureter

3.16.1 Epidemiology, aetiology and pathophysiology

Ureterocele and ectopic ureter are the two main anomalies associated with complete renal duplication, but they also occur in a single system. At present, antenatal US detects both conditions in the majority of cases if associated with obstruction, and diagnosis is confirmed after birth by further examination. Later in life, these anomalies are revealed by clinical symptoms: UTI, pain, calculus formation, disturbances of micturition, and urinary incontinence. There is a wide variation of symptoms in patients with ureterocele (from the asymptomatic patient to urosepsis, urinary retention and upper tract dilatation after birth).

3.16.1.1 Ureterocele

Ureterocele is four to seven times more frequent in female than in male patients; the overall incidence in autopsies is around one in 4,000 children. Around 80% is associated with the upper pole ureter in duplicated systems and 20% in single systems. About 10% of ureteroceles are bilateral [1105].

3.16.1.2 Ectopic ureter

Ectopic ureter is less frequent than ureterocele (10 in 19,046 autopsies), but is also more common in female patients (male to female ratio is 1:5). Some remain asymptomatic, therefore, the true incidence is difficult to determine [1106]. Eighty per cent of ectopic ureters are associated with complete renal duplication; however, in male patients about 50% of ectopic ureters are associated with a single system [1107]. The incidence of ectopic ureter is 3.5% in patients with anorectal malformations [1108].

3.16.2 Classification systems

3.16.2.1 Ureterocele

Ureteroceles usually cause obstruction of the upper pole, but the degree of obstruction and functional impairment is variable according to the type of ureterocele and upper pole dysplasia. In the orthotopic form, there is often no or only mild obstruction, and frequently the function of the moiety is normal or slightly impaired, and the corresponding ureter may be dilated. Cystic renal dysplasia is also associated with a single system ureterocele [1112]. Vesicoureteral reflux can be observed in 50% on the ipsilateral side and 20% on the contralateral side. Reflux into the ureterocele is uncommon [1113]. In the ectopic form, the upper pole is altered, frequently dysplastic, and hypo-functional or non-functional [1114]. The corresponding ureter is a mega-ureter. In the caeco-ureterocele (see definition below), the upper pole of the renal duplication is dysplastic and non-functional. Histological evaluation demonstrated that the changes represent a process of maldevelopment and may not result from infections or obstruction [1114].

3.16.2.1.1 Ectopic (extravesical) ureterocele

If any portion of the ureterocele extends into the bladder neck or urethra, it is called an ectopic ureterocele. Ectopic ureteroceles are the most common form of ureterocele (> 80%). It can be voluminous, dissociating the trigone and slipping into the urethra, and may prolapse through the urethral meatus (caeco-ureterocele). The ureterocele orifice is tight, and located in the bladder itself or below the neck. The ureter corresponding to the lower pole moiety is raised by the ureterocele and is frequently refluxing or compressed by the ureterocele, leading to an obstructive mega-ureter. A contralateral renal duplication is associated with 50% of cases. Occasionally, large ureteroceles are responsible for reflux or obstruction of the contralateral upper tract.

3.16.2.1.2 Orthotopic (intravesical) ureterocele

The intravesical or orthotopic ureterocele is completely located in the bladder. Intravesical ureteroceles are mostly combined with a single kidney system and account for about 15% of cases. It is diagnosed more in older children or adults.

3.16.2.2 Ectopic ureter

The term ectopic ureter describes a ureter with the orifice located at the bladder neck, in the urethra or outside the urinary tract. The ureter can drain the upper pole of a duplex or single system. There is a fundamental difference between the sexes. In boys, the ectopic orifice is never below the external sphincter.

In girls, the ureteral orifice may be located [1115]:
- in the urethra, from the bladder neck to the meatus (35%);
- in the vaginal vestibule (34%);
- in the vagina (25%);
- in the uterus and Fallopian tube (6%).
In boys, the ureteral orifice may be located [1115]:
- in the posterior urethra (47%);
- in the prostatic utricle (10%);
- in the seminal vesicles (33%);
- in the vas deferens or ejaculatory ducts (10%).

3.16.3  **Diagnostic evaluation**

3.16.3.1  **Ureterocele**

Prenatal US easily reveals voluminous obstructive ureteroceles [1116]. In cases with a small upper pole or a slightly obstructive ureterocele, prenatal diagnosis is difficult.

If prenatal diagnosis is impossible, the following clinical symptoms, besides incidental findings, can reveal the congenital anomaly at birth or later:
- At birth, a prolapsed and sometimes strangulated ureterocele may be observed in front of the urethral orifice. In a newborn boy, it might cause acute urinary retention, simulating urethral valves.
- The early symptom of pyelonephritis in either sex may lead to the diagnosis.
- Later symptoms can include dysuria, recurrent cystitis and urgency.

In cases of prenatal diagnosis, at birth US confirms the ureteral dilatation that ends at the upper pole of a renal duplication. It also demonstrates the presence of a ureterocele in the bladder, with a dilated ureter behind the bladder.

At this point, it is important to assess the function of the upper pole using nuclear renography of the region of interest. This is best assessed with DMSA, however this requires a careful systematic review of the images [1117]. Magnetic resonance urography may visualise the morphological status of the upper pole and lower moieties and of the contralateral kidney as well as it can detect renal scars [1118, 1119]. Using functional MR urography, differential renal function can be assessed with low intra- and interobserver variability [1120]. Based on the prevalence of high-grade reflux, VCUG is mandatory for identifying ipsilateral or contralateral reflux and assessing the degree of intra-urethral prolapse of the ureterocele [1121]. Urethrocystoscopy may reveal the pathology in cases where it is difficult to make the differential diagnosis between ureterocele and ectopic mega-ureter.

3.16.3.2  **Ectopic ureter**

Most of the ectopic mega-ureters are diagnosed primarily by US. In some cases, clinical symptoms can lead to diagnosis:
- In neonates: dribbling of urine, pyuria, and acute pyelonephritis.
- In young girls: permanent urinary incontinence besides normal voiding, or significant vaginal discharge as the equivalent of incontinence; an ectopic orifice may be found in the meatal region [1122].
- In pre-adolescent boys: epididymitis is the usual clinical presentation and the seminal vesicle may be palpable.

Ultrasound, radionuclide studies (DMSA, VCUG, MR urography, high-resolution MRI, and cystoscopy) are the diagnostic tools to assess function, to detect reflux and rule out ipsilateral compression of the lower pole and urethral obstruction [1123]. In some cases, the large ectopic ureter presses against the bladder and can look like a pseudo-ureterocele [1124].

Girls who present with life-long minimal urinary incontinence, never being dry, normal bladder function, complete emptying, and normal US are very suspicious for ectopic ureter. This needs to be excluded or confirmed by MRI as it is the most sensitive method [1125].

3.16.4  **Management**

3.16.4.1  **Ureterocele**

Management is controversial with a choice between a non-operative approach, endoscopic decompression, ureteral re-implantation, partial nephroureterectomy, or complete primary reconstruction [1126-1131]. The choice of a therapeutic modality depends on the following criteria: clinical status of the patient (e.g. urosepsis); patient age; function of the upper pole; presence of reflux or obstruction of the ipsilateral or contralateral ureter; presence of bladder neck obstruction caused by ureterocele; intravesical or ectopic ureterocele; and caregivers’ and the surgeon’s preferences [1131]. When the diagnosis is made by US, prophylactic antibiotic treatment maybe indicated until a VCUG is performed.

3.16.4.1.1  **Early treatment**

In the presence of febrile infection or obstruction at the bladder neck, immediate endoscopic incision or puncture of the ureterocele is recommended. In a clinically asymptomatic child with a ureterocele and a non
or hypofunctional upper pole, without significant obstruction of the lower pole and without bladder outlet obstruction, prophylactic antibiotic treatment is given until follow-up procedures are instigated. Decompression of the dilated system facilitates later reconstructive surgery [1132, 1133].

3.16.4.1.2 Re-evaluation
Active surveillance is an option for antenatally detected ureteroceles, but long-term follow-up is necessary [1134]. Conservative treatment may be adopted in asymptomatic patients without any bladder outlet obstruction, severe hydroureronephrosis of the uretercele moiety or high-grade (over grade III) reflux [1131, 1135]. A meta-analysis showed that, after primary uretercele-incision, the re-operation rate is higher in those with an ectopic uretercele compared to those with an intravesical uretercele [1127]. Secondary surgery is necessary if decompression is not effective, significant reflux is present, or there is obstruction of the ipsi- or contralateral ureters, and/or bladder neck obstruction or retained uretercele [1136].

Surgery may vary from upper pole nephrectomy to complete unilateral LUT reconstruction [1130, 1137-1139]. In an ectopic uretercele with severe hydroureronephrosis and without reflux, the primary upper tract approach without endoscopic decompression (partial upper-pole nephroureterectomy, pyelo/ureteropyelo/ureterostomy and upper-pole ureterectomy) has an 80% chance of being the definitive treatment [1131, 1140]. Also a LUT approach in those with a poorly or non-functioning upper pole is an option [1141]. Today, despite successful surgery, some authors think, that surgery may not be necessary at all in some patients [1142], as less aggressive surgical treatment and non-operative management over time can achieve the same functional results [1143]. There is emerging evidence on Minimally Invasive surgical approach (laparoscopic and robot assisted) for upper pole nephrectomy with similar operating time to open surgery [1144, 1145].

Figure 11: Algorithm for the management of duplex system ureteroceles after the first 3-6 months of life [1028]

DSU = duplex system ureterocele; HUN = hydroureronephrosis; UPPN = upper pole partial nephrectomy; VUR = vesicoureteric reflux to the lower pole.

Obstruction is considered to be the presence of non-refluxing dilatation of non-uretercele-bearing moieties (especially of the lower pole) or of an obstructive drainage pattern on diuretic renography.

3.16.4.2 Ectopic ureter
In the majority of cases, the upper pole is dysplastic and poorly functioning. There are a variety of therapeutic options, each with its advantages and disadvantages. In non-functioning moieties with recurrent infections, heminephro-ureterectomy is a definite solution. Ureteral reconstruction (ureteral re-implantation/ureterouretetomystomy/ureteropyelo/ureterectomy and upper-pole ureterectomy) are other therapeutic options especially in cases in which the upper pole has function worth preserving. These procedures can be performed through an open laparoscopic or robotic assisted approach [1145-1148]. So far there is no superior approach [1149]. In patients with bilateral single ectopic ureters (a very rare condition), an individual approach depending on the...
sex and renal and bladder function of the patient is necessary. Usually the bladder neck is insufficient in these patients [1150].

3.17 Disorders of sex development

3.17.1 Introduction

The formerly called ‘intersex disorders’ were the subject of a consensus document in which it was decided that the term ‘intersex’ should be changed to ‘disorders of sex development’ (DSD) [1151].

The new classification has arisen due to advances in knowledge of the molecular genetic causes of abnormal sexual development, controversies inherent to clinical management and ethical issues. Controversial and negative terminology, e.g. ‘pseudohermaphroditism’ and ‘hermaphroditism’, have been renamed according to the new pathophysiological insights. Furthermore, some conditions presenting with severe male genital malformation, such as penile agenesis and cloacal extrophy, which could not be categorised, have also been included. The term ‘disorders of sex development’ is proposed to indicate congenital conditions with atypical development of chromosomal, gonadal or anatomical sex.
In addition, in 2017, the Parliamentary Assembly of the Council of Europe decided on a resolution called: “Promoting the human rights of and eliminating discrimination against intersex people” [1152]. The Parliamentary Assembly concluded that the majority of intersex people are physically healthy and only a few suffer from medical conditions that put their health at risk. Furthermore, they state that the prevailing medical view has been that intersex children’s bodies can and should be made to conform to either a male or a female paradigm, often through surgical and/or hormonal intervention and that this should be done as early as possible and that the children should then be raised in the gender corresponding to the sex assigned to their body. The Parliamentary Assembly considers that this approach involves serious breaches of physical integrity, in many cases concerning very young children or infants who are unable to give consent and whose gender identity is unknown.

Therefore the Parliamentary Assembly called on Council of Europe member states with regard to effectively protecting children’s right to physical integrity and bodily autonomy and to empowering intersex people as regards the following rights: medically unnecessary sex-“normalising” surgery, sterilisation and other treatments practised on intersex children without their informed consent should be prohibited and in addition that it has to be ensured that, except in cases where the life of the child is at immediate risk, any treatment that seeks to alter the sex characteristics of the child, including their gonads, genitals or internal sex organs, is deferred until such time as the child is able to participate in the decision, based on the right to self-determination and on the principle of free and informed consent.

The Panel refers to the consensus documents mentioned above as well as on the Parliamentary Assembly resolution. This chapter will focus on what is relevant for the practising paediatric urologist as the urologist is likely to be involved in neonates with DSD conditions.

Overall, evidence-based literature on DSD is sparse. There are no RCTs and most studies are based on retrospective clinical descriptive studies or on expert opinion. An exception is the risk of gonadal cancer, for which the level of evidence is higher [1153].

Disorders of sex development can present as prenatal diagnosis, neonatal diagnosis and late diagnosis. Prenatal diagnosis can be based on karyotype or US findings; neonatal diagnosis is based on genital ambiguity and late diagnosis is made on early or delayed puberty. In this guideline, focus is on the neonatal presentation where the paediatric urologist plays a major role. For late diagnosis we refer to endocrinology and gynaecology guidelines on precocious and delayed puberty where paediatric urologists play a minor role [1154, 1155].

Dealing with neonates with DSD requires a multidisciplinary approach, which should include geneticists, neonatologists, paediatric and adult endocrinologists, gynaecologists, psychologists, ethicists and social workers. Each team member should be specialised in DSD and a team should have treated enough patients to ensure experience.

3.17.2 Current classification of DSD conditions
Since the International Consensus Conference on intersex and its subsequent publications on classification of the various conditions of DSD, several updates have been published with the latest published by the Global DSD Update Consortium in 2016 [1156]. As the field of DSD is continuously developing and knowledge and viewpoints change over time, an effort was made to include representatives from a broad perspective including support and advocacy groups with the goal to focus patient care upon the best possible QoL.

According to the international consensus in 2005, DSDs were defined as congenital conditions within which the development of chromosomal, gonadal and anatomical sex is atypical. The changes that were made according to terminology are as follows:

46XX DSD group formerly called female pseudohermaphrodite, over-virilisation of an XX female, and masculinisation of an XX female. In this group the vast majority is due to classic congenital adrenal hyperplasia (CAH) with various degrees of masculinisation. Among all DSD conditions together, 46XX CAH patients comprise approximately 80%. These conditions are extremely important since they can be potentially life threatening after birth because of salt loss phenomenon and immediate medical care is mandatory.

46XY DSD group in the past named male pseudohermaphrodite, undervirilisation of an XY male, and undermasculinisation of an XY male. This group is often quite heterogenous and includes the partial androgen insensitivity syndrome (PAIS) as well as the complete androgen insensitivity syndrome (CAIS) formerly called testicular feminisation.
Sex chromosome mosaicism DSD group (45X, 45X/46XY, 47XXY) consists of multiple variants with the mixed gonadal dysgenesis being the most important one. Many have a normal male phenotype and others asymmetric genitalia. One scrotal half often contains a gonad which is likely to be a testis whereas the other side is more a labia majora with usually no palpable gonad, most likely to be a streak gonad.

Ovotesticular DSD group was in the past called true hermaphrodite because of the presence of ovarian and testicular tissue in the same individual meaning that both – female and male structures – live together. There is great variability in phenotype with uni- or bilateral undescended gonads which can present as one ovary and one testis or as one or two ovotestes.

Non-hormonal/non-chromosomal DSD group was introduced as well, including newborns with cloacal extrophy where bladder and intestines are exposed, patients with aphallia, and severe micropenis. The latter one is a normally formed penis with a stretched length of < 2.5 standard deviation below the mean [1151, 1157].

Micropenis should be distinguished from buried and webbed penis, which are usually of normal size. The length of the penis is measured on the dorsal aspect, while stretching the penis, from the pubic symphysis to the tip of the glans [1151].

3.17.3 Diagnostic evaluation
3.17.3.1 The neonatal emergency
The first step is to recognise the possibility of DSD (Table 5) and to refer the newborn baby immediately to a tertiary paediatric centre, fully equipped with neonatal, genetics, endocrinology and paediatric urology units. Diagnosis of a 46XX DSD due to congenital adrenal hyperplasia should not be delayed and represents a neonatal emergency situation since the possibility of salt loss phenomenon can be fatal.

**Investigations**

| Blood analysis: 17-hydroxyprogesterone, electrolytes, LH, FSH, TST, cortisol, ACTH |
| Urine: adrenal steroids |
| Karyotype |
| Ultrasound |
| Genitogram |
| hCG stimulation test to confirm presence of testicular tissue |
| Androgen-binding studies |
| Endoscopy |

**ACTH** = adrenocorticotropic hormone; **FSH** = follicle-stimulating hormone; **hCG** = human chorionic gonadotropin; **LH** = luteinising hormone; **TST** = testosterone.

A thorough clinical examination in a neonate presenting with ambiguous genitalia is important. As well as an accurate description of the ambiguous genitalia, detailed information should be given on palpability and localisation of the gonads. Information gathered by the various examinations described below should help the team to come to a final diagnosis. Medical photography can be useful but requires sensitivity and consent [1158].

**Palpable gonad:** If it is possible to feel a gonad, it is most likely to be a testis; this clinical finding therefore virtually excludes 46XX DSD.

**Phallus:** The phallus should be measured. A cotton bud placed at the suprapubic base of the implant of the stretched phallus allows for a good measurement of phallic length.

**Urogenital sinus opening:** The opening of the urogenital sinus must be well evaluated. A single opening has to be identified as well as a hymenal ring. Attention needs to be paid to the fusion of the labioscrotal folds as well as whether they show rugae or some discolouration.

**Ultrasound** can help to describe the palpated gonads or to detect non-palpable gonads. However, the sensitivity and specificity are not high. Mülllerian structures like the vagina or utricular structures can be evaluated as well [1159, 1160].

**Genitography** can provide some more information on the urogenital sinus, especially on the exact position of the confluence. Moreover, it gives evidence of possible duplication of the vagina.

**Invasive diagnostics** under general anaesthesia can be helpful in some cases. On cystoscopy, the urogenital sinus can be evaluated as well as the level of confluence. It allows also for evaluation of the vagina or utriculus, the possible presence of a cervix at the top of the vagina.

**Laparoscopy** is necessary to obtain a final diagnosis on the presence of impalpable gonads and on the presence of Müllerian structures. If indicated, a gonadal biopsy can be performed [1161, 1162].

These investigations will help to distinguish the various conditions of DSD and provide quick evidence of congenital adrenal hyperplasia (CAH), which is the most frequently occurring DSD and the one that can become life-threatening within the first days of life because of salt loss phenomenon.

### 3.17.4 Gender assignment

Nowadays it is obvious and clear that open and complete communications with caregivers and eventually the affected person are mandatory. Education and psychological support regarding the impact are needed for each individual to make sense of the condition, relate to their community and establish relationships. The lack of outcome data and different preferences make it extremely difficult to determine whether and when to pursue gonadal or genital surgery. Shared decision making is necessary, combining expert healthcare knowledge and the right of a patient or surrogate to make fully informed decisions. This entails a process of education, sharing of risks/benefits, articulating the uncertainties in DSD care and outcomes and providing time for the patient and family to articulate back the risks and benefits of each option. The goal of all involved should be to individualise and prioritise each patient.

However, adverse outcomes have led to recommendations to delay unnecessary surgery to an age when the patient can give informed consent. Surgery that alters appearance is not urgent. Recently the Parliamentary Assembly of the Council of Europe, the European Society for Paediatric Urology (ESPU) as well as the Societies...
for Pediatric Urology have taken a position in the debate on surgery for DSD [1152, 1163, 1164]. In an open letter to the Council of Europe, the European Society for Paediatric Urology expressed its attitude to the abovementioned resolution and concentrated on a worrying issue dealing with medicosurgical care for children with DSD. It states that surgical interventions in children with DSD only being applied in emergency conditions is discordant with the definition of health according to the WHO, stating that health is not merely the absence of disease, but is a much broader concept, including physical, mental, and social domains. This especially applies to children, as favourable physical, social and emotional conditions are all critical factors for their optimal growth and development, which enables them to reach their full potential at adult age. As social and emotional interactions with the parents or caregivers, being the most important adults in a young child’s life, form the basis for their future, treatment of children with DSD can best be organised in a patient- and family-centred multidisciplinary setting, in an atmosphere based on openness, commitment and trust. Physicians, who daily take care of children with a variety of congenital conditions, the same as their parents or caregivers, are committed to the current as well as the future health and well-being of all children entrusted to their care. In contrast to what is alleged in the recommendation, parents and caregivers implicitly act in the best interest of their children and should be respected as their outstanding representatives, and should not be put aside by claiming prohibition regulations regarding the well-informed decisions they make on their behalf. Finally in that open letter the ESPU advocate keeping the dialogue open with the professionals active in specialised centres for multidisciplinary, patient- and family-centred care as well as with patient societies, for which the present resolution is recognised as being a solid starting base [1165].

3.17.5 Risk of tumour development
Individuals with DSD have an increased risk of developing cancers of the germ cell lineage, malignant germ cell tumours or germ cell cancer in comparison with to the general population [1166].

It is well-recognised that the highest risk prevalence (30-50%) is seen in conditions characterised by disturbed gonadal development such as incomplete testis development combined with a full block of embryonic germ cell maturation in patients with 46XY gonadal dysgenesis and in some patients with 45X/46XY DSDs. Conversely, patients with testosterone biosynthesis disorders and androgen action disturbances show a much lower risk (1-15%) for carcinoma in situ (CIS) development during childhood and a limited tendency towards invasive progression of the lesions [1167]. With regard to clinical management a gonadal biopsy at the time of a possible orchidopexy can be obtained for an initial assessment including regular self-exams and annual ultrasound [1153].

3.18 Congenital lower urinary tract obstruction (CLUTO)

Introduction
The term congenital lower urinary tract obstruction (CLUTO) is used for a foetus, which during intrauterine US screening shows a dilatation of the upper and lower urinary tract. During pregnancy the diagnosis is usually based only on US examinations. There is a broad spectrum of conditions, that could cause an intrauterine dilatation of the urinary tract. Post-partum diagnosis comprises any anatomical and functional disorder/anomaly/malformation causing a dilatation e.g. posterior/anterior urethral valve, urethral atresia/ dysplasia/stenosis prune belly syndrome, dilating reflux. Cloacal malformation, ureterocele, a Megacystis-Microcolonintestinal hypoperistalsis or Megacystis-Megaureter Syndrome [1168-1171].

Megacystis
In the first trimester, foetal megacystis is defined as a bladder with a longitudinal diameter ≥ 7 mm, and in the 2nd and 3rd trimester as an enlarged bladder failing to empty during an extended US examination lasting at least 40 minutes. Two thirds of cases are secondary to CLUTO and the remainder are associated with genetic syndromes, developmental or chromosomal abnormalities including anorectal malformations; 14% were normal or having isolated urological abnormality (e.g. VUR, Duplex system) [1172]. A more recent systematic review showed that at least 45% of cases have oligohydramnios and 15% have chromosomal abnormalities, most of them being trisomy
13, 18 and 21. Final diagnoses were posterior urethral valve (PUV) (57%), urethral atresia/stenosis (7%), prune-belly syndrome (4%), megacystis-microcolon-intestinal hypoperistalsis syndrome (MMIHS) (1%), cloacal abnormality (0.7%) and undefined pathologies (36.5%). Termination of pregnancy rate was 50% [1173].

The prognosis of the foetus depends on the underlying pathology, the timing of diagnosis, presence of an oligo-, anhydramnios and bladder volume. Fontanella et al developed a staging system of CLUTO. They described three groups: severe (Bladder volume $\geq 5.4$ cm$^3$ and/or oligo-, an hydramnios before 20 weeks), moderate (Bladder volume $< 5.4$ cm$^3$ and/or normal amniotic fluid at 20 weeks) and mild (Normal AF at 26 weeks) [1174]. This staging system can be used to predict perinatal mortality and post-natal estimated GFR. Another recent systematic review on prognosis of megacystis patients revealed an overall intrauterine spontaneous resolution of 32%, with better resolution rates in early (before 18 weeks) megacystis cases (40% vs. 12%) [1175].

3.18.1 **Posterior urethral valves**

3.18.1.1 Epidemiology, aetiology and pathophysiology

Posterior urethral valves are one of the few life-threatening congenital anomalies of the urinary tract found during the neonatal period. A recent systematic review showed, that the risk for chronic kidney disease (CKD) could be up to 32% and for end-stage kidney disease (ESKD) up to 20% [1176]. Up to 17% of paediatric ESKD can be attributed to PUV [1177]. An incidence of PUV of 1 in 7,000-8,000 live-births has been estimated [1169, 1178].

3.18.2 **Classification systems**

3.18.2.1 **Urethral valve**

Up until today, the original classification by Hugh Hampton Young is the most commonly used classification [1179]. Hugh Hampton Young described three categories: type I, type II and type III. However, today, only type I and type III are found to be obstructive. As type II seems to be more like a fold and not obstructive, it is no longer referred to as a valve. Hampton Young's descriptions of type I and III are as follows:

Type I (90-95%). ‘In the most common type there is a ridge lying on the floor of the urethra, continuous with the verumontanum, which takes an anterior course and divides into two fork-like processes in the region of the bulbomembranous junction. These processes are continued as thin membranous sheets, direct upward and forward which may be attached to the urethra throughout its entire circumference. It is generally supposed that the valves have complete fusion anteriorly, leaving only an open channel at the posterior urethral wall. Yet, the fusion of the valves anteriorly may not be complete in all cases, and at this point a slight separation of the folds exists’ [1179].

Type III. ‘There is a third type which has been found at different levels of the posterior urethra and which apparently bears no such relation to the verumontanum. This obstruction was attached to the entire circumference of the urethra, with a small opening in the centre [1169]. The transverse membrane described has been attributed to incomplete dissolution from the urogenital portion of the cloacal membrane [1180]. The embryology of the urethral valves is poorly understood. The membrane may be an abnormal insertion of the mesonephric ducts into the foetal cloaca [1181].

3.18.3 **Diagnostic evaluation**

An obstruction above the level of the urethra affects the whole urinary tract to varying degrees.

- The prostatic urethra is distended and the ejaculatory ducts may be dilated due to urinary reflux.
- The bladder neck is hypertrophied and rigid.
- The hypertrophied bladder occasionally has multiple diverticula.
- Nearly all valve patients have dilatation of both upper urinary tracts. This may be due to the valve itself and the high pressure in the bladder, or due to obstruction of the ureterovesical junction by the hypertrophied bladder.
- If there is secondary reflux, the affected kidney functions poorly in most cases.

During prenatal US screening, bilateral hydroureteronephrosis and a distended bladder are suspicious signs of a urethral valve. A thick-walled bladder seems to be of better prediction of a PUV than a dilated posterior urethra (‘keyhole’ sign) [1182]. However, differentiation between obstructive and non-obstructive aetiologies on prenatal US is challenging as both have a similar US appearance [1183]. In the presence of increased echogenicity of the kidney, dilatation of the urinary tract and oligohydramnion, the diagnosis of a PUV should strongly be considered. Prenatal US is adequate in most of the cases (90%) [1184]. However in some circumstances when technical US conditions are poor such as oligo- or anhydramnios, large maternal body habitus, unfavourable position of the foetus or in suspicion of complex foetal anomalies such as accompanying gastrointestinal system, foetal MRI may provide additional information [1184-1186].
Post-natally, a voiding cystourethrogram confirms the diagnosis of a PUV. This study is essential whenever there is a question of an infravesical obstruction, as the urethral anatomy is well-outlined during voiding. A secondary reflux is observed in at least 50% of patients with PUV [1187]. Reflux is consistently associated with renal dysplasia in patients with PUV. It is generally accepted that reflux in the renal units acts as a ‘pressure pop-off valve’, which would protect the other kidney, leading to a better prognosis [1188]. Other types of pop-off mechanisms include bladder diverticula and urinary extravasation, with or without urinary ascites [1189]. However, in the long-term, this supposed protective effect did not show a significant difference compared to other patients with PUV [1190, 1191].

Nuclear renography with split renal function is important to assess kidney function (DMSA or MAG3). Creatinine, blood urea nitrogen and electrolytes should be monitored closely during the first few days. Initial management includes a multi-disciplinary team involving a paediatric nephrologist. The clinician must be aware of a noteworthy association between PUV and undescended testes and/or inguinal hernia [1192]. Undescended testes occurred in 12-17% of PUV which is consistent with a 10-fold increase [1193].

3.18.4 Management
3.18.4.1 Antenatal treatment
Today most of PUV are discovered before birth [1168-1171]. The intrauterine obstruction leads to a decreased urine output, which could result in an oligo- or anhydramnios. Amniotic fluid is necessary for normal development of the lung and its absence may lead to pulmonary hypoplasia, causing a life-threatening problem.

Kids start to produce urine at around 10th weeks of antenatal life. Many of the megacystis cases (7-15 mm) with normal karyotype spontaneously resolve before 20 weeks, whereas it is unlikely in those with a bladder length > 15mm (> 12mm before age of 18 Weeks of gestation) [1183, 1194, 1195]. Antenatal imaging of kidneys before 20 weeks is difficult and in rare instances imaging could be done earlier via transvaginal route [1196]. The possible spontaneous resolution chance of bladder enlargement and timing of proper kidney imaging are possibly the main obstacles on the optimum timing for prenatal intervention.

As renal dysplasia is not reversible, it is important to identify those foetuses with good renal function. A sodium level below 100 mmol/L, a chloride value of < 90 mmol/L, and an osmolarity below 200 mOsm/L found in three foetal urine samples gained on three different days are associated with a better prognosis [1197]. Urine samples before 23 weeks of gestation (ß2-microglobline, sodium, chloride and calcium) may be helpful to distinguish between those who could benefit from intrauterine therapy and those in whom the outcome is most likely to be compromised [1198]. The status of amniotic fluid, the appearance of the kidneys as well as the foetal urine biochemistry could be helpful in counselling the caregivers.

Prenatal interventions aim to restore amniotic fluid volume and attenuate the risk of pulmonary hypoplasia or further renal damage [1199]. Decision for prenatal intervention can be based on a staging system that is composed of renal ultrasonographic findings, amnion amount and foetal urine biochemistry [1170]. Early intervention – before the age of 16 weeks of gestation, may be beneficial for the renal function, however making the correct diagnosis and the detection of other severe co-morbidities is extremely difficult at this time point [1200]. Later interventions are mostly of benefit for the lung development, but not for renal function.

The placing of a vesicoamniotic shunt has a complication rate of 21-59% with dislocation of the shunt being the most common one [1199]. The PLUTO-trail (randomised study) failed to show any long-term benefit on renal function by placing a visual analogue scale (VAS) [1201]. A recent meta-analysis on interventions for CLUTO reported that VAS resulted in a higher perinatal survival rate than conservative management (57.1% vs 38.8%) with no significant differences in 6-12 month survival, 2-year survival or postnatal renal function [1202]. Foetal cystoscopy with laser ablation has a high complication rate without evidence for the effectiveness of these interventions [1203]. To avoid the severe complication of the laser ablation, balloon dilation is tried [1204]. The number of patients included and designs of these studies are insufficient to give any recommendations. Parental information is very important and the natural history of CLUTO including the postnatal outcomes with or without prenatal treatment as well as the uncertainties and/or controversies about CLUTO diagnosis and treatment should be discussed [1199].

3.18.4.2 Postnatal treatment
Bladder drainage. If a boy is born with suspected PUV, drainage of the bladder and, if possible, an immediate VCUG is necessary. A neonate can be catheterised with a small catheter without a balloon, preferably a feeding tube. A VCUG is performed to see if the diagnosis is correct and whether the catheter is within the bladder and not in the posterior urethra. An alternative option is to place a suprapubic catheter, perform a VCUG and leave the tube until the neonate is stable enough to perform an endoscopic incision or resection of the valve.
Valve ablation. When the medical situation of the neonate has stabilised and the creatinine level decreased, the next step is to remove the intravesical obstruction. In cases where the urethra is too small to safely pass a small foetal cystoscope, a suprapubic diversion is performed until valve ablation can be performed. Small paediatric cystoscopes and resectoscopes are now available either to incise, ablate or to resect the valve at the 4-5, 7-8 or 12 o’clock position, or at all three positions, depending on the surgeon’s preference. It is important to avoid extensive electrocaulation, as the most common complication of this procedure is stricture formation. Two studies demonstrated a lower urethral stricture rate using the cold knife compared to diathermy [1205, 1206]. Within the three months following initial treatment, effectiveness of the treatment should be demonstrated either by clinical improvement (US and renal function), control VCUG or a re-look cystoscopy, depending on the clinical course [1207-1209].

Vesicostomy. If the child is too small and/or too ill to undergo endoscopic surgery, a suprapubic diversion is performed to drain the bladder temporarily. If initially a suprapubic tube has been inserted, this can be left in place for six to twelve weeks. Otherwise, a cutaneous vesicostomy provides an improvement or stabilisation of the UUT in up to 90% of cases [1210, 1211]. Although there has been concern that a vesicostomy could decrease bladder compliance or capacity, so far there are no valid data to support these expectations [1212, 1213]. Moreover, it was shown in PUV patients with stage 3 CKD that adding vesicostomy to valve ablation no long-term benefit was noted from diversion in the ultimate incidence of ESKD [1214].

High diversion. If bladder drainage is insufficient to drain the UUT, high urinary diversion should be considered. Diversion may be suitable if there are recurrent infections of the upper tract, no improvement in renal function and/or an increase in upper tract dilatation, despite adequate bladder drainage. The choice of urinary diversion depends on the surgeon’s preference for high-loop ureterostomy, ring ureterostomy, end ureterostomy or pyeloostomy, with each technique having advantages and disadvantages [1215-1218]. Diversion can delay progression to end stage renal failure [1214]. Reconstructive surgery should be delayed until the UUT has improved as much as can be expected.

Reflux is very common in PUV patients (up to 72%) and it is described bilaterally in up to 32% [1219]. During the first months of life, antibiotic prophylaxis may be given especially in those with high-grade reflux [930] and in those with a phimosis, circumcision can be discussed in order to reduce the risk of UTIs [1220]. However, there are no randomised studies to support this for patients with PUV. Early administration of oxybutynin may improve bladder function as shown in one study with eighteen patients [1221]. High-grade reflux is associated with a poor functioning kidney and is considered a poor prognostic factor [1222, 1223]. However, early removal of the renal unit seems to be unnecessary, as long as it causes no problems. Moreover, in the long term it may be necessary to augment the bladder and in this case the ureter may be used [1224]. Deterioration of renal function without a fixed obstruction and higher urine output (polyuria) may lead to an overdistension of the bladder during the night. Drainage of the bladder during the night by a catheter may be beneficial for the renal function. If initially a suprapubic tube has been inserted, this can be left in place for six to twelve weeks. Otherwise, a cutaneous vesicostomy provides an improvement or stabilisation of the UUT in up to 90% of cases [1210, 1211]. Although there has been concern that a vesicostomy could decrease bladder compliance or capacity, so far there are no valid data to support these expectations [1212, 1213]. Moreover, it was shown in PUV patients with stage 3 CKD that adding vesicostomy to valve ablation no long-term benefit was noted from diversion in the ultimate incidence of ESKD [1214].

Follow-up
Several prognostic factors have been described. Different serum nadir creatinine levels are given in the literature (0.85 mg/dL-1.2 mg/dL (μmol/L) [1230-1233]. Renal parenchyma quantity (total renal parenchymal area) and quality (corticomedullary differentiation and renal echogenicity) on initial postnatal US also have prognostic value [1234].

Life-long monitoring of these patients is mandatory, as bladder dysfunction ('valve bladder') is not uncommon and the delay in day- and night-time continence is a major problem [1235, 1236]. The literature demonstrates that urodynamic studies plays an important role in the management of patients with valve bladder especially in those with suspicion of bladder dysfunction [1237, 1238]. Poor bladder sensation and compliance, detrusor instability and polyuria (especially at night) and their combination are responsible for bladder dysfunction. In those with bladder instability, anticholinergic therapy can improve bladder function. However, there is a low risk of reversible myogenic failure (3/37 patients in one study) [1239, 1240]. In patients with poor bladder emptying, α-blocker can be used to reduce the PVR urine, as demonstrated in one study with 42 patients using terazosin (mean PVR was reduced from 16 to 2 mL) [1241]; in another study tamsulosin was effective [1242]. Concerning bladder neck incision, there is no Panel consensus concerning indication and efficacy. High creatinine nadir (> 1 mg/dL) and severe bladder dysfunction are risk factors for renal replacement therapy [1243, 1244]. Renal transplantation in these patients can be performed safely and effectively [1245, 1246]. Deterioration of the graft function is mainly related to LUTD [1245]. Therefore, it is essential to have and keep a good reservoir function. An assessment and treatment algorithm is provided in Figure 12.
There are only few reports on sexual function and fertility in patients with PUV demonstrating some impairment especially in those who are on dialysis [1247, 1248]. In a review the majority have good erectile function (74-94%) and a fertility comparable to the normal population [1249]. However, a negative influence of the individual patient’s fertility has to be taken into account, as these patients have a higher risk for bilateral cryptorchidism, recurrent epididymitis and ESRD [1249].

**Figure 12: An algorithm on the assessment, management and follow-up of newborns with possible PUV**

CIC = clean intermittent catheterisation; OAB = overactive bladder; PUV = posterior urethral valve; RF = renal function; UT = urinary tract; UUT = upper urinary tract; VCUG = voiding cystourethrogram.

### 3.18.6 Summary

Posterior urethral valves are one of the few life-threatening congenital anomalies of the urinary tract found during the neonatal period and despite optimal treatment result in renal insufficiency in nearly one-third of cases. Bilateral hydroureretonephrosis and a distended bladder are suspicious signs of a PUV in neonates. A VCUG confirms a PUV diagnosis. Nuclear renography with split renal function is important to assess kidney function and serum creatinine nadir above 80 μmol/L is correlated with a poor prognosis. Today, antenatal therapy is becoming more and more popular. Identification of those with an obstructive uropathy and definition of those who would benefit from early antenatal intervention are the major challenges. Postnatal treatment
includes bladder drainage, either transurethral or suprapubic and if the child is stable enough, endoscopic incision of the valve is performed. If a child is too small and/or too ill to undergo endoscopic surgery, a vesicostomy is an option for bladder drainage. If bladder drainage is insufficient to drain the UUT, high urinary diversion should be considered.

In all patients life-long monitoring is mandatory, as bladder dysfunction is quite common and may cause progressive upper tract deterioration, if not managed properly. In the long-term between 10 and 47% of patients may develop end-stage renal failure. Renal transplantation in these patients can be performed safely and effectively.

- **Anterior urethral valve (AUV)**
  Anterior urethral valve is a semilunar or iris-like band of tissue on ventral aspect of urethra. It can be isolated, in association with or confused with urethral diverticulum. The aetiology of isolated AUV is speculated to be secondary to congenital urethral obstruction, malunion of glanular and penile urethra, congenital cystic dilatation of peri-urethral glands or ruptured distal lip of a syringocele [1250]. Anterior urethral valve occurs less frequently than PUV. It can be present in the bulbous urethra, the penoscrotal junction and penile urethra. Patients may present with poor urinary stream, penile ballooning, UTI or haematuria. Anterior urethral valves have been classified by Firlit et al. depending on the presence of diverticulum and the dilatation of urethra and upper tract [1251]. The diagnosis is based on VCUG with possible findings of dilated or elongated posterior urethra, a dilatation of the anterior urethra, a thickened trabeculated bladder, a hypertrophied bladder neck, VUR, and urethral diverticula. In doubtful cases, retrograde urethrogram may be helpful showing linear filling defect along the ventral wall, or it may show a dilated urethra ending in a smooth bulge or an abrupt change in the caliber of the dilated urethra on VCU [1252]. Treatment is performed mainly by endoscopic valve ablation. In selected patients, a temporary diversion may be considered until the child is big enough for endoscopy to be possible. Open surgery is reserved in patients with very large diverticulum and defective spongiosum. Renal failure may develop in 22% and the risk is highest in patients with pre-treatment azotaemia, VUR and UTI [1253].

- **Anterior urethral diverticulum (AUD):**
  Common postnatal presenting features of AUD are compressible ventral penile swelling, urinary dribble postmicturition, voiding difficulty, poor stream, and recurrent UTIs [1254-1256]. Diagnosis is made by VCUG with or without a retrograde urethrogram. In small AUD, endoscopic cutting or deroofing of distal lip of the diverticulum can be used as a treatment modality. Larger diverticulum requires excision of the diverticulum with a twolayered urethroplasty; or marsupialisation with staged urethroplasty. In cases of urosepsis and obstructive uropathy, a suprapubic catheter may be placed. Once the infant’s condition improves, temporary urinary diversion with vesicostomy or proximal cutaneous urethrostomy can be performed before definitive surgical management [1257, 1258]. The diverticulum is associated with a distal lip-like tissue which may be confused with a valve. Anatomically, AUV have normal corpus spongiosum development whereas AUD have incomplete spongiose tissue formation [1257].

- **Syringocele**
  Cowper glands are two bulbourethral glands located within the urogenital diaphragm and secrete pre-ejaculatory mucus on both sides through the external sphincter into the urethra 1-2 cm distal to the sphincter. Syringocele is the cystic dilatation of these glands. The aetiology can be congenital (retention cyst of the intraurethral portion of the duct) or acquired (trauma or infection). It has been classified as simple, perforate, perforate and ruptured [1259]. A simpler grouping is suggested to merge simple, perforate and ruptured into “open syringocele” and imperforate to “closed syringocele”. Closed syringoceles cause obstructive symptoms and open ones act as a diverticula and cause post-voiding dripping and sometimes obstruction due to orientation of one membrane into urethra [1260]. However, it is better to simply categorise into two groups as obstructing and non-obstructing in terms of understanding pathophysiology and management [1261]. Depending on the syringocele type, patients present with post-void dribbling, urethral discharge, UTI, perineal pain, haematuria, obstructive voiding symptoms, dysuria and retention. Diagnosis is based on antegrade and/ or retrograde urethrogram which shows a cystic defect distal to prostate. If the VUC/RGU are inconclusive, US and/or MRI may be used if open reconstruction is being planned. Endoscopic deroofing of the cyst in both obstructing and non-obstructing syringoceles is an effective method of marsupialisation [1262]. In cases where endoscopic approach is not feasible open correction may be considered.

- **Cobb’s collar**
  Cobb’s collar is a congenital membranous stricture of the bulbar urethra. It is different from congenital obstructive posterior urethral membrane (COPUM) and is independent of the verumontanum and external sphincter and may represent a persistence of part of the urogenital membrane [1263]. Voiding cystourethrogram shows narrowing in the proximal bulbar urethra with folds extending proximally, a dilated
posterior urethra, prominent bladder neck and other findings of infravesical obstruction. Treatment is an endoscopic incision; using cold-knife showed lower recurrence rates than electrocautery [1264].

- **Urethral atresia/hypoplasia**
  Male urethral atresia is a congenital, complete obstruction of the urethra caused by a membrane that is usually located at the distal end of the prostatic urethra. The urethra distal to this point is usually hypoplastic, presumably from lack of foetal voiding [1265]. Urethral atresia is associated with bladder distention, VUR, hydronephrosis and renal dysplasia [1266]. Most cases reported have the phenotypic characteristics of the prune belly syndrome. Antenatal intervention may be beneficial in terms of foetal survival [1267]. Although progressive augmentation by dilating the urethra anterior (PADUA) procedure was described as a treatment modality, the majority of cases requires some form of supravesical diversion [1265, 1266].

- **Posterior Urethral Polyps:**
  Although, posterior urethral polyps (PUP) does not cause antenatal hydronephrosis, it could cause obstruction later in life. Posterior Urethral Polyps is a polypoid, pedunculated, fibroepithelial lesion arising in posterior urethra proximal to the verumontanum. It lies on the floor of the urethra with its tip reaching into the bladder neck and obstruction occurs because of distal displacement of polyp during urination [1268]. Patients complain of dysuria, haematuria and obstructive symptoms such as poor urinary stream and intermittent retention episodes. Diagnosis can be suspected by VCUG and/or US but is confirmed during cystourethroscopy. Treatment is usually an endoscopic resection of the polyp. The course of the disease is benign and no recurrences were reported in the literature [1269, 1270].

3.19 **Rare Conditions in Childhood**

3.19.1 **Urachal remnants**

3.19.1.1 **Introduction**

The urachus is an embryonic structure arising as a result of the separation of the allantois from the ventral cloaca. The allantois appears on day sixteen as a tiny, fingerlike outpouching from the caudal wall of the yolk sac, which is contiguous with the ventral cloaca at one end and the umbilicus at the other. The ventral portion of the cloaca develops into the bladder after cloacal division by the urogenital septum. Thus, the bladder
initially extends all the way to the umbilicus [1271]. With progressive foetal development, as the bladder descends into the pelvis, the attachment between the umbilicus and the urachus becomes looser and the apical portion progressively narrows to a small, epithelialised, fibromuscular strand by the fourth or fifth month of gestation. The urachus then obliterates completely by birth, forming the median umbilical ligament [1272-1274].

The urachus varies from 3 to 10 cm in length and from 8 to 10 mm in diameter. It is a three-layered tubular structure, the innermost layer being lined with transitional epithelium, the middle layer composed of connective tissue, and the outermost muscular layer in continuity with the detrusor muscle [1275].

Urachal remnants (URs) originate from failure of the obliteration of the allantois, resulting in a urachal anomaly such as (1) urachal sinus, (2) urachal cyst, (3) vesico-urachal diverticulum, and (4) patent urachus [1272, 1273, 1276]. Most often the urachal anomaly is asymptomatic, but it occasionally may become infected, may cause urinary symptoms, or develop a urachal carcinoma in later life [1275, 1277].

3.19.1.2 Epidemiology
Reports of occurrence rates in the literature vary broadly from a very rare disease in the older literature to a fairly common problem. Robert et al. found that URs were present in 61.7% of patients younger than 16 years [1278]. They also noted that the frequency of URs decreased with increasing age. This supports a physiological regression of URs with age. Stopak et al. attributed this upsurge to increased awareness among community paediatricians and improvements in US that made visualisation of urachal remnants easier [1279].

Clinical studies and paediatric autopsy studies in the past have shown a much lower incidence. Rubin found an incidence of 1 in 7,610 cases of patent urachus and 1 in 5,000 cases of urachal cysts [1280]. Nix et al. noted three anomalies out of 1,168,760 hospital admissions, and Blichert-Toft et al. reported five UR cases out of 40,000 patients [1281, 1282]. The incidence rate in males is a little higher than in females [1283, 1284].

The range of the various URs reported in the literature is 10% to 48% for patent urachus, 31% to 43% for urachal cyst, 18% to 43% for urachal sinus and 3% to 4% for urachal diverticulum [1285, 1286].

3.19.1.3 Symptoms
A patent urachus causes continuous or intermittent urine leakage from the umbilicus causing umbilical granulation and erythema in infants [1285]. A urachal cyst is usually diagnosed (1) incidentally, or (2) when it becomes infected causing abdominal pain and discharge of pus from the umbilicus or recurrent UTIs when it drains into the bladder.

The most common symptom is umbilical granulation, discharge and erythema in infants and abdominal pain in older children [1285].

Other symptoms of infected urachal anomalies can vary from high fever, abdominal pain, urinary tract infections, LUTS and/or an abdominal mass [1286-1290]. A urachal diverticulum is often asymptomatic and is usually found incidentally during investigations for other problems. An alternating sinus can empty either into the bladder or the umbilicus and this characteristic is responsible for various presentations [1291]. Infection has been reported as the most common complication in urachal anomalies [1292]. Severe infection may develop into peritonitis and sepsis. Cultures from umbilical discharge usually show *Staphylococcus*, *Streptococcus* and *E. Coli* [1293].

Other congenital anomalies:
Ashley found a simultaneous anomaly in 17 of 46 children, of which VUR was the most common anomaly (6 patients) [1294]. Other investigators reported associated anomalies in cases of persistent URs including meatal stenosis, hypospadias, umbilical and inguinal hernias, cryptorchidism, anal atresia, omphalocele, ureteropelvic obstruction and most frequently, VUR [1284, 1295-1297].

3.19.1.4 Diagnosis
In the majority of cases with complaints of a UR, a careful history and physical examination will confirm the suspicion of a UR. In many patients this can be confirmed by US studies [1278]. An MRI or CT scan may be necessary in a minority of children [1289]. Because of the association with other congenital abnormalities, other studies such as a VCUG or cystoscopy may be undertaken as well. In general, the VCUG is only undertaken when the child also presents with UTI or when the US shows signs of upper tract abnormalities. For the diagnosis per se it is not necessary [1298]; however, a VCUG may be useful for defining the type of urachal anomaly and evaluating a population that may be at higher risk for VUR.
3.19.1.5 Treatment
If a UR is symptomatic, the standard approach has been surgical removal. In most cases it should be done as an elective procedure, following appropriate treatment of active inflammation, and infection is possible. Pre-operative IV-dosage of antibiotic like Cefazolin is generally sufficient. A Pfannenstiel, periumbilical or infraumbilical midline incision can all be used for the open surgical approach [1288, 1299]. Even in symptomatic infants a more conservative approach is possible as well, especially in children less than six months old. Observation and treatment with antibiotics if necessary and radiographic monitoring are a safe approach [1285, 1300, 1301]. Dethlefs et al. reported a 90% successful outcome [1287], while Naiditch et al. reported that 44 of 78 symptomatic patients resolved under observation [1290]. More recently the laparoscopic approach has been advocated, and shown to be safe [1301-1303]. Surgery is not without risk. The rate of complications following surgical removal varies from 0 to 20%: usually wound infections [1279, 1287-1290, 1299]. Considering the probable additional risk of anaesthesia in very young children any surgical procedure needs to be assessed carefully [1304, 1305].

3.19.1.6 Pathology of removed remnants
Removed specimens may show inflammation or a cystic structure [1287]. Patients presenting without symptoms are as likely to have epithelial elements in the UR as those presenting with symptoms [1289].

3.19.1.7 Urachal cancer
Urachal anomalies are thought to be associated with an increased risk of bladder adenocarcinoma in adults, and urachal adenocarcinoma has an estimated incidence of 0.18 per 100,000 individuals yearly [1306]. These cases account for 0.1 to 0.3% of all bladder malignancies and 20 to 39% of bladder adenocarcinomas [1307]. Urachal adenocarcinoma (UrC) is very rare, especially when one considers that up to 62% of children under 16 years of age may have a UR [1278, 1308]. A study by Copp et al. found no association between the presence of UR symptoms and the presence or absence of epithelial tissue in pathology specimens, leading them to conclude that UR symptoms have poor predictive value for malignancy potential in these remnants [1284].

Gleason et al. found that 5,721 URs would need to be excised to prevent a single case of urachaladenocarcinoma out of the nearly 65,000 patients reviewed [1306]. Assuming that epithelium is required in the development of urachal adenocarcinoma, the extrapolated Number Needed to Treat (NNT) would be more than 8,000, as nearly 30% of urachal anomalies are void of an epithelial component. Less than 5% of urachal cancers have a non-epithelial origin such as sarcoma [1309]. The presenting symptoms in adults are different from those in children: in a study of 130 adult patients, Ashley et al. found that 49% presented with haematuria and 27% with pain. In 51% a urachal carcinoma was diagnosed: adenocarcinoma, with 58% high grade cancer. In addition, 20% had metastases at diagnosis, the overall 5-year cancer specific survival rate in the UrC cohort was 49% [1310]. Stasis of urine and crystallisation promotors such as mucus or desquamated epithelium in the UR are most likely the cause for malignant degeneration as well as stone formation in the adult patient. At present no long-term follow-up on untreated UR in children is available and there is no evidence that urachal anomalies in children increase the likelihood of future malignancy [1285, 1311].

3.19.1.8 Conclusion
Urachal remnants appear to be more common than previously reported. During the first 6-12 months of life spontaneous resolution is common. Excision of symptomatic urachal anomalies is an effective and safe means of treatment, with minimal morbidity. However, most patients with simple and asymptomatic lesions do not appear to benefit from excision, as the risk of malignancy later in life is vanishingly remote. Early intervention (< 6 months of age) should be reserved for patients with persistent documented urine draining from the urachus or a documented abscess. Incidental (US) UR management remains a challenge and should be done with patient and family involvement to make the most informed decision. While surgical intervention has minimal risk and morbidity, it is performed unnecessarily in a large proportion of asymptomatic patients due to the unnecessary removal of non-epithelial containing urachal anomalies and the inability to predict which anomalies will undergo malignant transformation [1312].

3.19.1.9 Recommendation for management of urachal remnants

<table>
<thead>
<tr>
<th>Recommendations</th>
<th>Strength rating</th>
</tr>
</thead>
<tbody>
<tr>
<td>Urachal remnants (URs) with no epithelial tissue carry little risk of malignant transformation.</td>
<td>Strong</td>
</tr>
<tr>
<td>Asymptomatic and non-specific atretic urachal remnants can safely be managed non-operatively.</td>
<td>Strong</td>
</tr>
<tr>
<td>Urachal remnants incidentally identified during diagnostic imaging for non-specific symptoms should also be observed non-operatively since they tend to resolve spontaneously.</td>
<td>Strong</td>
</tr>
</tbody>
</table>
A small UR, especially at birth, may be viewed as physiological. Strong
Urachal remnants in patients younger than 6 months are likely to resolve with non-operative management. Strong
Follow-up: is necessary only when symptomatic for 6 to 12 months. Strong
Surgical excision of URs solely as a preventive measure against later malignancy appears to have minimal support in the literature. Strong
Only symptomatic URs should be safely removed by open or laparoscopic approach. Strong
A voiding cystourethrogram is only recommended when presenting with febrile UTIs. Strong

3.19.2 Papillary tumours of the bladder in children and adolescents (Papillary urothelial neoplasm of low malignant potential or transitional cell carcinoma)

3.19.2.1 Incidence
Papillary tumours of the bladder in children and adolescents are extremely rare and are different from papillary tumours in adults. A “grape-like” papillary tumour in young children will be more likely a rhabdomyosarcoma of the bladder, which are not the focus of this guideline. A papillary tumour in older children or adolescents will be more likely be a papillary urothelial neoplasm of low malignant potential (PUNLMP) [1313]. Children with risk factors, such as previous bladder surgery and immunosuppressive medication can also develop a nephrogenic adenoma of the bladder, also presenting as a papillary tumour of the bladder.

3.19.2.2 Differences and similarities of papillary tumours of the bladder in children and adults

Gender
The overall the risk of a papillary tumour in the bladder in paediatric and young adult patients is approximately double in males compared to females [1314].

Risk factors
The majority of these patients have no identifiable risk factors.

Presentation
The most common symptom at presentation is haematuria; other less common symptoms include abdominal pain, storage LUTS including frequency, dysuria and at times obstructive symptoms [1314].

Investigations and treatment
Ultrasound of the genitourinary tract is the first investigation of choice. It is an excellent screening tool and can often accurately diagnose the nature and location of lesion. In children and adolescents, a bladder US of the full bladder is more sensitive compared with adults due to reduced abdominal fat and thinner muscle layer [1315]. In the event of a need to differentiate the renal or bladder origin of the haematuria, a red blood cell morphology will reveal isomorphic blood cells, differentiating a bladder origin. Urine cytology can be performed, however it has very limited value likely due to the low-grade nature of these tumours in children. Cystoscopy should be reserved if a bladder tumour is suspected on imaging for simultaneous diagnosis and treatment, transurethral resection of the tumour. In children, cystoscopy requires general anaesthesia [1316].

Histology
All the lesions in the children and adolescent age-group are identified as papillary and over 85% are solitary [1315]. Papillary bladder tumours in patients younger than twenty years of age have low-grade non-invasive disease (WHO classification) [1317]. These findings let pathologists conclude that in children and adolescents, a papillary bladder tumour can be classified as Papillary Urothelial Neoplasm of Low Malignant Potential (PUNLMP). PUNLMP has minimal or no cytological atypia and it differs from low grade transitional cell carcinoma (TCC) which has cytologic atypia, hyperchromatic nuclei and scattered mitosis [1318].

Additional treatment
Mitomycin C and Bacillus Calmette-Guérin have both been used in children but there is no evidence of their efficacy due to the rarity of TCC, and especially of high grade TCC [1314]. Hence, as per current evidence, there is no place for instillations in children.

Prognosis, recurrence and surveillance
The prognosis of papillary tumours of the bladder in children is overall good. The recurrence rate in children and adolescents varies from 8 to 15% [1313-1315]. Mean time to recurrence can vary from 11 to 29 months depending on the study, with recurrences occurring up to 90 months from diagnosis; though 64% occur in the first year [1314]. In certain cases, recurrences can be fairly aggressive [1315].
Strategies are based on the guidelines and protocols of papillary tumours of the bladder in adults. It is advised to follow-up children and adolescents with a history of a PUNLMP initially with a short interval of three to six months in the first year, and thereafter at least yearly with urinalysis for haematuria and an US of the full bladder. In the event of sudden gross haematuria, the evaluation must be performed immediately. If the tumour was completely resected at primary surgery, standard follow-up cystoscopy is not necessary and may be reserved for children or adolescents with a high recurrence risk or suspected recurrence on bladder US [1315]. The exact duration of follow-up is unknown but this Panel recommends follow-up for at least five years.

**Inflammatory myofibroblastic tumours of the bladder (IMTB)** are rare with nearly 200 cases reported in the literature [1319, 1320]. Around 25% occur in children with a median age at diagnosis of 7.5 years and a median tumour size of 5.5 cm. Boys and girls are equally affected [1321]. Usually these tumours are benign, with only very few reported malignant cases [1322]. Treatment is mostly surgical with transurethral resection, but local resection, or partial cystectomy maybe needed in selected cases [1321, 1323]. Additionally, a conservative approach is reported [1324]. Histological examination is required to exclude other malignant tumours such as a rhabdomyosarcoma. In children, no recurrence has been reported so far. However due to the malignant potential and few recurrences in adults, follow-up the same as for papillary bladder tumours is recommended.

**Eosinophilic cystitis**

Though well described in adults, this inflammatory condition is rare in the paediatric population with less than 100 cases reported in the literature to date [1325]. Its etiology remains unknown, but is thought to be incited by IgE mediated attraction of eosinophils to bladder wall followed by mast cell degranulation. It has been linked to medications, specifically antibiotics such as penicillin, chemotherapeutic agents e.g. cyclophosphamide and mitomycin, and chronic bladder catheterisation [1326, 1327]. In children, as opposed to adults, males are more frequently afflicted with seven years being the mean age of presentation, however the condition can be seen throughout childhood even in LUTS [1325, 1328].

Irritative bladder symptoms such as dysuria, frequency, urgency and incontinence are the most frequent and can mimic UTI [1329]. Other symptoms include haematuria, suprapubic tenderness and systemic symptoms. Obstructive manifestations due to mass formation in the bladder wall can result in ureteral obstruction leading to hydro-ureteronephrosis, suprapubic mass in infants in addition to voiding dysfunction [1325, 1328, 1330].

Although associated with allergy only about a third of reported cases had a history of other allergic conditions whereas half had significant eosinophilia or eosinophiluria. Diagnosis is often delayed as symptoms of eosinophilic cystitis (EC) mimic other more common conditions such as UTI and LUTS and most patients will ultimately have undergone imaging studies such as ultrasound, VCUg, CT and MRI, which although not specially diagnostic for the condition, may show bladder wall thickening or even mass formation, with rhabdomyosarcoma constituting an important differential diagnosis. A high index of suspicion for the diagnosis should therefore be maintained when dealing with protracted urinary symptoms not responsive to conventional intervention. Definitive diagnosis can only be attained on tissue biopsy obtained by cystoscopy. Histologically, eosinophilic infiltration of lamina propria and muscularis are seen in acute phases with > 25 eosinophils per high power field considered to be significant [1325, 1328, 1330]. Management is not standardised; removal of any possible allergens is the obvious first step and there are reports of self-limiting course of the disease. However, empirical treatment with corticosteroids, antibiotics, anticholinergics, and antihistamines, in addition to cyclosporine A have been utilised and lead to resolution of symptoms in most cases. Partial cystectomy has been performed in circumscribed lesions that do not disappear spontaneously. No standard follow-up recommendations exist however surveillance is justified as recurrence has been reported in about a third of patients [1325, 1328].

**Nephrogenic adenoma**

Nephrogenic adenomas (NA) in children are rare benign lesions that usually occur in the setting of previous surgery or chronic irritation of urinary tract [1331]. These benign proliferative lesions are most commonly found in the bladder. There is a significant predominance of girls compared to boys (5:1). The exact pathogenesis is unknown. It is proposed to be a metaplastic process of native urothelium in response to chronic injury. Recent evidence suggest that they can be derived from renal tubular cells that shed, migrate, reimplant and proliferate within urothelial mucosa [1332]. Though they are known to occur concurrently with bladder cancer, there are no de novo cases of bladder cancer diagnosed after nephrogenic adenoma. Previous history of bladder surgery such as bladder augmentation or presence of chronic inflammation or irritation is important [1333]. Lesions tend to develop at sites prone to chronic catheterisation injury. Other risk factors include trauma, immunosuppression and radiation. They present with haematuria and storage LUTS with a papillary/polyoid mass on cystoscopy. The recurrence rate is as high as 80% over 4 years [1331]. The final diagnosis
is established by cystoscopy and histopathological review of biopsy specimen. Treatment is excision either by transurethral resection which often requires reresections, partial cystectomy or open excision. Again no standard follow-up recommendations exist however regular follow-up with cystoscopy has been advocated especially for patients with augmented bladders as recurrence seem particularly high in this subgroup [1333].

Recommendations

| Ultrasound is the first investigation of choice for the diagnosis of paediatric bladder tumours. | 3 | Strong |
| Cystoscopy should be reserved if a bladder tumour is suspected on imaging for diagnosis and treatment. | 3 | Strong |
| After histological confirmation, inflammatory myofibroblastic bladder tumours should be resected locally. | 4 | Weak |
| Follow-up should be every 3-6 months in the first year, and thereafter at least annually with urinalysis and an ultrasound for at least 5 years. | 4 | Weak |
| Have a high index of suspicion of eosinophilic cystitis (EC) in protracted urinary tract symptoms unresponsive to regular treatment. | 4 | Strong |
| Remove any possible allergens as the obvious first step in managing EC. | 4 | Strong |
| Eosinophilic cystitis can be managed medically with corticosteroids, antibiotics, anticholinergics, and antihistamines, in addition to cyclosporine A. | 4 | Weak |
| Manage nephrogenic adenoma (NA) by resection either transuretherally or by open excision. | 4 | Strong |
| Regular endoscopic follow-up especially for augmented patients with NA is justified. | 4 | Weak |

3.19.3 Penile rare conditions

Paediatric lesions of the penis are uncommon but an important part of the paediatric urological practice. The most common of these lesions are cystic penile lesions followed by vascular malformations and neurogenic lesions [1334]. Soft tissue tumours of the male external genitalia are uncommon, but have been described in the paediatric age group and can be malignant [1335].

3.19.3.1 Cystic lesions

- **Epidermal inclusion cysts** are the most common genital cystic lesion and can occur anywhere on the body in both men and women; in the penis it occurs most commonly over the penile shaft varying from 0.1 to 1 cm in diameter. Their epithelium is lined and filled with keratin. It is a painless swelling and can
present in the age group with a history of circumcision. Treatment by total surgical excision is mainly indicated for cosmetic or symptomatic (e.g. infection) reasons and should be performed without rupturing the cyst to avoid recurrence [1336].

- **Mucoid cyst of the penis** is synonymous with parameatal cyst or genitoperineal cyst of median raphe; they are midline developmental cysts arising from ectopic urethral mucosa filled with mucoid material. They present since birth but are usually detected during adolescence or later. They are usually asymptomatic developing over penile ventral surface around glans and require surgical removal for either cosmetic, functional or symptomatic reasons [1337].

- **Median raphe cysts** arise from incomplete closure of genital fold during embryogenesis; they are commonly diagnosed in the first decade of life but can present later as they tend to be asymptomatic [1338]. They are either unilocular or multilocular fluid containing cysts, with a mean size of 0.8 cm but cysts larger than 2 cm have also been reported [1339]. Cysts are centred in dermis, with no connection to urethra or epidermis. Histopathologically, there are 4 types: urethral (urothelium-like epithelium, account for 55% cases), epidermoid, glandular and mixed. They can be treated conservatively and can resolve spontaneously or persist. Cyst aspiration is associated with high risk of recurrence and surgical excision is the treatment of choice. Though most penile cysts are asymptomatic, they may get infected resulting in pain and tenderness. They can also present with ulceration, rupture and urinary obstruction if they are close to the urethral meatus. This along with cosmetic issues means that most caregivers and patients opt for surgical excision.

- **Smegmal cysts or smegmal pearls** can be a differential for the cysts above; they are a benign collection of smegma in the sub-preputial space in uncircumcised boys with anticipated spontaneous resolution [1340].

- **Dermoid cyst** are congenital, asymptomatic, firm, solitary, subcutaneous cystic lesions occurring commonly in the region of the corona involving the foreskin. Histopathologically they contain sweat and sebaceous glands with elements of hair and squamous epithelium. Pilosebaceous cysts have been described on the glans; they are benign and usually diagnosed after excision.

### 3.19.3.2 Vascular malformations

A broad classification of penile vascular lesions into haemangiomas and vascular malformations was proposed by Ramos in 1999 [1341]. **Haemangiomas** develop rapidly at birth and involute slowly; they also include **pyogenic granulomas** which are benign outgrowths of cutaneous capillary vessels formed usually from chronic irritation [1334]. The growth cycle of infantile haemangiomas is divided into early and late proliferative stages, followed by a slow involution phase, completing growth by nine months of age [1342]. Propranolol is currently first line treatment for infantile haemangiomas, the exact mechanism of action is unknown but can include inhibition of angiogenesis, vasoconstriction among others. The dose is in the range of 1.5-2.5 mg/kg, which needs to be continued for 12 to 18 months and then tapered through active or passive weaving to reduce risk of rebound growth [1342]. Other factors leading to rebound growth after propranolol treatment include deep haemangiomas, which occur in about 38% patients despite propranolol therapy, requiring local therapy such as topical timolol, pulsed dye laser or intralxional steroids. After twelve months, the median improvement with treatment is reported as 81% (range 70-90%) based on VAS scores of serial patient photographs.

Vascular malformations are congenital lesions of capillary, lymphatic and venous (or slow-flow) or arterial/arteriovenous (fast-flow) origin that grow as the patient grows. These include **glomus tumours**, which are primarily congenital arteriovenous shunts that develop from thermo-regulatory glomus bodies (fastflow vascular malformations). Glomus tumours of the penis can arise on the glans penis, corpora of the penis and as periurethral masses, sometimes accompanied by glomus tumours of fingers and feet [1343]. These are usually asymptomatic at presentation or may have symptoms such as priapism, palpitation and perineal pain. Glomus tumours are benign despite exhibiting high grade nuclear polymorphism. Vascular malformations are usually benign and treated either with laser, sclerotherapy or surgical excision. However, glomus tumours specifically need surgical treatment and follow-up due to the risk of recurrence from incomplete excision [1344].

### 3.19.3.3 Neurogenic lesions

**Penile neurofibroma** is an extremely rare lesion arising from perineural and Schwann cells, and occurs usually with evidence of systemic neurofibromatosis or von Recklinghausen syndrome [1345]. They are treated successfully with complete excision [1334]. Rare cases of **malignant schwannomas** on the penis presumably secondary to malignant transformation of benign neurofibromas have been reported in boys with a strong family history of neurofibromatosis. This type of malignant degeneration of neurofibromatosis occurs in
reportedly 5-16% children [1345]. Hence, these patients require long-term follow-up due to risk of recurrence, new tumour formation and malignant transformation.

3.19.3.4 Soft tissue tumours of penis
Mesenchymal tumours are rare in the external genitalia and they require excision in order to differentiate between benign and malignant neoplasms. Histopathological characterisation is essential to ensure malignant tumours receive radical treatment with adjuvant therapy or close follow-up [1335].

Presentation is usually of a painless penile mass, that is non-tender and rubbery on examination. Ultrasound maybe useful in characterising the lesion but is not diagnostic; it can exclude urethral invasion if it is close to urethra [1335]. Once an excision biopsy is performed, if aggressive malignant components are found, a further wider resection may be needed.

Fibrosarcoma is a rare non-rhabdomyosarcoma soft tissue tumour that arises from fibrous tissue. The infantile form of fibrosarcoma is rare and those occurring on the penis are even rarer in the paediatric age-group. Surgical intervention has a favourable prognosis in the paediatric age group with long-term survival of 90% in sporadic cases [1346]. Myofibroma is a benign congenital lesion that occurs either as a solitary lesion or as a part of myofibromatosis with multiple soft tissue tumours. Excision is necessary for histological diagnosis [1335].

Primary penile teratomas are extremely rare subtype of congenital germ cell tumours, and they tend to be asymptomatic and are subdermal on US with no blood flow on Doppler [1347]. They need aggressive treatment with surgical resection due to their unpredictable behavior and unresponsiveness to chemotherapy. Mature teratomas are benign but immature teratoma or even mixed teratomas with immature components can turn malignant and have the potential to metastasise and recur.

3.19.3.5 Penile Lymphedema
Lymphedema in adults is usually secondary to malignancy or infectious disease affecting lymphatic drainage. In the paediatric age group, however, lymphedema is usually primary and generally very rare, affecting 1.2 per 100,000 persons under the age of 20 years [1348]. Of these, only a very small fraction relates to the genital region. Regardless of underlying aetiology, inefficient lymphatic drainage leads to accumulation of subcutaneous lymph which causes tissue swelling and inflammation. This in turn stimulates adipose deposition and fibrosis further exacerbating enlargement. With time the edematous tissue becomes vulnerable to infection, chronic cutaneous changes and disfigurement [1349]. Additionally, when occurring in the genital region urological complications may ensue; such as phimosis, haematuria, bleeding, bladder outlet obstruction, pain, dysuria, lymphorrhrea and severe psychological distress due to resultant deformity [1350, 1351].

In the largest cohort of male genital oedema in the paediatric age group, 92% of cases were primary; of these only 25% had a discernable familial or syndromic association such as Noonan syndrome, lymphedemadistichiasis or Milroy disease [1350]. Secondary genital lymphedema in children has been reported after inguinal surgery, and non-caseating granulomatous lymphangitis as seen with metastatic Crohn's disease [1350-1352]. Average age of onset was reported to be 4.5 ± 6.3 years with 61% presenting in infancy, 13% in childhood and the remaining 26% in adolescence. Edema is usually penoscrotal in 72%, isolated scrotal in 24% and very rarely confined exclusively to the penis in 4%. Moreover, concomitant lower limb edema is the rule in two thirds of cases [1350].

There is no general consensus on diagnostic work-up of these patients. History and physical examination (including family history) is usually sufficient. However lymphoscintigraphy can be used as a confirmatory test, more so for limb than genital edema where results can be difficult to interpret [1350]. Ultrasonography is nonspecific, but has been advocated by some to exclude secondary lymphedema by examining the patency of iliac and caval vessels [1353]. Magnetic resonance imaging is useful to exclude other differential diagnoses such as other venous or lymphatic anomalies [1350].

Conservative treatment is the accepted first-line treatment. The mainstay is compression therapy to maintain and prevent further swelling. This can be achieved by compression stockings and undergarments. Additionally, close observation and protection of the skin to prevent excoriations and infection is essential [1350, 1353]. Compression therapy is however, less effective on genital oedema than it is on limb edema, especially in growing children. When conservative management fails, and especially in symptomatic cases, or in patients with functional impairment, surgical debulking may be necessary. This can either take the form of circumcision in cases where the foreskin is affected or excision of affected skin and subcutaneous tissues with restructuring and contouring for optimal cosmetic outcome. Complete skin excision and grafting may also be required.
Surgical management can be challenging and needs to be restricted to patients with significant symptoms. Complications include recurrences, continuous lymphatic leakage, haematoma, infection and poor cosmetic outcome [1348, 1353, 1354].

### 3.20 Paediatric urological trauma

Trauma is the leading cause of morbidity and mortality in children and is responsible for more childhood deaths than the total of all other causes [1355]. In about 3% of children seen at paediatric hospital trauma centres, there is significant involvement of the genitourinary tract [1356]. This is caused by either blunt injuries from falls, car accidents, sports injuries, physical assault, sexual abuse, or penetrating injuries, usually due to falls onto sharp objects or from gunshot or knife wounds.

#### 3.20.1 Paediatric renal trauma

##### 3.20.1.1 Epidemiology, aetiology and pathophysiology

In blunt abdominal trauma, the kidney is the most commonly affected organ, accounting for about 10% of all blunt abdominal injuries [1355]. Children are more likely than adults to sustain renal injuries after blunt trauma because of their anatomy. Compared to an adult kidney, a child’s kidney is larger in relation to the rest of the body and often retains foetal lobulations, so that blunt trauma is more likely to lead to a local parenchymal disruption. The paediatric kidney is also less well protected than the adult kidney. Children have less peri-renal fat, much weaker abdominal muscles, and a less ossified and therefore much more elastic and compressible thoracic cage [1357].

Blunt renal trauma is usually a result of sudden deceleration of the child’s body, particularly due to sport accidents, falls, and contact with blunt objects. Deceleration or crush injuries result in contusion, laceration or avulsion of the less well-protected paediatric renal parenchyma.

##### 3.20.1.2 Classification systems

Renal injuries are classified according to the kidney injury scale of the American Association for the Surgery of Trauma (Table 7) [1358].

3.20.1.3 Diagnostic evaluation

In a child who has sustained blunt abdominal trauma, renal involvement can often be predicted from the history, physical examination and laboratory evaluation. Renal involvement may be associated with abdominal or flank tenderness, lower rib fractures, fractures or vertebral pedicles, trunk contusions and abrasions, and haematuria.

3.20.1.3.1 Haematuria

Haematuria may be a reliable finding. In severe renal injuries, 65% suffer visible haematuria and 33% non-visible, while only 2% have no haematuria at all [1359].

The radiographic evaluation of children with suspected renal trauma remains controversial. Some centres rely on the presence of haematuria to diagnose renal trauma, with a threshold for renal involvement of 50 RBCs/HPF. Although this may be a reliable threshold for significant non-visible haematuria in trauma, there have been many reports of significant renal injuries that manifest with little or even no blood in the urine [1360]. It is therefore compulsory to consider all the clinical aspects involved, including the history, physical examination, consciousness of the child, overall clinical status and laboratory findings to decide on the diagnostic algorithm and whether or not a child needs further imaging studies.

3.20.1.3.2 Blood pressure

It is important to consider that children, unlike adults, are able to maintain their blood pressure, even in the presence of hypovolaemia, due to compliance of the vascular tree and mechanisms for cardiac compensation [1361]. As blood pressure is an unreliable predictor of renal involvement in children, some centres recommend imaging of the urinary tract in children with any degree of haematuria following significant abdominal trauma.

3.20.1.3.3 Choice of imaging method

Nowadays, CT is the best imaging method for renal involvement in children. Computed tomography scanning is the cornerstone of modern staging of blunt renal injuries especially when it comes to grading the severity of renal trauma.

Computed tomography scanning is quite rapid and usually performed with the injection of contrast media. To detect extravasation, a second series of images is necessary since the initial series usually finishes 60 seconds after injection of the contrast material and may therefore fail to detect urinary extravasation. In acute trauma, US may be used as a screening tool and for reliably following the course of renal injury. However, US is of limited value in the initial and acute evaluation of trauma. The standard intravenous pyelogram (IVP) is a good alternative imaging method if a CT scan is not available. It is superior to US but not as good as CT scanning for diagnostic purposes.

3.20.1.4 Disease management

The modern management of trauma is multidisciplinary, requiring paediatricians, emergency physicians, surgeons, urologists, and other specialties as required.

Non-surgical conservative management with bed rest, fluids and monitoring has become the standard approach for treating blunt renal trauma. Even in high-grade renal injuries, a conservative approach is effective and recommended for stable children. However, this approach requires close clinical observation, serial imaging, and frequent re-assessment of the patient’s overall condition. Therefore, a good initial trauma CT with delayed images to check for urinary extravasation is recommended since this may prevent repeat ionising scans. In stable patients with grade 2 or higher lesions a close follow-up with US 48 to 72 hours after the initial scan is sufficient and should be considered before repeating a CT scan [1362]. A systematic review supports application of conservative management protocols also to high-grade blunt paediatric renal trauma. At this time, emergent operative intervention only for haemodynamic instability is recommended. Minimally invasive interventions including angio-embolisation, stenting, and percutaneous drainage should be used when indicated [1363]. Absolute indications for surgery include persistent bleeding into an expanding or unconfined haematoma. Relative indications for surgery are massive urinary extravasation and extensive non-viable renal tissue [1364]. A recently published meta-analysis concluded with the following recommendations: (1) In paediatric patients with blunt renal trauma of all grades, non-operative management vs. operative management in haemodynamically stable patients is strongly recommended. (2) In haemodynamically stable paediatric patients with high-grade (AAST grade III-V) renal injuries, angio-embolisation vs. surgical intervention for ongoing or delayed bleeding is strongly recommended; and, (3) In paediatric patients with renal trauma, routine blood pressure checks to diagnose hypertension is recommended in the long-term follow-up [1365]. However, long-term data on the risk of developing hypertension is lacking.

### Paediatric ureteral trauma

Injuries to the ureter are rare. The ureter is well protected; the upper part is protected by its close approximation to the vertebral column and paraspinal muscles and the lower part by its route through the bony pelvis. In addition, the ureter is a small target, and both flexible and mobile. This also means that ureteral injuries are caused more often by penetrating trauma than blunt trauma [1366]. Since the ureter is the sole conduit for urinary transport between the kidney and the bladder, any ureteral injury can threaten the function of the ipsilateral kidney.

#### 3.20.2.1 Diagnostic evaluation

Since there are no classical clinical symptoms suggestive of ureteral trauma, it is important to carry out a careful diagnostic work-up using different imaging modalities. Unfortunately, initial imaging studies, such as IVP and routine CT scans, are unreliable. A study of eleven disruptions of the ureteropelvic junction found that 72% had a normal or non-diagnostic IVP on initial studies [1366]. Diagnostic accuracy of CT scanning can be improved by performing a delayed CT scan up to ten minutes after injection of the contrast material [1367]. The most sensitive diagnostic test is a retrograde pyelogram. Quite a few patients present several days after the injury, when the urinoma produces flank and abdominal pain, nausea and fever.

Due to symptoms being often vague, it is important to remain suspicious of a potential undiagnosed urinary injury following significant blunt abdominal trauma in a child.

#### 3.20.2.2 Management

Immediate repair during abdominal exploration is rare. Minimally invasive procedures are the method of choice, especially since many ureteral injuries are diagnosed late after the traumatic event. Percutaneous or nephrostomy tube drainage of urinomas can be successful, as well as internal stenting of ureteral injuries [1368]. If endoscopic management is not possible, primary repair of partial lacerations should be followed by internal stenting. The management of complete lacerations, avulsions or crush injuries depends on the amount of ureter lost and its location. If there is an adequate healthy length of ureter, a primary ureteroureterostomy can be performed. If primary re-anastomosis is not achievable, distal ureteral injuries can be managed using a psoas bladder hitch, Boari flap or even nephropexy. Proximal injuries can be managed using transureteroureterostomy, auto-transplantation or ureteral replacement with bowel or appendix [1369].

### Paediatric bladder injuries

The paediatric bladder is less protected than the adult bladder, and is therefore more susceptible to injuries than the adult bladder, especially when it is full, due to:

- Its higher position in the abdomen and its exposure above the bony pelvis.
- The fact that the abdominal wall provides less muscular protection.
- The fact that there is less pelvic and abdominal fat surrounding the bladder to cushion it in trauma.

Blunt trauma is the most common cause of significant bladder injury. In adults, bladder injury is often associated with pelvic fractures. This is less common in children because the paediatric bladder sits above
the pelvic ring. In a large prospective study, only 57% of children with pelvic fractures also had a bladder injury compared to 89% of adults [1370].

3.20.3.1 Diagnostic evaluation
The characteristic signs of bladder injury are suprapubic pain and tenderness, an inability to urinate, and visible haematuria (95% of injuries). Patients with a pelvic fracture and visible haematuria present with a bladder rupture in up to 45% of cases [1371].

The diagnosis of bladder rupture can be difficult in some cases. The bladder should be imaged both when fully distended and after drainage using standard radiography or a CT scan. The best results can be achieved by retrograde filling of the bladder using a catheter. Despite advances in CT imaging, the bladder must still be filled to capacity to accurately diagnose a possible bladder injury [1372].

Blunt injuries to the bladder are categorised as:
• contusions with damage to the bladder mucosa or muscle, without loss of bladder wall continuity or extravasation;
• ruptures, which are either intraperitoneal or extraperitoneal.

Intraperitoneal bladder ruptures are more common in children because of the bladder’s exposed position and the acute increase in pressure during trauma. These cause the bladder to burst at its weakest point, i.e. the dome. Extraperitoneal lesions occur in the lower half of the bladder and are almost always associated with pelvic fractures. A cystogram will show extravasation into the perivesical soft tissue in a typical flame pattern and the contrast material is confined to the pelvis.

3.20.3.2 Management
Contusions usually present with varying degrees of haematuria and are treated with catheter drainage alone.

3.20.3.2.1 Intraperitoneal injuries
The accepted management of intraperitoneal bladder ruptures is open surgical exploration and primary repair. Post-operative drainage with a suprapubic tube is mandatory. Recent data suggest that transurethral drainage may be as effective, with fewer complications, resulting in shorter periods of diversion [1373]. Usually, after about seven to ten days, a repeat cystogram is performed to ensure healing is taking place properly.

3.20.3.2.2 Extraperitoneal injuries
Non-operative management with catheter drainage for seven to ten days alone is the method of choice for extraperitoneal bladder rupture. However, if there are bone fragments within the bladder, these must be removed and the bladder must then be repaired and drained, according to the principles for treating intraperitoneal ruptures [1374].

3.20.4 Paediatric urethral injuries
Except for the penile part of the urethra, the paediatric urethra is quite well protected. In addition, its shape and elasticity mean the urethra is seldom injured by trauma. However, a urethral injury should be suspected in any patient with a pelvic fracture or significant trauma to the perineum until confirmed otherwise by a diagnostic work-up.

3.20.4.1 Diagnostic evaluation
Patients with suspected urethral trauma and pelvic fractures usually present with a history of severe trauma, often involving other organ systems.

Signs of urethral injury are blood at the meatus, visible haematuria, and pain during voiding or an inability to void. There may also be perineal swelling and haematoma involving the scrotum. A rectal
examination to determine the position and fixation of the prostate is important in any male with a suspected urethral injury. The prostate, as well as the bladder, may be displaced up out of the pelvis, especially in membranous urethral trauma.

Radiographic evaluation of the urethra requires a retrograde urethrogram. It is important to expose the entire urethral length, including the bladder neck. If a catheter has already been placed by someone else and there is suspected urethral trauma, the catheter should be left in place and should not be removed. Instead, a small infant feeding tube can be placed into the distal urethra along the catheter to allow the injection of contrast material for a diagnostic scan [1375].

3.20.4.2 **Disease management**

Since many of these patients are unstable, the urologist’s initial responsibility is to provide a method of draining and monitoring urine output.

A transurethral catheter should only be inserted if there is a history of voiding after the traumatic event, and if a rectal and pelvic examination, as described above, has not suggested a urethral rupture. If the catheter does not pass easily, an immediate retrograde urethrogram should be performed.

A suprapubic tube may be placed in the emergency department percutaneously, or even in the operating room, if the patient has to undergo immediate exploration because of other life-threatening injuries.

There are often no associated injuries with a bulbous urethral or straddle injury and management is therefore usually straightforward. In these cases, a transurethral catheter is the best option for preventing urethral bleeding and/or painful voiding [1376].

The initial management of posterior urethral injuries remains controversial, mainly regarding the long-term results with primary realignment compared to simple suprapubic drainage with later reconstruction.

The main goals in the surgical repair of posterior urethral injuries are:
- Providing a stricture-free urethra.
- Avoiding the complications of urinary incontinence and impotence.

Suprapubic drainage and late urethral reconstruction was first attempted because immediate surgical repair had a poor outcome, with significant bleeding and high rates of incontinence (21%) and impotence in up to 56% of cases [1377]. In adults, a study of the success rates of delayed repair reported re-structure rates of 11-30%, continence rates of 90-95% and impotence rates of 62-68% [1378]. However, in children, there is significantly less experience with delayed repair. The largest paediatric series of delayed repair in 68 boys reported a success rate of 90% [1379]. Another study reported strictures and impotence in 67% of boys, although all the boys were continent [1186]. A recently published follow-up study on 15 patients who underwent delayed urethroplasty for blunt urethral trauma during childhood reported high long-term success rates with a low rate of long-term urinary and sexual dysfunction in adulthood [1380].

An alternative to providing initial suprapubic drainage and delayed repair is primary realignment of the urethra via a catheter. The catheter is usually put in place during open cystostomy by passing it from either the bladder neck or meatus and through the injured segment. In a series of fourteen children undergoing this procedure, this resulted in a stricture rate of 29% and incontinence in 7% of patients [1381].

3.21 **Peri-operative fluid management**

3.21.1 **Epidemiology, aetiology and pathophysiology**

Children have a different total body fluid distribution, renal physiology and electrolyte requirements, as well as weaker cardiovascular compensation mechanisms, compared to adults [1382]. During development, children have a high metabolic rate and lower fat and nutrient stores which means they are more susceptible to metabolic disturbances caused by surgical stress [1383]. The metabolic response to anaesthesia and surgery in infants and children is related to the severity of the operation [1384].
3.21.2 Disease management

3.21.2.1 Pre-operative fasting

Pre-operative fasting has been advocated for elective surgery to avoid the complications associated with pulmonary aspiration during induction of anaesthesia. New regimens include a 30-60 minute limitation for clear liquids [1385, 1386] without increased risk of pulmonary aspiration [1387]. Several studies have shown that fasting times in clinical practice often exceed the guidelines with average fasting times of 6-10 hours [1386-1388]. Compared to adults, children have a higher metabolic rate and low glycogen stores and impaired gluconeogenesis, which makes hypoglycaemia an important issue to consider, especially in children < 36 months old [1386]. Therefore, it is important to prevent too long fasting times. Clear-liquid carbohydrate drinks have been proposed to reduce these fasting times [1389].

Table 8 provides the current six, four and one hour guidelines for pre-operative fasting for elective surgery [1386, 1388].

3.21.2.2 Maintenance therapy and intra-operative fluid therapy

Generally, the anaesthetist is responsible for intra-operative management and the surgeon is responsible for post-operative instructions. The goal of intra-operative fluid management is to sustain homeostasis by providing the appropriate amount of parenteral fluid; this maintains adequate intravascular volume, cardiac output and oxygen delivery to tissues at a time when normal physiological functions have been altered by surgical stress and anaesthetic agents.

In recent years new strategies for maintenance and replacement fluid management have been developed and this has changed intra-operative fluid management significantly. The main goal of intra-operative fluid management is to maintain a normal extracellular fluid volume (EFV). During the intra-operative period fluid deficits may be induced by blood loss or pre-operative fasting. These fluid deficits can be replaced by balanced isotonic electrolyte solutions to restore a normal EFV. It is recommended that maintenance intravenous (IV) fluids should consist of balanced isotonic solutions with appropriate potassium chloride and dextrose in order to decrease the risk of hyponatraemia development [1390]. No increased risk for hypernatraemia, fluid overload with oedema and hypertension, and hyperchloremic acidosis was found, which was always feared for isotonic solutions [1390].

When children are clinically unstable due to third-space losses, these losses should be replaced with crystalloids (normal saline or Ringer’s lactate). Third-space losses may vary from 1 mL/kg/h for a minor surgical procedure to 15-20 mL/kg/h for major abdominal procedures, or even up to 50 mL/kg/h for surgery of necrotising enterocolitis in premature infants. When this fluid management is insufficient replacement management with colloids (albumin, gelatine and hydroxyethyl starch [HES]) should be adopted, using a restrictive approach [1391].

Clinical guidelines have been proposed by Sümpelmann et al. [1391] regarding intra-operative fluid management (Table 9).

3.21.2.3 Post-operative feeding and fluid management

It is not obligatory to check serum chemistry after uncomplicated surgery in children with normal pre-operative renal and hepatic function. However, if oral intake has been postponed for > 24 hours (e.g. as in intestinal surgery), there is an increased risk of electrolyte abnormalities, requiring further assessment and subsequent
management, particularly with potassium. Post-operative findings, such as decreased bowel movements and ileus, may be signs of hypokalaemia.

Children who undergo interventions to relieve any kind of obstructive diseases deserve particular attention, especially due to the risk of polyuria as a result of post-obstructive diuresis [1392]. In children who develop polyuria, it is important to monitor fluid intake and urine output, as well as renal function and serum electrolytes. If necessary, clinicians should not hesitate in consulting with a paediatric nephrologist.

In children who have undergone non-abdominal surgery, studies have suggested that gastric motility returns to normal one hour after emergence from anaesthesia [1393]. Early post-operative intake of fluid in children who have undergone minor or non-abdominal urological surgery is associated with reduced post-operative vomiting and lower opioid use [1394] and is therefore encouraged.

In abdominal surgery the enhanced recovery after surgery (ERAS) protocol has been implemented in the paediatric population following its success in adults [1389, 1395]. The ERAS protocol is a multimodal approach to prevent the post-operative effects of the surgical stress response. This protocol includes pre- and intraoperative element such as minimal pre-operative fasting and careful intra-operative fluid management, and also focuses on post-operative care. The post-operative ERAS protocol suggests starting clear fluid intake on the evening of surgery and a normal diet the day after surgery and thereby early discontinuation of IV fluids. Further focus is on early mobilisation, preventing epidurals and omitting or early removal of external tubes [1389, 1395].

The implementation of an ERAS protocol has resulted in shorter length of hospital stays, faster bowel recovery and opioid-free post-operative need [1389, 1395, 1396]. When implementing ERAS in children with neurological abnormalities special attention should be given to bowel management with pre-operative treatment of constipation and early post-operative continuation of routine bowel management.

### Post-operative pain management: general information

#### Epidemiology, aetiology and pathophysiology

The provision of adequate pain control requires proper pain evaluation, accurate choice of drug and route of administration, and consideration of age, physical condition and type of surgery and anaesthesia [1397].

Traditional medical beliefs that neonates are incapable of experiencing pain have now been abandoned following recent and better understanding of how the pain system matures in humans, better pain assessment methods and a knowledge of the clinical consequences of pain in neonates [1398, 1399]. Many studies have indicated that deficient or insufficient analgesia may be the cause of future behavioural and somatic sequelae [1400, 1401]. Our current understanding of pain management in children depends fully on the belief that all children, irrespective of age, require adequate pain treatment.
3.22.2 **Diagnostic evaluation**

Assessment of pain is the first step in pain management. Several pain assessment tools have been validated according to the child’s age, cultural background, mental status, communication skills and physiological reactions [1402]. Depending on the child’s age, the 0-10 Numeric Rating Scale, Faces Revised Pain Scale or Colour Analog Scale, for example, can be used [1403]. One of the most important topics in paediatric pain management is informing and involving the child and caregivers during this process. Patient-family-controlled-analgesia is the preferred pain management in the hospital and at home if provided with the correct information [1403, 1404].

3.22.3 **Disease management**

3.22.3.1 **Drugs and route of administration**

Pre-emptive analgesia is an important concept that aims to induce the suppression of pain before neural hypersensitisation occurs [1405]. Regional anaesthesia are given intra-operatively which can include a regional nerve block, caudal blocks or local wound infiltration and has proven to reduce the need for post-operative analgesia [1406]. The WHO’s ‘pain ladder’ is a useful tool for the pain management strategy [1407]. A three level strategy seems practical for clinical use. Post-operative management should be based on sufficient intraoperative pre-emptive analgesia with regional or caudal blockade followed by balanced analgesia. Paracetamol and non-steroidal anti-inflammatory drugs (NSAIDs) are the drugs of choice at the first level. As they become insufficient to prevent pain, weak and strong opioids are added to oral drugs to achieve balanced analgesia. Every institute must build their own strategy for post-operative analgesia. A proposed strategy for postoperative analgesia may be as follows:

1. Intra-operative regional or caudal block.
2. Paracetamol + NSAID.
3. Paracetamol + NSAID + weak opioid (e.g. tramadol or codeine).
4. Paracetamol + NSAID + strong opioid (e.g. morphine, fentanyl, oxycodone or pethidine).

The use of opioids in children has long held a standard role in the post-operative management of pain. Increased recognition of the adverse effects of opioids and prolonged opioid dependency demand a balanced intra-operative administration of opioids [1403, 1408]. Intra-operative adequate dosage of paracetamol and NSAIDs results in a decrease in opioid requirement in children [1409, 1410]. Furthermore, opioid awareness among physicians could reduce opioid use. When prescribing lower opioid dosage, this did not increase pain scores in urological outpatient surgeries [1411]. Caution is necessary to take account of renal function when using NSAIDs. Paediatric dependent dosages for most common used pain medication can be found in this publication [1412].

3.22.3.2 **Circumcision**

Circumcision requires anaesthesia and proper pain management [1413]. Potential analgesic interventions during circumcision include the use of a dorsal penile nerve block (DPNB) or ring block, topical anaesthetics (e.g. lidocaine-prilocaine cream, or 4% liposomal lidocaine cream), and sucrose preferably in combination [1406, 1412]. Caudal blockade methods have similar efficacy compared to DPNB. However, caregivers should be informed about the more frequent incidence of post-operative motor weakness and micturition problems [1414]. Ultrasound guidance can be used [1412].

3.22.3.2.1 **Penile, inguinal and scrotal surgery**

Caudal blocks and peripheral nerve blocks (DPNB and pudendal) are commonly used methods for analgesia following surgery for hypospadias. Several agents with different doses, concentrations and administration techniques have been used and shown to be adequate. Overall post-operative pain scores were lower with pudendal nerve blocks. No increase in post-operative complications was seen with these types of blocks [1406, 1415, 1416]. Severe bladder spasms caused by the presence of the bladder catheter may sometimes cause more problems than pain and is managed with antimuscarinic medications. For inguinoscrotal surgery, various regional anaesthesia methods have been investigated, such as transversus abdominis plane block, ilioinguinal/iliohypogastric nerve blocks and caudal blocks. All have been shown to have adequate postoperative analgesic properties. Additional local anaesthetics such as clonidine or dexmedetomidine may improve results [1406].

3.22.3.3 **Bladder and kidney surgery**

Continuous local infusion reduces the need for post-operative opioids [1417-1419], as well as systemic (intravenous) application of analgesics [1420], has been shown to be effective. Ketorolac is an effective agent that is underused. It decreases the frequency and severity of bladder spasms and the length of post-operative hospital stay and costs [1421, 1422]. Open kidney surgery is particularly painful because all three muscle layers
are cut during conventional loin incision. A dorsal lumbotomy incision may be a good alternative because of the shorter post-operative hospital stay and earlier return to oral intake and unrestricted daily activity [1423]. Caudal and paravertebral blocks continuous epidural analgesia, as well as rectus sheath and transversus abdominis plane blocks have decreased post-operative morphine requirement after abdominal and renal surgery [1424-1426]. For laparoscopic approaches, intra-peritoneal spraying of local anaesthetic before incision of the perirenal fascia may be beneficial [1427].

### 3.23 Basic principles of laparoscopic surgery in children

#### 3.23.1 Epidemiology, aetiology and pathophysiology

The use of laparoscopy and robot-assisted laparoscopic surgery is rapidly increasing and has gained widespread acceptance for many urological surgeries in children. Diagnostic laparoscopy for undescended testis, nephrectomy, heminephrectomy, varicocelectomy, pyeloplasty and ureteral reimplantation are some of the indications which are commonly being performed. This expanding scope related to technological advancements allows surgeons to perform more complex procedures in a minimally invasive fashion even in infants and younger children. Generally, well established benefits of minimally invasive surgery are decreased pain, shorter convalescence and better cosmetics compared to traditional open surgery [861]. Additional advantages of robotic surgery over conventional laparoscopy include ergonomics, 3D vision, better manoeuvrability, decreased tremor and easy learning curve. Limitations to be considered are increased operative time, smaller working space at young age, cost and experience of the surgeon and anaesthesiologist. While the success and complication rates are comparable for nephrectomy and pyeloplasty (see chapter 3.13.3.2) advantages of laparoscopy and robotic surgery for ureteral reimplantation have not been proven and this can only be recommended for experienced centres (see chapter 3.14.3.2.3).

As worldwide experience increases, there is an accumulating awareness about the physiological consequences related to intra- and retroperitoneal carbon dioxide (CO\(_2\)) insufflation in children. In contrast to traditional open surgery pneumoperitoneum may have physiological responses which require close monitoring during surgery and should be taken seriously.

#### 3.23.2 Technical considerations and physiological consequences

##### 3.23.2.1 Pre-operative evaluation

Laparoscopy in children requires specific anaesthetic precautions. Physiological effects of CO\(_2\) pneumoperitoneum, positioning of the patient and in potentially increased operative time need to be considered by the anaesthesiology team. Therefore, a detailed medical examination and risk assessment is mandatory pre-operatively. Especially cardiac and pulmonary system should be assessed since increased intra-abdominal pressure may lead to decreased ventricular preload [1428].

##### 3.23.2.2 Abdominal insufflation

Abdominal insufflation is the main principle of laparoscopic surgery to create working space for the surgeon. Carbon dioxide is the most commonly used insufflant in laparoscopic centres throughout the world. Other alternatives reported are nitrous oxide, helium, argon and air. However, CO\(_2\) is considered to be the best available gas as it is colourless, cheap, has high solubility in the vascular system [1429] and is excreted by the pulmonary system making it the safest option. Smaller children and infants absorb more CO\(_2\) than older children [1430], suggesting the need for more attention both during and early after laparoscopic surgery for these children.
Most complications of laparoscopy are attributable to gaining access to the abdominal cavity. One study reporting complications of > 5,400 paediatric laparoscopic surgeries showed that there was an overall complication rate of 5.3% of which 4.2% were related to problematic insufflation (subcutaneous emphysema, gas embolism, injury to the organs and vascular structures, mis-insufflation etc.) [1431]. There are two main and well-established techniques for initial access to the abdomen or retroperitoneum: open technique (Hasson) and Veress needle. Studies comparing these two different access techniques in paediatric laparoscopic urological procedures showed similar complication rates [1432]. The vast majority of the complications were minor and related to lack of surgical experience. Particularly in infants and smaller children, the open access technique is recommended by the Panel to reduce the chance of complications.

Elasticity of the abdominal wall is age-related and is higher in infants and small children compared to older children [1433].

Pneumoperitoneal pressure (PnP in mmHg) is one of the critical points that needs to be carefully considered by laparoscopic surgeons. A recent RCT compared two different pneumoperitoneal pressure groups (6-8 mmHg vs. 9-10 mmHg) in infants less than 10 kg [1434]. It demonstrated that higher pressures were associated with more pronounced respiratory and haemodynamic changes as well as increased post-operative pain scores and prolonged time to resume feeding.

### 3.23.2.3 Pulmonary effects

After intra-abdominal insufflation the diaphragm is pushed upwards due to increased abdominal pressure. This leads to decreased total pulmonary compliance. Combined with CO₂ absorption this may lead to hypercarbia and acidosis, particularly in case of prolonged operative time or low pulmonary reserve such as in infants. Trendelenburg position may also aggravate the situation in operations in the pelvic region, such as anti-reflux or bladder neck surgeries. Several studies revealed increased end tidal CO₂ (ET CO₂) related to CO₂ absorption [1430, 1435, 1436]. One study showed a 33% increase in ET CO₂ in the majority of neonatal laparoscopic and thoracoscopic procedures [1244]. Shorter operative time and lower intra-abdominal pressures decrease the risk of increased ET CO₂. Hypoxemia is rarely seen, even in neonates and can easily be adjusted by increasing minute ventilation. These findings highlight the importance of close monitoring of the children.

### 3.23.2.4 Cardiovascular effects

Intra-abdominal pressure, CO₂ absorption and positioning may also affect the cardiovascular system. It has been shown in adults that after initiation of pneumoperitoneum, cardiac output and stroke volume decrease while mean arterial pressure, central venous pressure and systemic vascular resistance increase [1437]. Similar outcomes have been reported during paediatric laparoscopy with some nuances. Cardiac output was 30% decreased while blood pressure remained stable during laparoscopic orchidopexy with PnP of 10 mmHg in children between aged 6-30 months [1438]. When PnP was lowered from 12 mmHg to 6 mmHg, cardiac index and other vascular parameters normalised [1439]. Using high intra-abdominal pressures in infants with congenital cardiac abnormalities may result in re-opening of cardiac shunts such as the foramen ovale and ductus arteriosus [1440]. Although cardiovascular effects of using high PnP are clinically measurable, they may not have a significant clinical impact on healthy children. However, it is clear that using lower pressures is safer especially in smaller children.

### 3.23.2.5 Effects on renal function

Although clinical studies in children are lacking, pneumoperitoneum may also have adverse effects on renal blood flow [1441]. High intra-abdominal pressures and reverse Trendelenburg position may cause decreased glomerular filtration rate and decreased urine output. One study has shown that 88% of infants and 14% of children more than one year old develop anuria within 45 minutes after initiation of PnP with 8 mmHg [1442]. However, urine output recovers with temporary polyuria after the operation. Although the clinical relevance of decreased urine output seems insignificant, it is important to monitor the fluid and electrolyte balance of the children during and after laparoscopic surgery.

### 3.23.2.6 Effects on neurological system

Another effect of pneumoperitoneum is increased intracranial pressure (ICP) which normalises after desufflation of the abdomen [1443]. Trendelenburg position, high PnP and hypoventilation are additional risk factors for increased ICP. Laparoscopy is therefore contraindicated in patients with intracranial space occupying lesions [1444]. Children with ventriculo-peritoneal shunts require precautions with regards to shunt drainage, however laparoscopy is not contraindicated [1445].

1. INTRODUCTION

1.1 Aim and objectives
The European Association of Urology (EAU) Guidelines Panel for Urological Trauma have prepared these guidelines in order to assist medical professionals in the management of urological trauma in adults. Paediatric trauma is addressed in the EAU Paediatric Urology Guidelines [1].

It must be emphasised that clinical guidelines present the best evidence available to the experts but following guideline recommendations will not necessarily result in the best outcome. Guidelines can never replace clinical expertise when making treatment decisions for individual patients, but rather help to focus decisions – also taking personal values and preferences/individual circumstances of patients into account. Guidelines are not mandates and do not purport to be a legal standard of care.

1.2 Panel composition
The EAU Urological Trauma Guidelines Panel consists of an international group of urologists and an interventional radiologist, all with particular expertise in urological trauma. All experts involved in the production of this document have submitted potential conflict of interest statements, which can be viewed on the EAU Website Uroweb: http://uroweb.org/guideline/urological-trauma/?type=panel.

1.3 Available publications
A quick reference document, the Pocket Guidelines, is available in print and as an app for iOS and Android devices. These are abridged versions which may require consultation together with the full text version. A number of translated versions, alongside several scientific publications in European Urology, the Associations scientific journal, are also available [2-5]. All documents can be viewed through the EAU website: http://uroweb.org/guideline/urological-trauma/.

1.4 Publication history
The Urological Trauma Guidelines were first published in 2003. Standard procedure for EAU Guidelines includes an annual assessment of newly published literature in the field to guide future updates. All sections of the 2022 Urological Trauma Guidelines have been fully updated.

2. METHODS

2.1 Evidence sources
For the 2022 Urological Trauma Guidelines, new and relevant evidence has been identified, collated and appraised through a structured assessment of the literature. A broad and comprehensive literature search, covering all sections of the Urological Trauma Guidelines was performed. Databases searched included Medline, EMBASE, and the Cochrane Libraries, covering a time frame between April 1st 2020 and May 1st 2021. A total of 1,412 unique records were identified, retrieved and screened for relevance. A detailed search strategy is available online: http://uroweb.org/guideline/urological-trauma/?type=appendices-publications. The majority of identified publications were comprised of case reports and retrospective case series. The lack of high-powered randomised controlled trials (RCTs) makes it difficult to draw meaningful conclusions. The panel recognises this critical limitation.

For each recommendation within the guidelines there is an accompanying online strength rating form the bases of which is a modified GRADE methodology [6, 7]. Each strength rating form addresses a number of key elements namely:

1. the overall quality of the evidence which exists for the recommendation, references used in this text are graded according to a classification system modified from the Oxford Centre for Evidence-Based Medicine Levels of Evidence [8];
2. the magnitude of the effect (individual or combined effects);
3. the certainty of the results (precision, consistency, heterogeneity and other statistical or study related factors);
4. the balance between desirable and undesirable outcomes;
5. the impact of patient values and preferences on the intervention;
6. the certainty of those patient values and preferences.
These key elements are the basis which panels use to define the strength rating of each recommendation. The strength of each recommendation is represented by the words ‘strong’ or ‘weak’ [9]. The strength of each recommendation is determined by the balance between desirable and undesirable consequences of alternative management strategies, the quality of the evidence (including certainty of estimates), and nature and variability of patient values and preferences.

Additional information can be found in the general Methodology section of this print, and online at the EAU website; http://www.uroweb.org/guideline/. A list of associations endorsing the EAU Guidelines can also be viewed online at the above address.

2.2 Peer review
The Urological trauma Guidelines was peer reviewed prior to publication in 2019.

3. EPIDEMIOLOGY, CLASSIFICATION & GENERAL MANAGEMENT PRINCIPALS

3.1 Definition and Epidemiology
Trauma is defined as a physical injury or a wound to living tissue caused by an extrinsic agent. Trauma is the sixth leading cause of death worldwide, accounting for 10% of all mortalities. It accounts for approximately five million deaths each year and causes disability to millions more [10, 11].

About half of all deaths due to trauma are in people aged 15-45 years; trauma is the leading cause of death in this age group [12]. Death from injury is twice as common in males, especially in relation to motor vehicle accidents (MVAs) and interpersonal violence. Trauma is therefore a serious public health problem with significant social and economic costs. Significant variation exists in the causes and the effects of traumatic injuries between geographical areas, and between low, middle, and high-income countries. It should be noted that alcohol and drug abuse increase the rate of traumatic injuries by precipitating interpersonal violence, child and sexual abuse, and MVAs.

3.2 Classification of trauma
Traumatic injuries are classified by the World Health Organization (WHO) into intentional (either interpersonal violence related, war-related or self-inflicted injuries), and unintentional injuries (mainly MVAs, falls, and other domestic accidents). Intentional trauma accounts for approximately half of the trauma-related deaths worldwide [11]. A specific type of unintentional injury is iatrogenic injury which occurs during therapeutic or diagnostic procedures by healthcare personnel. Traumatic insults are classified according to the basic mechanism of the injury into penetrating, when an object pierces the skin, and blunt injuries. Penetrating trauma is further classified according to the velocity of the projectile into:

1. high-velocity projectiles (e.g. rifle bullets - 800-1,000 m/sec);
2. medium-velocity projectiles (e.g. handgun bullets - 200-300 m/sec);
3. low-velocity items (e.g. knife stab).

High-velocity weapons inflict greater damage due to a temporary expansive cavitation that causes destruction in a much larger area than the projectile tract itself. In lower velocity injuries, the damage is usually confined to the projectile tract. Blast injury is a complex cause of trauma which includes blunt and penetrating trauma and burns.

The most commonly used classification grading system is the AAST (American Association for the Surgery of Trauma) injury scoring scale [13]. It is useful for managing renal trauma, but for the other urological organs, the injuries are commonly described by their anatomical site and severity (partial/complete).

3.3 General management principals
3.3.1 The Initial evaluation
The initial emergency assessment of a trauma patient is beyond the focus of these guidelines. It is usually carried out by emergency medicine and trauma specialised personnel following ATLS principles. Detailed further assessment involves cross-sectional imaging, laboratory analysis and specialist surgical input. The management of individual organ injury will follow in the sections below. Tetanus vaccine status should be assessed for all penetrating injuries.
3.3.2 Polytrauma managed in major trauma centres leads to improved survival

Urological trauma is often associated with significant injuries in the polytraumatised patient [14]. Lessons from civilian trauma networks, military conflict, and mass casualty events have led to many advances in trauma care [15, 16]. These include the widespread acceptance of damage control principles and trauma centralisation to major trauma centres staffed by dedicated trauma teams. The re-organisation of care to these centres has been shown to reduce mortality by 25% and length of stay by four days [15]. Urologists increasingly understand their role in the context of polytrauma with the ultimate aims of improving survivability and decreasing morbidity in these patients.

3.3.3 Damage control

Damage control is a life-saving strategy for severely injured patients that recognises the consequences of the lethal triad of trauma - hypothermia, coagulopathy and acidosis [17-19]. The first of a three phased approach consists of rapid control of haemorrhage and wound contamination. The second phase involves resuscitation in the intensive care unit (ICU), with the goal of restoring normal temperature, coagulation, and tissue oxygenation. The final stage involves definitive surgery when more time-consuming reconstructive procedures are performed in the stabilised patient [20]. Urological intervention needs to be mindful of the phase of management. Temporary abbreviated measures followed by later definitive surgery are required. Complex reconstructive procedures, including organ preservation, are not undertaken. The decision to enter damage control mode is taken by the lead trauma clinician following team discussion.

Urological examples include haemodynamically unstable patients due to suspected renal haemorrhage or pelvic fracture with associated urethral or bladder injury. The options of abdominal packing and temporary urinary drainage by ureteric, bladder or urethral catheterisation are valuable adjuncts to care.

3.3.4 Mass casualty events and Triage

A mass casualty event is one in which the number of injured people and the severity of their injuries exceed the capability of the faculty and staff [21]. Triage, communication and preparedness are important components for a successful response.

Triage after mass casualty events involves difficult moral and ethical considerations. Disaster triage requires differentiation of the few critically injured individuals who can be saved by immediate intervention from the many others with non-life-threatening injuries for whom treatment can be delayed and from those whose injuries are so severe that survival is unlikely in the circumstances [22, 23].

3.3.5 The role of thromboprophylaxis and bed rest

Trauma patients are at high risk of deep venous thrombosis (DVT). Concerns with regard to secondary haemorrhage result in prolonged bed rest post-injury which effectively compounds this risk. Established prophylaxis measures reduce thrombosis and are recommended following systemic review [24]. However, the strength of evidence is not high and as yet there is no evidence to suggest that mortality or pulmonary embolism risk is reduced [25]. Compression stockings and low molecular weight heparins are favoured. The risk of secondary haemorrhage is thought to be low and the practice of strict bed rest has waned in patients who are able to mobilise.

3.3.6 Antibiotic stewardship

Single shot antibiotic doses are common in major trauma. The indication for continuing antibiotics is governed by injury grade, associated injuries and the need for intervention. Patients with urinary extravasation tend to be kept on antibiotics but there is no evidence base for this. Antibiotics should be avoided in lesser trauma e.g. Grade 1-3 renal trauma, and regular review undertaken for those continued on regular dosing.

3.3.7 Urinary catheterisation

Prolonged catheterisation is required in all forms of bladder and urethral injury. Catheterisation is not necessary in stable patients with low-grade renal injury. Patients with heavy haematuria, who require monitoring or ureteric stenting, benefit from catheterisation. This can be removed once haematuria lightens and there is an improvement in the clinical situation. The shortest possible period of catheterisation is advised.
4. UROGENITAL TRAUMA GUIDELINES

4.1 Renal Trauma

4.1.1 Epidemiology, aetiology and pathophysiology
Renal trauma is present in up to 5% of all trauma cases [26]. It is most common in young males and has an overall population incidence of 4.9 per 100,000 [27]. Most injuries can be managed non-operatively with successful organ preservation [28-31].

Blunt injuries result from MVAs, falls, sporting injuries, and assault [32]. The kidney and/or hilar structures are directly crushed as a result. Less commonly, sudden deceleration may result in an avulsion injury affecting the vascular structures of the hilum or the ureteropelvic junction (UPJ).

Penetrating injuries are due to stab and gunshot wounds. They tend to be more severe and less predictable than blunt trauma. The prevalence is higher in urban settings [33]. Penetrating injury produces direct tissue disruption of the parenchyma, vascular pedicles, or collecting system. High-velocity bullets or fragments have the potential for greatest parenchymal destruction and are most often associated with multiple-organ injuries [34].

The most commonly used classification system is that of the AAST [13]. It is validated and predicts morbidity and the need for intervention [35, 36]. This remains the most useful of urological trauma classifications; however, the majority of Grade 1 - 4 injuries are now managed conservatively and debate has centred around updating the classification of high-grade injury i.e. identifying the injuries most likely to benefit from early angiographic embolisation, repair or nephrectomy [29, 37].

*Advance one grade for bilateral injuries up to Grade 3.

Note: The AAST renal injury scale was updated in 2018 and is presented in Table 4.1.1; however, all references included in this text are based on the AAST 1989 renal injury scale. The 2018 injury scale does not outperform the previous grading system in predicting bleeding and the need for treatment intervention and does not impact on the validity of the current recommendations [38].

4.1.2 Evaluation
The evaluation of stable patients with renal trauma is now based on a trauma protocol computed tomography (CT) scan, often performed prior to involvement of a urologist [39, 40]. It is important to consider all parameters in the evaluation of the patient and to understand the indications for scanning when these are not absolute. Indicators of injury include a direct blow to the flank or rapid deceleration event (fall, high-speed MVAs). Special consideration should be given to pre-existing renal disease [41] or the injured solitary kidney [42]. Pre-existing abnormality e.g. hydronephrosis makes injury more likely following trauma [43].

Vital signs should be recorded throughout the initial evaluation and give the most reliable indication of the urgency of the situation. Physical examination may reveal flank bruising, stab wounds, or bullet entry or exit wounds and abdominal tenderness.

Urinalysis, haematocrit and baseline creatinine are required. Haematuria (visible or non-visible) is the key finding. However, major injury such as disruption of the UPJ, pedicle injuries, segmental arterial thrombosis and stab wounds may not have haematuria [44-46]. Haematuria that is out of proportion to the history of
trauma may suggest pre-existing pathology [47]. Urine dipstick quickly evaluates for haematuria, but false-negative results can range from 3-10% [48]. An increased creatinine level usually reflects pre-existing renal pathology.

4.1.3 **Imaging: criteria for radiographic assessment**

The goals of imaging are to grade the renal injury, document pre-existing renal pathology, demonstrate presence of the contralateral kidney and identify injuries to other organs. Haemodynamic status will determine the initial imaging pathway with unstable patients potentially requiring immediate intervention. The majority of patients with moderate to major trauma will have had a CT scan performed soon after presentation. In patients who have not had any imaging the indications for renal imaging are [32, 49-52]:

- visible haematuria;
- non-visible haematuria and one episode of hypotension;
- a history of rapid deceleration injury and/or significant associated injuries;
- penetrating trauma;
- clinical signs suggesting renal trauma e.g. flank pain, abrasions, fractured ribs, abdominal distension and/or a mass and tenderness.

4.1.3.1 **Computed tomography**

Computed tomography is the imaging modality of choice in stable patients. It is quick, widely available, and can accurately identify grade of renal injury [53], establish the presence of the contralateral kidney and demonstrate concurrent injuries to other organs. It is ideally performed as a three-phase study [54]:

1. The arterial phase assesses vascular injury and presence of active extravasation of contrast.
2. The nephrographic phase optimally demonstrates parenchymal contusions and lacerations.
3. The delayed phase imaging (5 minutes) identifies collecting system/ureteric injury.

In practice, trauma patients usually undergo standardised whole-body imaging protocols and delayed phase imaging of the renal tract is not routinely performed. If there is suspicion that renal injuries have not been fully evaluated, delayed phase imaging is recommended. The rates of contrast-induced nephropathy seen in trauma patients is low [55].

4.1.3.2 **Ultrasonography (US)**

In the primary survey of a critically injured patient, FAST (Focused Assessment Sonography in Trauma) is used to identify haemoperitoneum as cause of hemorrhage and hypovolemia. However, it is not routinely used for the assessment of solid organ injury as it is insensitive, operator dependant, does not define the injury well, and is inferior to CT. It is an option for follow-up [56-58].

4.1.3.3 **Intravenous pyelography (IVP)**

Intravenous pyelography has been superseded by cross-sectional imaging and should only be performed when CT is not available [50]. One-shot intra-operative IVP can be used to confirm the presence of a functioning contralateral kidney in patients too unstable to have had pre-operative imaging [59]. The technique consists of a bolus intravenous injection of 2 mL/kg of radiographic contrast followed by a single plain film taken after ten minutes. The quality of the resulting imaging is generally poor. Palpation of the contralateral (unaffected) kidney is a pragmatic surrogate of function [18].

4.1.3.4 **Magnetic resonance imaging (MRI)**

The diagnostic accuracy of MRI in renal trauma is similar to that of CT [60, 61]. However, the logistical challenges of MRI make this modality impractical in acute trauma.

4.1.3.5 **Radionuclide scans**

Radionuclide scans do not play a role in the immediate evaluation of renal trauma patients. In the longer term, follow-up scans can be used to identify areas of scarring, functional loss or obstruction [62].

4.1.4 **Disease management**

4.1.4.1 **Non-operative management**

The non-operative management of renal trauma can be viewed as a “package of care”; a step-wise approach starting with conservative treatment, followed by minimally invasive and/or surgical exploration, if necessary. It should be noted that an algorithm for “package of care” will vary in different centres according to available interventions; however, the importance of escalation in treatment interventions should be emphasised [29]. This approach has likely resulted in the rate of nephrectomy for high-grade renal injuries decreasing over time [63].
4.1.4.1.1 Blunt renal injuries

Haemodynamic stability is the primary criterion for the management of all renal injuries. Non-operative management has become the treatment of choice for most cases. In stable patients, this means a period of bed rest, serial blood tests, regular observation and re-imaging as indicated. Primary conservative management is associated with a lower rate of nephrectomies, and no increase in immediate or long-term morbidity [64].

Grade 1 - 3 injuries are managed non-operatively [65, 66]. Grade 4 injuries are also mostly treated conservatively, but the requirement for subsequent intervention is higher [67]. Persistent urinary extravasation from an otherwise viable kidney after blunt trauma often responds to stent placement and/or percutaneous drainage [68].

Grade 5 injuries often present with haemodynamic instability and major associated injuries. There is thus a higher rate of exploration and nephrectomy [69, 70]. However, several studies now support expectant management in patients with Grade 4 and 5 injuries [29, 30, 71-75]. Similarly, unilateral main arterial injuries or arterial thrombosis are normally managed non-operatively in haemodynamically stable patients with surgical repair reserved for bilateral artery injuries or injuries involving a solitary functional kidney [76]. Pre-hospital prolonged warm ischaemia usually results in irreparable damage and renal loss.

One study designed a nomogram to predict the need for an intervention to stop bleeding in high-grade renal trauma. Factors which increased risk of intervention were a haematoma size of > 12 cm, penetrating trauma, vascular contrast extravasation, pararenal haematoma extension, concomitant injuries and shock [77].

4.1.4.1.2 Penetrating renal injuries

Penetrating abdominal wounds have traditionally been managed surgically. However, selective non-operative management of penetrating abdominal wounds is now accepted following detailed assessment in stable patients [67, 78-80].

For renal injuries, the site of the wound, haemodynamic stability, and diagnostic imaging are the main determinants for intervention. The majority of low-grade stab wounds posterior to the anterior axillary line can be managed non-operatively in stable patients [81]. Grade 3 or higher injuries due to stab wounds in stable patients can be managed expectantly, but warrant closer observation as the clinical course is more unpredictable and associated with a higher rate of delayed intervention [81, 82]. High-grade injuries, concomitant abdominal injuries and gunshot wounds are most likely to fail non-operative management [80]. Overall, non-operative management of penetrating injuries in selected stable patients is associated with a successful outcome in up to 50% of stab wounds and up to 40% of gunshot wounds [30, 83-86].

4.1.4.1.3 Selective angioembolisation

Selective angioembolisation (AE) has a key role in the non-operative management of blunt renal trauma in haemodynamically stable patients [87-89]. Currently there are no validated criteria to identify patients who require AE and its use in renal trauma remains heterogeneous. Accepted CT findings indicating the need for AE are active extravasation of contrast, arteriovenous fistula (AVF) and pseudo-aneurysm [90]. The presence of both active extravasation of contrast and a large haematoma (> 25 mm depth) predict the need for AE with good accuracy [90, 91].

Angioembolisation has been utilised in the non-operative management of all grades of renal injury; however, it is likely to be most beneficial in the setting of high-grade renal trauma (AAST > 3) [87-89]. Non-operative management of high-grade renal trauma, where AE is included in the management algorithm, can be successful in up to 94.9% of Grade 3, 89% of Grade 4 and 52% of Grade 5 injuries [87, 88]. Increasing grade of renal injury is associated with increased risk of failed AE and need for repeat intervention [92]. Gross haematuria, haemodynamic instability, Grade 5 trauma and urinary extravasation are significant predictors of selective AE failure [93].

Repeat embolisation prevents nephrectomy in 67% of patients. Open surgery after failed embolisation usually results in nephrectomy [92, 94]. Despite concerns regarding parenchymal infarction and the use of iodinated contrast media, AE does not appear to affect the occurrence or course of acute kidney injury following renal trauma [95]. For high-grade injuries, AE has also been shown to have a high success rate and to provide the greatest protection of renal function, with no difference in renal function after long-term follow-up [96]. In severe polytrauma or high operative risk, the main artery may be embolised, either as a definitive treatment or as a step to a more controlled nephrectomy.

The evidence supporting AE in penetrating renal trauma is sparse. One study found that AE is three times more likely to fail in penetrating trauma [78]. However, AE has been used successfully to treat acute haemorrhage, AVF and pseudo-aneurysms resulting from penetrating renal trauma [97].
4.1.4.1.4 Urinary catheterisation
Catheterisation is not necessary in stable patients with low-grade injury. Patients with severe visible haematuria, who require monitoring or stenting, benefit from catheterisation. A longer period of catheterisation is required if a stent is placed. Once the haematuria lightens and the patient is mobile, the catheter should be removed.

4.1.4.1.5 Repeat imaging (early)
Computed tomography scans should be performed on patients with fever, unexplained decreased haematocrit or significant flank pain. Repeat imaging is also recommended in high-grade injury and in penetrating trauma two to four days after trauma to minimise the risk of missed complications. Repeat imaging can be safely omitted for patients with Grade 1-3 injuries as long as they remain clinically well [98].

4.1.4.2 Surgical management
4.1.4.2.1 Indications for renal exploration
A non- or transient-response to initial fluid resuscitation is an strong indication for exploration [78, 79]. There is a trend towards ongoing resuscitation and AE [99]. Exploration is influenced by aetiology and grade of injury, transfusion requirements, the need to explore associated abdominal injuries, and the discovery of an expanding or pulsatile peri-renal haematoma at laparotomy [100]. Grade 5 vascular injury is an absolute indication for exploration [35].

4.1.4.2.2 Operative findings and reconstruction
The overall exploration rate for blunt trauma is low [101]. The goals of exploration following renal trauma are control of haemorrhage and renal salvage. Most series recommend the transperitoneal approach for surgery [102, 103]. Entering the retroperitoneum and leaving the confined haematoma undisturbed within the perinephric fascia is recommended; temporarily packing the fossa tightly with laparotomy pads can salvage the kidney in instances of intra-operative haemorrhage [104]. Access to the pedicle is obtained either through the posterior parietal peritoneum, which is incised over the aorta, just medial to the inferior mesenteric vein or by bluntly dissecting along the plane of the psoas muscle fascia, adjacent to the great vessels, and directly placing a vascular clamp on the hilum [104].

Stable haematomas detected during exploration for associated injuries should not be opened. Central or expanding haematomas indicate injuries of the renal pedicle, aorta, or vena cava and are potentially life-threatening and warrant further exploration [105].

Feasibility of renal reconstruction should be judged during the operation. The overall rate of patients who undergo a nephrectomy during exploration is approximately 30% [106]. Other intra-abdominal injuries also increase the likelihood of nephrectomy [107]. Mortality is associated with overall severity of the injury and not often a consequence of the renal injury itself [108]. High velocity gunshot injuries make reconstruction difficult and nephrectomy is usually required [109]. Since nephrectomy is independently associated with increased risk of mortality in injured patients it should be avoided when possible [110].

Renorrhaphy is the most common reconstructive technique. Partial nephrectomy is required when non-viable tissue is detected. Watertight closure of the collecting system is desirable, although closing the parenchyma over the injured collecting system is acceptable.

The use of haemostatic agents and sealants in reconstruction is helpful [111]. In all cases, drainage of the ipsilateral retroperitoneum is recommended.

The repair of vascular injuries is seldom, if ever, effective [112]. Repair should be attempted in patients with a solitary kidney or bilateral injuries [113]. Nephrectomy for main artery injury has outcomes similar to those of vascular repair and does not worsen post-treatment renal function in the short-term. Bleeding or dissection of the main renal artery may also be managed with a stent.

4.1.5 Follow-up
The risk of complications relates to aetiology, injury grade, and mode of management [114, 115]. Follow-up includes physical examination, urinalysis, diagnostic imaging, blood pressure measurement and serum creatinine [69]. Potential complications are primarily identified by imaging; however, follow-up imaging is not recommended in low-grade uncomplicated injury. Ultrasound can be used to define the post-injury anatomy avoiding further ionising radiation. Nuclear scans are useful for documenting functional recovery following renal injury and reconstruction [62]. Annual blood pressure monitoring is recommended to exclude renovascular hypertension [116].
4.1.5.1 Complications

Early (≤ 1 month) complications include bleeding, infection, perinephric abscess, sepsis, urinary fistula, hypertension, urinary extravasation and urinoma. Delayed complications include bleeding, hydronephrosis, calculus formation, chronic pyelonephritis, hypertension, AVF, hydronephrosis and pseudo-aneurysms. Bleeding may be life-threatening with elective angiographic embolisation the preferred treatment [117]. Perinephric abscess formation is initially managed by percutaneous drainage [101].

Hypertension is rare [118, 119]. It may occur acutely as a result of external compression from perirenal haematoma (Page kidney), chronically due to compressive scar formation, or as a result of renal artery thrombosis, segmental arterial thrombosis, renal artery stenosis (Goldblatt kidney), or AVF. Arteriography may be required. Treatment, including medical management, excision of the ischaemic parenchymal segment, vascular reconstruction, or nephrectomy, is indicated if hypertension persists [116].

Arteriovenous fistulae usually present with delayed onset of significant haematuria, most often after penetrating trauma. Percutaneous embolisation is often effective for symptomatic AVF, but larger fistulae may require surgery [120]. The development of pseudo-aneurysm is a rare complication following blunt trauma.

4.1.6 Iatrogenic renal injuries

Iatrogenic renal trauma needs to be recognised and managed promptly to minimise morbidity and mortality. The most common causes of iatrogenic renal injuries are percutaneous access to kidney, stone surgery, cancer surgery (laparoscopic and open) and transplantation [3]. The diagnosis and management follow the same principles as outlined previously.

4.2 Ureteral Trauma

4.2.1 Incidence

Trauma to the ureters is relatively rare as they are protected from injury by their small size, mobility, and the adjacent vertebrae, bony pelvis and muscles. Iatrogenic trauma is the most common cause of ureteral injury (approximately 80%) [121]. It is seen in open, laparoscopic or endoscopic surgery and is often missed intra-operatively. Any trauma to the ureter may result in severe sequelae [122].

4.2.2 Epidemiology, aetiology, and pathophysiology

Overall, ureteral trauma accounts for 1-2.5% of urinary tract trauma [121, 123-125], with even higher rates in modern combat injuries [126]. Penetrating external ureteral trauma, mainly caused by gunshot wounds, dominates most of the modern series, both civilian and military [121, 123, 127]. About one-third of cases of external trauma to the ureters are caused by blunt trauma, mostly MVAs [124, 125].

Ureteral injury should be suspected in all cases of penetrating abdominal injury, especially gunshot wounds, as it occurs in 2-3% of cases [121]. It should also be suspected in blunt trauma with a deceleration mechanism, as the renal pelvis can be torn away from the ureter [121]. The distribution of external ureteral injuries along the ureter varies between series, but it is more common in the upper ureter [123-125].

Iatrogenic ureteral trauma can result from various mechanisms: ligation or kinking with a suture, crushing from a clamp, partial or complete transection, thermal injury, or ischaemia from devascularisation [127-129]. It usually involves the lower ureter [121, 127, 128, 130]. Gynaecological operations are the most common cause of iatrogenic trauma (Table 4.2.1), but it may also occur in colorectal operations, especially abdominoperineal resection and low anterior resection [131, 132]. The incidence of urological iatrogenic trauma has decreased in the last twenty years due to improvements in technique, instruments and surgical experience [127, 133]. In colorectal surgery there has been a significant decrease in the rate of ureteral injury for robot-assisted procedures [134]. However, minimally invasive laparoscopic/robotic hysterectomy techniques have not further reduced the rate of ureteral injuries [135-137].

Ureteroscopy is a common cause of iatrogenic ureteric trauma up to 71.6% in some series [138]. The post-ureteroscopic lesion scale (PULS) may standardise intra-operative traumatic findings during ureteroscopy [139]. A smaller proximal ureter diameter in non-contrast CT is a predictor for high-grade ureteral injury during ureteral access sheath (UAS) placement [140]. In a small RCT pre-operative Silodosin 8 mg for three days significantly reduced Grade 2 or higher ureteral injuries, due to UAS insertion [141]. Male gender, longer operation and UAS insertion times are predictors for high grade ureteric injury [138].

Risk factors for iatrogenic trauma include conditions that alter the normal anatomy, e.g. advanced malignancy, prior surgery or irradiation, diverticulitis, endometriosis, anatomical abnormalities, and major haemorrhage [127, 131, 142, 143]. Occult ureteral injury occurs more often than reported and not all injuries are diagnosed intra-operatively [122].

4.2.3 Diagnosis
The diagnosis of ureteral trauma is challenging; therefore, a high index of suspicion should be maintained. In penetrating external trauma, it is usually made intra-operatively during laparotomy [151], while it is delayed in most blunt trauma and iatrogenic cases [127, 130, 152].

4.2.3.1 Clinical diagnosis
External ureteral trauma usually accompanies severe abdominal and pelvic injuries. Penetrating trauma is usually associated with vascular and intestinal injuries, while blunt trauma is associated with damage to the pelvic bones and lumbosacral spinal injuries [124, 125]. Haematuria is an unreliable and poor indicator of ureteral injury, as it is present in only 50–75% of patients [121, 127, 153].

Iatrogenic injury may be noticed during the primary procedure, when intravenous dye (e.g. indigo carmine) is injected to exclude ureteral injury. Early recognition facilitates immediate repair and provides better outcome [142, 151]. However, it is usually noticed later in the same admission, when it is discovered by subsequent evidence of upper tract obstruction, urinary fistulae formation or sepsis. The following clinical signs are characteristic of delayed diagnosis flank pain, urinary incontinence, vaginal or drain urinary leakage, haematuria, fever and uraemia or urinoma. When the diagnosis is missed, the complication rate increases [121, 126, 152].

4.2.3.2 Radiological diagnosis
Multi-phase CT is the mainstay imaging technique for trauma patients. Generally, it is widely available and allows for multi-phasic assessment of all of the structures in the pelvis and abdomen. Computed tomography urography (CTU) is the examination of choice when ureteral injuries are suspected [154]. Extravasation of contrast medium in the delayed phase is the hallmark sign of ureteral trauma. However, hydronephrosis, ascites, urinoma or mild ureteral dilation are often the only signs. In unclear cases, a retrograde or antegrade urography is the optimum standard for confirmation [127]. Intravenous pyelography, especially one-shot IVP, is unreliable in diagnosis, as it is negative in up to 60% of patients [121, 127].

4.2.4 Prevention of iatrogenic trauma
The prevention of iatrogenic trauma to the ureters depends upon the visual identification of the ureters and careful intra-operative dissection in their proximity [127-129]. The use of prophylactic pre-operative ureteral stent insertion assists in visualisation and palpation and is used in complicated cases (about 4% in a large cohort) [155, 156] or patients with previous surgery [157]. It is probably also advantageous in making it easier to detect ureteral injury intra-operatively [128]; however, it is not associated with a decrease in the likelihood of ureteric injury [148]. Apart from its evident disadvantages (potential complications, increased surgical time and cost), a stent may alter the location of the ureter and diminish its flexibility [128, 147]. A retrograde instillation of indocyanine green in the ureters has been shown to safely allow their identification and preservation in complex robotic-assisted colorectal surgeries [158, 159].

4.2.5 Management
Management of ureteral trauma depends on many factors concerning the nature, severity and location of the injury. Immediate diagnosis of a ligation injury during an operation can be managed by de-ligation and stent placement. Partial injuries can be repaired immediately with a stent or urinary diversion via a nephrostomy tube. Stenting is helpful because it provides canalisation and may decrease the risk of stricture [127, 160]. On the other hand, its insertion has to be weighed against potentially aggravating the severity of the ureteral injury. Immediate repair of complete ureteral injury is usually advisable as it significantly decreases the need for secondary or tertiary procedures compared to delayed repair [160]. The ureter is mobilised on both ends and a spatulated end-to-end anastomosis is performed. Primary repair by uretero-ureterostomy or ureteric re-implantation can be safely performed laparoscopically at the time of the iatrogenic injury, with good midterm results [161]. In cases of unstable trauma patients, a ‘damage control’ approach is preferred with ligation of the ureter, diversion of the urine (e.g. via a nephrostomy), and a delayed definitive repair [162]. A national trauma database study reported that the majority of blunt low- and high-severity traumatic ureteric injuries in both stable and unstable patients were treated by nephrostomy or stenting [163]. Ureteral reconstruction was more frequently performed in high-grade injuries in unstable patients. Exploratory laparotomy for associated traumatic injuries was a predictor for immediate ureteral reconstruction [163]. Injuries that are diagnosed late are usually managed first by placement of a nephrostomy tube or stent [127].

Endo-urological treatment of delayed-diagnosed ureteral injuries by internal stenting, with or without dilation, is the first step in most cases. It is performed either retrogradely or antegrade through a percutaneous nephrostomy, and it has a variable success rate of 14-19% [164-166]. An open or robot-assisted laparoscopic surgical repair is necessary in case of failure [167]. The basic principles for any surgical repair of a ureteral injury are outlined in Table 4.2.2. Wide debridement is highly recommended for gunshot wound injuries due to the ‘blast effect’ of the injury.
4.2.5.1 Proximal and mid-ureteral injury
Injuries shorter than 2-3 cm can usually be managed by a primary uretero-ureterostomy [121]. When this approach is not feasible, a uretero-calycostomy should be considered. In case of a large extra-renal pelvis and a stricture at the UPJ, a pelvic spiral flap according to Culp-DeWeerd is an option [168]. In extensive ureteral loss, a transuretero-ureterostomy is a valid option, where the proximal stump of the ureter is transposed across the midline and anastomosed to the contralateral ureter. The reported stenosis rate is 4% and re-intervention or revision occur in 10% of cases [169].

4.2.5.2 Distal ureteral injury
Distal injuries are best managed by ureteral re-implantation (uretero-neocystostomy) because the primary trauma usually jeopardises the blood supply to the distal ureter. The question of refluxing vs. non-refluxing ureteral re-implantation remains unresolved in the literature. The risk for clinically significant reflux should be weighed against the risk for ureteral obstruction.

A psoas hitch between the bladder and the ipsilateral psoas tendon is usually needed to bridge the gap and to protect the anastomosis from tension. The contralateral superior vesical pedicle may be divided to improve bladder mobility. The reported success rate is very high (97%) [169]. In extensive mid-lower ureteral injury, the large gap can be bridged with a tubularised L-shaped bladder flap (Boari flap). It is a time-consuming operation and not usually suitable in the acute setting. The success rate is reported to be 81-88% [170].

4.2.5.3 Long segment ureteral injury
A longer ureteral injury can be replaced using a segment of the intestines, usually the ileum (ileal interposition graft). This should be avoided in patients with impaired renal function or known intestinal disease. Follow-up should include serum chemistry to diagnose hyperchloremic metabolic acidosis [171]. The long-term complications include anastomotic stricture (3%) and fistulae (6%) [172]. Another option could be downward nephropexy associated with a long Boari flap. In cases of extensive ureteral loss or after multiple attempts at ureteral repair, the kidney can be relocated to the pelvis (auto-transplantation). The renal vessels are anastomosed to the iliac vessels and a ureteral re-implantation is performed [173, 174].

Buccal mucosa ureteroplasty is another option for long segment ureteral injury, especially after a previous failed reconstruction, as an alternative to auto-transplantation. The overall success rate is 90%, but experience is limited [175].

4.2.5.4 Permanent urinary diversion/nephrectomy
Following early or late repairs, up to 38% patients develop secondary ureteric strictures requiring interventions [176] or palliative management by indwelling ureteric catheter or nephrostomy tube [160, 177]. Moreover, in some series up to 10% of failed repairs have evidence of renal parenchyma or function loss, leading to nephrectomy [160, 176].

4.3 Bladder Trauma

4.3.1 Classification

Bladder trauma is primarily classified according to the location of the injury: intraperitoneal, extraperitoneal, and combined intra-extraperitoneal [178], as it guides further management [179]. Bladder trauma is categorised by aetiology: non-iatrogenic (blunt and penetrating) and iatrogenic (external and internal).

4.3.2 Epidemiology, aetiology and pathophysiology

Motor vehicle accidents are the most common cause of blunt bladder injury, followed by falls and other accidents. The main mechanisms are pelvic crush and blows to the lower abdomen [124, 178, 180]. Most patients with blunt bladder injury have associated pelvic fractures (60-90%) and other intra-abdominal injuries (44-68.5%) [181, 182]. Pelvic fractures are associated with bladder injury in about 3% of cases [124, 183]; however, this can be as high as 26.5% in cases of severe pelvic injury [184]. Bladder injury is associated with urethral injury in 5-20% of cases [179, 182, 185].

Extraperitoneal (22.4-61.1%), and intraperitoneal (38.9-65.8%) injuries varies among series [186]. Extraperitoneal injury is almost always associated with pelvic fractures [180, 182]. It is usually caused by distortion of the pelvic ring, with shearing of the anterolateral bladder wall near the bladder base (at its fascial attachments), or by a contrecoup at the opposite side. The highest risk of bladder injury was found in disruptions of the pelvic circle with displacement > 1 cm, diastasis of the pubic symphysis > 1 cm, and pubic rami fractures [124, 179]. An isolated acetabular fracture is not likely to be associated with bladder injury [179, 182, 187]. Occasionally, the bladder is directly perforated by a sharp bony fragment [179].

Intraperitoneal injury is caused by a sudden rise in intravesical pressure of a distended bladder, secondary to a blow to the pelvis or lower abdomen. The bladder dome is the weakest point of the bladder and ruptures will usually occur there [179]. Penetrating injuries, mainly gunshot wounds, are rare except in conflict zones and violent urban areas [178, 188, 189]. Improvised explosive devices are the main cause of combat related bladder injuries in asymmetric warfare [190].

4.3.2.1 Iatrogenic bladder trauma (IBT)

The bladder is the urological organ that is most commonly affected by iatrogenic injury [191]. Table 4.3.1 shows the incidence of IBT during various procedures. External IBT occurs most often during obstetric and gynaecological procedures, followed by urological and general surgical operations [191]. Main risk factors are previous surgery, inflammation and malignancy [191]. Bladder perforations occur in up to 4.9% of mid-urethral slings operations for stress urinary incontinence in women. This rate is significantly lower in the obturator route compared to the retropubic route [192].

Internal IBT mainly occurs during transurethral resection of the bladder (TURB). Reported risk factors are larger tumours, older age, pre-treated bladders (previous TURB, intravesical instillations) and location at the bladder dome [193, 194]. Tumours at the lateral wall pose a risk factor because of the obturator jerk [195, 196]. Extraperitoneal perforations are more frequent than intraperitoneal perforations [194, 197], and perforations requiring intervention are rare (0.16-0.57%) [193].

4.3.3 Diagnostic evaluation
The principal sign of bladder injury is visible haematuria [179, 180]. Absolute indications for bladder imaging include: visible haematuria and a pelvic fracture [179] or non-visible haematuria combined with high-risk pelvic fracture (disruption of the pelvic circle with displacement > 1 cm or diastasis of the pubic symphysis > 1 cm) or posterior urethral injury [179]. Bladder trauma should also be suspected in patients with blunt urethral trauma and high Injury Severity Score (ISS) [211]. In the absence of these absolute indications, further imaging is based on clinical signs and symptoms including [179, 180, 188, 212]:
• inability to void or inadequate urine output;
• abdominal tenderness or distension due to urinary ascites, or signs of urinary ascites in abdominal imaging;
• uraemia and elevated creatinine level due to intraperitoneal re-absorption;
• entry/exit wounds at lower abdomen, perineum or buttocks in penetrating injuries.

Intra-operative signs of external iatrogenic bladder injury include: extravasation of urine, visible laceration, visible bladder catheter, and blood and/or gas in the urine bag during laparoscopy [200]. Direct inspection is the most reliable method of assessing bladder integrity [191]. Intravesical instillation of dye helps to detect smaller lesions [213]. If bladder perforation is close to the trigone, the ureteric orifices should be inspected [191, 200].

Internal bladder injury is recognised by cystoscopic identification of fatty tissue, dark space, or bowel [204]. It may also be detected by the inability to distend the bladder, low return of irrigation fluid, or abdominal distension [214].

Post-operatively, missed bladder trauma is diagnosed by haematuria, abdominal pain, abdominal distension, ileus, peritonitis, sepsis, urine leakage from the wound, decreased urinary output, or increased serum creatinine [191, 200]. An IBT during hysterectomy or caesarean delivery can result in vesico-vaginal or vesico-uterine fistulae [200, 215].

4.3.3.1 Cystography
Cystography is the preferred diagnostic modality for non-iatrogenic bladder injury and for a suspected IBT in the post-operative setting [215, 216]. Both plain and CT cystography have a comparable sensitivity (90-95%) and specificity (100%) [180, 217]. However, CT cystography is superior in the identification of bony fragments in the bladder and bladder neck injuries, as well as concomitant abdominal injuries [179, 182].

Cystography must be performed using retrograde filling of the bladder with a minimum volume of 300-350 mL of dilute contrast material [216, 218]. Passive bladder filling by clamping the urinary catheter during the excretory phase of CT or IVP is not sufficient to exclude bladder injury [180]. Intraperitoneal extravasation is visualised by free contrast medium in the abdomen outlining bowel loops or abdominal viscera [219]. Extraperitoneal bladder injury is typically diagnosed by flame-shaped areas of contrast extravasation in the peri-vesical soft tissues. Contrast medium in the vagina is a sign of vesico-vaginal fistula [215].

4.3.3.2 Cystoscopy
Cystoscopy is the preferred method for detection of intra-operative bladder injuries as it may directly visualise the laceration and can localise the lesion in relation to the position of the trigone and ureteral orifices [219]. A lack of bladder distension during cystoscopy suggests a large perforation. Cystoscopy is recommended to detect perforation of the bladder (or urethra) following retropubic sub-urethral sling operations [192, 210]. Routine intra-operative cystoscopy during other gynaecologic procedures is not recommended [220], although the threshold to perform it should be low in any suspected bladder injury.

4.3.3.3 Ultrasound
Ultrasound alone is insufficient in the diagnosis of bladder trauma, although it can be used to visualise intraperitoneal fluid or an extraperitoneal collection of fluid.

4.3.4 Prevention
The risk of bladder injury is reduced by emptying the bladder by urethral catheterisation in every procedure where the bladder is at risk [213, 221]. Furthermore, the catheter’s balloon can aid in identification of the bladder [213]. For tumours at the lateral wall, obturator nerve block or general anaesthesia with adequate muscle relaxation can reduce the incidence of internal IBT during TURB [196]. There is conflicting evidence
whether bipolar TURB can reduce the risk for an obturator jerk [195, 196]. The use of combat pelvic protection systems reduces the risk of bladder and other genitourinary injuries due to the blast mechanism of improvised explosive devices [190, 222].

4.3.5 Disease management
4.3.5.1 Conservative management
Conservative treatment, which comprises of clinical observation, continuous bladder drainage and antibiotic prophylaxis [194], is the standard treatment for an uncomplicated extraperitoneal injury due to blunt [179, 182, 185] or iatrogenic trauma [194].

Conservative treatment can also be chosen for uncomplicated intraperitoneal injury after TURB or other operations, but only in the absence of peritonitis and ileus [205, 219]. Placement of an intraperitoneal drain is advocated, especially when the lesion is larger [214, 223]. Penetrating extraperitoneal bladder injuries (only if minor and isolated) can also be managed conservatively [186, 212, 224].

4.3.5.2 Surgical management
Bladder closure is performed with absorbable sutures [186, 191]. There is no evidence that two-layer is superior to watertight single-layer closure [182, 186].

4.3.5.2.1 Blunt non-iatrogenic trauma
Most extraperitoneal ruptures can be treated conservatively; however, bladder neck involvement, bone fragments in the bladder wall, concomitant rectal or vaginal injury or entrapment of the bladder wall necessitate surgical intervention [179, 225]. There is an increasing trend to treat pelvic ring fractures with open stabilisation and internal fixation with osteosynthetic material. During this procedure, an extraperitoneal rupture should be sutured concomitantly in order to reduce the risk of infection [226]. Likewise, an extraperitoneal rupture should be sutured during surgical exploration for other injuries, in order to decrease the risk of complications and to reduce recovery time [185].

Intraperitoneal ruptures should always be managed by surgical repair [179, 182] because intraperitoneal urine extravasation can lead to peritonitis, intra-abdominal sepsis and death [181]. Abdominal organs should be inspected for possible associated injuries and urinomas must be drained if detected. Laparoscopic suturing of the intraperitoneal rupture is also possible [180].

4.3.5.2.2 Penetrating non-iatrogenic trauma
Penetrating bladder injury is managed by emergency exploration, debridement of devitalised bladder wall and primary bladder repair [188, 189]. A midline exploratory cystotomy is advised to inspect the bladder wall and the distal ureters [186, 188]. In gunshot wounds, there is a strong association with intestinal and rectal injuries, usually requiring faecal diversion [188, 212]. Most gunshot wounds are associated with two transmural injuries (entry and exit wounds) and the bladder should be carefully checked for these two lesions [188]. As the penetrating agent (bullet, knife) is not sterile, antibiotic treatment is advised [189].

4.3.5.2.3 Iatrogenic bladder trauma
Perforations recognised intra-operatively are primarily closed [227]. Bladder injuries not recognised during surgery or internal injuries should be managed according to their location. The standard of care for intraperitoneal injuries is surgical exploration and repair [219]. If surgical exploration is performed after TURB, the bowel must be inspected to rule out concomitant injury [193]. For extraperitoneal injuries, exploration is only needed for perforations complicated by symptomatic extravesical collections. It requires drainage of the collection, with or without closure of the perforation [228]. If bladder perforation is encountered during mid-urethral sling or transvaginal mesh procedures, sling re-insertion and urethral catheterisation (two to seven days) should be performed [229].

4.3.6 Follow-up
Continuous bladder drainage is required to prevent elevated intravesical pressure and to allow the bladder to heal [191, 230]. Conservatively treated bladder injuries (traumatic or external IBT) are followed up by cystography to rule out extravasation and ensure proper bladder healing [179]. The first cystography is planned approximately ten days after injury [186]. In case of ongoing leakage, cystoscopy should be performed to rule out bony fragments in the bladder, and a second cystography is warranted one week later [179].

After operative repair of a simple injury in a healthy patient, the catheter can be removed after five to ten days without cystography [230, 231]. In cases of complex injury (trigone involvement, ureteric re-implantation) or risk factors of impaired wound healing (e.g. steroids, malnutrition) cystography is advised [186, 230]. For conservatively treated internal IBT, catheter drainage, lasting five days for extraperitoneal and seven days for intraperitoneal perforations, is proposed [194, 197].

4.4 Urethral Trauma

4.4.1 Epidemiology, aetiology and pathophysiology

4.4.1.1 Anterior male urethral injury

The bulbar urethra is the most common site affected by blunt trauma. In bulbar injuries, the bulb is compressed against the pubic symphysis, resulting in rupture of the urethra at the site of compression [232]. Possible mechanisms are straddle injuries or kicks to the perineum. A penile fracture can be complicated by a urethral injury in approximately 15% of cases [233, 234]. Penetrating anterior injuries are rare and are usually caused by gunshot wounds, stab wounds, dog bites, impalement or penile amputations [232, 235]. Depending on the affected segment, penetrating injuries are usually associated with penile, testicular and/or pelvic injuries [235]. Insertion of foreign bodies is another rare cause of anterior injury. It is usually a result of autoerotic stimulation or may be associated with psychiatric disorders [236].

Iatrogenic injury is the most common type of urethral trauma [237]. The incidence of male urethral injury during transurethral catheterisation is 13.4 per 1,000 catheters inserted [238]. Injuries can occur due to creation of a false passage by the tip of the catheter or inadvertent inflation of the anchoring balloon in the urethra [238]. The importance of catheter insertion training programmes [239, 240] and the implementation of difficult urinary catheterisation protocols [241], to prevent urethral injury during transurethral catheterisation, have been demonstrated. Preliminary data suggests that guidewire led catheter insertion, or use of a safety
value for balloon inflation may prevent urethral trauma in difficult catheterisation cases [242, 243]. During penile prosthesis insertion, the risk of urethral perforation is 0.1-4%. Proximal urethral injuries are more common than distal ones [244].

4.4.1.2 Posterior male urethral injuries

Blunt posterior urethral injuries are almost exclusively related to pelvic fractures and the risk increases with fracture configuration severity [245]. These injuries are referred to as pelvic fracture urethral injuries (PFUI) [232], and are mainly caused by MVAs [246]. Pelvic fracture urethral injuries are divided into partial or complete ruptures [245, 246]. In complete ruptures, there is a gap between the disrupted ends of the urethra, which fills up with scar tissue. There is no urethral wall in the scarred space and any lumen represents a fistulous tract between the urethral stumps [247]. Injuries of the bladder neck and prostate are rare and mostly occur at the anterior midline of both the bladder neck and prostatic urethra [248]. It is highly uncommon to find a complete transection of the bladder neck or an avulsion of the anterior part of the prostate [248]. Concomitant injuries to the head, thorax, abdomen and/or spine are frequent (up to 66%) [246].

Penetrating injuries of the pelvis, perineum or buttocks (mostly gunshot wounds) can also damage the posterior urethra, but are extremely rare in the civilian setting [245]. There is a high probability of associated injuries (approx. 90%), mainly intra-abdominal [188].

The associated injuries which occur with both blunt and penetrating posterior urethral injuries can be life-threatening, and if so, will govern the patient’s assessment and treatment [246]. Delayed morbidities of posterior urethral injuries include strictures, incontinence and erectile dysfunction, all of which may have a detrimental effect on the patient’s quality of life [249]. The pooled estimate for the proportion of patients with erectile dysfunction following PIFU is 34% [250].

Iatrogenic injury has been reported with transanal total mesorectal excision in 1-11% of cases. This injury is usually partial and located at the membranous urethra [251].

4.4.1.3 Female urethral injuries

Birth related injuries to the female urethra are rare and consist of minor (peri)urethral lacerations during vaginal delivery. Pelvic fractures are the main cause of blunt trauma [252]; however, PFUIs in females are rare and less common than in males [245]. This is usually attributed to the flexibility provided by the vagina and the greater inherent elasticity of the female urethra [252], it may also be the result of less severe and more frequent stable pelvic fractures in females [179, 246]. In unstable pelvic fractures in females, a high suspicion for a urethral injury should be maintained [252]. Female urethral injuries are classified into two types: longitudinal or partial (most frequent) injuries and transverse or complete injuries [252]. Concomitant bladder or vaginal injury is possible; therefore, females are at risk of developing urinary incontinence and urethrovaginal fistula [246, 252].

Insertion of a synthetic sub-urethral sling for the treatment of female stress urinary incontinence is complicated by an intra-operative urethral injury in 0.2-2.5% of cases [253] and is an important cause of iatrogenic urethral injury.

4.4.2 Evaluation

4.4.2.1 Clinical signs

Blood at the meatus is the cardinal sign, but the absence of it doesn’t rule out a urethral injury [179, 246]. Inability to void (with a palpable distended bladder) is another classic sign and is often associated with a complete rupture [246, 247]. Haematuria and pain on urination may be present in incomplete ruptures. Urinary extravasation and bleeding may result in scrotal, penile and/or perineal swelling and ecchymosis, depending on the location and extent of the trauma. The presentation of these clinical symptoms may be delayed (>1 hour) [247].

Rectal examination should always be done to exclude an associated rectal injury (up to 5% of cases), and may reveal a ‘high-riding’ prostate, which is an unreliable finding [179, 247]. Failure to detect a rectal injury can cause significant morbidity and even mortality. A rectal injury is suggested by blood on the examining finger and/or a palpable laceration [179]. Another sign of urethral injury is difficulty or inability to pass a urethral catheter [179, 247].

A female urethral injury should be suspected from the combination of a (unstable) pelvic fracture with blood at the vaginal introitus, vaginal laceration, haematuria, urethrorrhagia, labial swelling, urinary retention or difficulties passing a urethral catheter [179, 249]. Vaginal examination is indicated to assess vaginal lacerations [179, 249].

4.4.2.2 Urethrography

Retrograde urethrography (RUG) is the standard in the early evaluation of a male urethral injury [179, 254] and is conducted by injecting 20-30 mL of contrast material while occluding the meatus. Films should be taken in a 30° oblique position. In patients with PFUI, it is important to move the X-ray beam to the 30° angle rather than the patient [246]. In an unstable patient, RUG should be postponed until the patient has been stabilised [179, 188].
During RUG, any extravasation outside the urethra is pathognomonic for urethral injury [247]. A typical image for incomplete rupture shows extravasation from the urethra which occurs while the bladder is still filling. A complete rupture is suggested by massive extravasation without bladder filling [246]. Although RUG is able to reliably identify the site of injury (anterior vs. posterior), the distinction between a complete and partial rupture is not always clear [246, 255]. Therefore, any proposed classification system based on RUG is not reliable [246, 255]. In females, the short urethra and vulvar oedema makes adequate urethrography nearly impossible [256].

Prior to deferred treatment, a combination of RUG and antegrade cysto-urethrography is the standard to evaluate site and extent of the urethral stenosis, and to evaluate the competence of the bladder neck [246].

4.4.2.3 **Cysto-urethroscopy**
Flexible cysto-urethroscopy is a valuable alternative to diagnose an acute urethral injury and may distinguish between complete and partial rupture [254]. Flexible cysto-urethroscopy is preferred to RUG in suspected penile fracture-associated urethral injury as RUG is associated with a high false-negative rate [257, 258]. In females, where the short urethra often precludes adequate radiological visualisation, cysto-urethroscopy and vaginoscopy are the diagnostic modalities of choice [179, 252]. If, prior to deferred treatment, the competence of the bladder neck is not clear upon antegrade cysto-urethrography, a suprapubic cystoscopy is advised [246].

4.4.4.2.4 **Ultrasound and magnetic resonance imaging**
In the acute phase, US scanning is used for guiding the placement of a suprapubic catheter [246]. In complex PFUIs, MRI before deferred treatment provides valuable additional information, which can help to determine the most appropriate surgical strategy [259]. This information includes a better estimation of the length of the distraction defect, degree of prostatic displacement and presence/absence of a false passage [259].

4.4.3 **Disease Management**

4.4.3.1 **Male anterior urethral injuries**

4.4.3.1.1 **Immediate exploration and urethral reconstruction**
This is indicated for penile fracture related injuries [260] and non-life threatening penetrating injuries [249]. Small lacerations can be repaired by simple closure [234]. Complete ruptures without extensive tissue loss are treated with anastomotic repair [234, 235]. Only 2% of cases will develop a urethral stricture after immediate urethral reconstruction for penile fracture [260]. In the case of longer defects or apparent infection (particularly bite wounds), a staged repair with urethral marsupialisation is needed [254]. Penetrating injuries require peri- and post-operative antibiotic treatment [261].

Immediate urethroplasty has been performed in blunt injuries. The long term-outcomes (patency rate, potency rate) of patients treated with immediate urethroplasty is similar to these initially treated with suprapubic diversion and delayed urethroplasty [262]. The main advantage of performing immediate urethroplasty is that this strategy significantly reduces the time to spontaneous voiding from two to six months to three weeks on average [262, 263]. Spongiosal contusion and haematoma during immediate urethroplasty will make the operation technically more demanding; therefore, immediate urethroplasty should be performed by a dedicated urethral surgeon [263].

Perforation of the distal urethra during penile prosthesis insertion needs to be repaired over a catheter; in this instance the initial procedure should be abandoned [264].

4.4.3.1.2 **Urinary diversion**
Blunt anterior urethral injuries are associated with spongiosal contusion. Evaluation of the limits of urethral debridement in the acute phase might be difficult and as a consequence, it is reasonable to start with urinary diversion only [254].

If urinary diversion is performed, the therapeutic options are suprapubic diversion or a trial of early endoscopic re-alignment with transurethral catheterisation [254]; there is conflicting evidence as to which intervention is superior [262, 263, 265]. Urinary diversion is maintained for one to two weeks for partial ruptures and three weeks for complete ruptures [254, 265]. A review of 49 Chinese studies (1,015 patients), reported a 57% (range: 0-100%) success rate for endoscopic re-alignment of blunt anterior injuries [262]. The wide range in success rate most likely reflects a mix of partial and complete ruptures which was not further specified in the review. For complete ruptures, urinary diversion on its own is unlikely to result in a successful outcome (0-25% patency rate) [263, 265].

Transurethral or suprapubic urinary diversion are treatment options for iatrogenic or life-threatening penetrating injuries [249, 266]. Minor iatrogenic urethral injuries and urethral contusions do not require urinary diversion [3].
4.4.3.2 Male posterior urethral injuries

4.4.3.2.1 Emergency room management

As these injuries are usually associated with other severe injuries, resuscitation and immediate treatment of life-threatening injuries have absolute priority [246]. Penetrating injuries especially have a very high likelihood of associated injuries requiring immediate exploration [188, 267]. There is no urgency to treat the urethral injury and urinary diversion is not essential during the first hours after trauma [247]; however, it is preferable to establish early urinary diversion to:

- monitor urinary output, since this is a valuable sign of the haemodynamic condition and the renal function of the patient;
- treat symptomatic retention if the patient is still conscious;
- minimise urinary extravasation and its secondary effects, such as infection and fibrosis [246].

Insertion of a suprapubic catheter is an accepted practice in urgent situations [247, 267]. However, insertion of a suprapubic catheter is not without risk, especially in the unstable trauma patient where the bladder is often displaced by a pelvic haematoma or because of poor bladder filling due to haemodynamic shock or concomitant bladder injury. In these circumstances, an attempt at urethral catheterisation can be carried out by experienced personnel. It is extremely unlikely that the gentle passage of a urethral catheter will do any additional damage [246]. If there is any difficulty, a suprapubic catheter should be placed under US guidance or under direct vision, for example, during laparotomy for associated injuries [246]. Suprapubic catheter placement does not increase the risk of infectious complications in patients undergoing internal fixation to stabilise a pelvic fracture [268]. Therefore, the assertion that suprapubic catheter placement would increase the risk of orthopaedic hardware infection and subsequent explantation is not justified [268].

4.4.3.2.2 Early urethral management (less than six weeks after injury)

For partial injuries, urinary diversion (suprapubic or transurethral) is sufficient as these injuries can heal without significant scarring or obstruction [247, 249]. A complete injury will not heal, and formation of an obliterated segment is inevitable in case of suprapubic diversion alone [247, 249]. To avoid this obliteration and a long period of suprapubic diversion followed by deferred urethroplasty, the urethral ends can be sutured (urethroplasty) or approximated over a transurethral catheter (re-alignment).

4.4.3.2.2.1 Immediate urethroplasty

Urethroplasty within 48 hours after injury is difficult because of poor visualisation and the inability to accurately assess the degree of urethral disruption, due to extensive swelling and ecchymosis, which may result in extensive unjustified urethral debridement. Another problem is the risk of severe bleeding (average 3 L) following entry into the pelvic haematoma [246]. In addition, with high rates of impotence (23%), incontinence (14%) and strictures (54%), urethroplasty within 48 hours is not indicated [246].

4.4.3.2.2.2 Early urethroplasty

Urethroplasty can be performed after two days and up to six weeks after the initial injury, if associated injuries have been stabilised, the distraction defect is short, the perineum is soft and the patient is able to lie down in the lithotomy position [269, 270]. This avoids a long period of suprapubic diversion with its discomfort and complications [269, 270]. As the results (complications, stricture recurrence, incontinence and impotence) are equivalent to delayed urethroplasty [270-272], early urethroplasty might be an option for patients fulfilling the above-mentioned criteria.

Lacerations (blunt or penetrating) at the bladder neck and prostatic urethra are a specific entity: they will never heal spontaneously, will cause local cavitation (presenting a source of infection) and compromise the intrinsic sphincter mechanism (with increased risk of urinary incontinence) [248]. They must be reconstructed as soon as possible [249, 255, 267]. For penetrating injuries with severe lesions to the prostate, prostatectomy (bladder neck sparing) must be performed [267].

4.4.3.2.2.3 Early re-alignment

Early re-alignment can be performed when a stable patient is on the operating table for other surgery or as a stand-alone procedure in the absence of concomitant injuries [188, 273]. In a partial injury, re-alignment, and transurethral catheterisation avoids extravasation of urine in the surrounding tissues reducing the inflammatory response. In complete injuries, the aim of re-alignment is to correct severe distraction injuries rather than to prevent a stricture [249, 274].

Re-alignment can be done by an open or endoscopic technique [274, 275]. The open technique is associated with longer operation times, more blood loss and longer hospital stays; as such, endoscopic re-alignment is now preferred [262]. Using a flexible/rigid cystoscope and biplanar fluoroscopy, a guidewire is placed inside the bladder under direct visual control, over this, a catheter is placed. If necessary, two
cystoscopes can be used: one retrograde (per urethra) and one antegrade (suprapubic route through the bladder neck) [246]. The duration of catheterisation is three weeks for partial and six weeks for complete ruptures with voiding urethrography upon catheter removal [246]. It is important to avoid traction on the balloon catheter as it can damage the remaining sphincter mechanism at the bladder neck [246].

With contemporary endoscopic re-alignment procedures, stricture formation is reduced to 44-49% [274, 275] compared to a 89-94% stricture rate with suprapubic diversion [275, 276]. There is no evidence that early re-alignment increases the risk of urinary incontinence (4.7-5.8%) or erectile dysfunction (16.7-20.5%) [275, 276].

Another potential benefit of early re-alignment is that when a stricture occurs it will be shorter and therefore, easier to treat. For short, non-obliterative strictures following re-alignment, direct vision urethrotomy can be performed. Approximately 50% of strictures after endoscopic re-alignment can be treated endoscopically [274]. However, repetitive endoscopic procedures in case of stricture formation might delay the time to definitive cure and can increase the incidence of adverse events (false passage, abscess formation) [277, 278]. In light of this, repetitive endoscopic treatments after failed re-alignment are not recommended; instead, urethroplasty must be performed.

Koraitim et al., found a shorter stricture length after early (open) re-alignment and as a consequence, a tendency for less complex manoeuvres to be needed to allow for a tension-free anastomosis during urethroplasty [279]. On the other hand, Tausch et al., reported an equal stricture length and no greater facilitation of urethroplasty after failed endoscopic re-alignment compared to suprapubic diversion only [277]. The proposed benefit is thus highly questionable. Furthermore, there is conflicting evidence as to whether failed early re-alignment jeopardises the success of definitive urethroplasty [246].

Differences between series in the rates of incontinence, impotence and re-stricture can be explained by differences in patient selection (severe vs. less severe trauma), a mix of partial and complete ruptures, and differences in follow-up duration. Furthermore, these differences make the comparison with other techniques difficult, especially with urethroplasty [179, 274].

4.4.3.2.3 Deferred management (greater than three months after injury)
The standard treatment remains deferred urethroplasty [13, 14]. In the case of a complete rupture, treated with an initial period of three months suprapubic diversion, obliteration of the posterior urethra is almost inevitable [247]. Endoscopic treatment of a complete obliteration is not successful [246]. After at least three months of suprapubic diversion, the pelvic haematoma is nearly always resolved, the prostate has descended into a more normal position, the scar tissue has stabilised [269] and the patient is clinically stable and able to lie down in the lithotomy position [254, 269]. Associated life-threatening injuries often preclude early management of penetrating membranous urethral injuries. In those cases, suprapubic diversion with delayed urethroplasty is also advised [17, 25, 26]. Perineal anastomotic repair is the surgical technique of choice, but a combined abdominoperineal approach is necessary in rare cases of concomitant bladder neck injury or recto-urethral fistula [280].

The overall success rate for deferred urethroplasty is 86% [246]. Deferred urethroplasty does not significantly affect erectile function [281]. Although, a small proportion (< 7%) of patients report de novo erectile dysfunction after delayed urethroplasty, others (6-20%) have recovery of erectile dysfunction after delayed urethroplasty [246]. Incontinence is rare with deferred urethroplasty (approximately 5%), and is usually due to incompetence of the bladder neck [246]. The assessment of sexual function and the decision on definitive treatment (e.g. penile prosthesis), should be undertaken two years after the trauma due to the potential return of potency within that time [255, 282].

4.4.3.3.2.4 Iatrogenic posterior injuries
Urethral defects during transanal total mesorectal excision were repaired by direct suture repair via a transperineal approach in a small case series (n=32). Despite direct repair, 26% developed complications including urethral stricture, urethral dehiscence, recto-urethral fistula, and recto-perineal fistula. No evidence on other strategies is available [251].

4.4.3.3 Female urethral injuries
Emergency room management of PFUIs in females is the same as in males (section 4.4.3.2.1); however, subsequent management differs. Treatment options are [252]:

- **Early realignment**: This is associated with a high stricture and fistula rate.
- **Early repair (less than or equal to seven days)**: Complication rate is the lowest with early repair; therefore, this strategy is preferred once the patient is haemodynamically stable [249, 252].
- **Delayed repair (greater than seven days)**: Delayed repair often requires complex abdominal or combined abdominal-vaginal reconstruction with elevated risk of urinary incontinence and vaginal stenosis.
The approach (vaginal, abdominal or combined) for early repair depends on the location of the injury [252]. Proximal and mid-urethral disruptions require immediate exploration and primary repair using the retropubic and transvaginal routes, respectively, with primary suturing of the urethral ends or urethral laceration. Concomitant vaginal lacerations are repaired (two-layer closure) transvaginally at the same time [252]. Distal urethral injuries can be left hypospadic since they do not disrupt the sphincter mechanism, but a concomitant vaginal laceration must be closed [179, 256]. In case of urethral injury during synthetic sub-urethral sling insertion, immediate repair is warranted with abandonment of sling insertion [253].

Treat complete blunt anterior urethral injuries by immediate urethroplasty, if surgical expertise is available, otherwise perform suprapubic diversion with delayed urethroplasty.  

Treat pelvic fracture urethral injuries (PFUIs) in haemodynamically unstable patients by transurethral or suprapubic catheterisation initially.  

Perform early endoscopic re-alignment in male PFUIs when feasible.  

Do not repeat endoscopic treatments after failed re-alignment for male PFUI.  

Treat partial posterior urethral injuries initially by suprapubic or transurethral catheter.  

Do not perform immediate urethroplasty (< 48 hours) in male PFUIs.  

Perform early urethroplasty (two days to six weeks) for male PFUIs with complete disruption in selected patients (stable, short gap, soft perineum, lithotomy position possible).  

Manage complete posterior urethral disruption in male PFUIs with suprapubic diversion and deferred (at least three months) urethroplasty.  

Perform early repair (within seven days) for female PFUIs (not delayed repair or early re-alignment).

**4.5 Genital Trauma**

**4.5.1 Epidemiology, aetiology and pathophysiology**

Of all urological injuries, 33-66% involve the external genitalia [283]. Genital trauma is much more common in males than in females, especially between the ages of 15 and 40 years. This is due to anatomical differences, increased frequency of MVAs and increased participation in physical sports, war and crime [284]. The risk of associated injuries to neighbouring organs (bladder, urethra, vagina, rectum and bowel), after blunt trauma is higher in females than in males.

Genital trauma is commonly caused by blunt injuries (80%). In males, blunt genital trauma frequently occurs unilaterally with approximately 1% presenting as bilateral scrotal or testicular injuries [285]. Any kind of contact sport, without the use of protective aids, may be associated with genital trauma. Off-road cycling, motor biking (especially on motorbikes with a dominant petrol tank), rugby, football and hockey are all activities associated with blunt testicular trauma [286-289]. Penetrating injuries are most commonly caused by firearms (75.8%) with the majority requiring surgical intervention [290, 291].

---

**RUG = retrograde urethrography; DVIU = direct visual internal urethrotomy.**
Accidents during sexual intercourse can also cause genital trauma; men of younger age are the most affected. The major pathologies are penile fractures, strangulation, necrosis, and assorted injuries from various sexual practices [292, 293].

The most important presentation of blunt penile trauma is penile fracture. The most common causes are sexual intercourse, forced flexion (taqaandan), masturbation and rolling over in 46%, 21%, 18% and 8.2%, respectively [294]. It has also been reported that penile fracture patients have a significantly higher rate of substance abuse [295]. The usual mechanism of injury is when the penis slips out of the vagina and strikes against the symphysis pubis or perineum. Sixty per cent of cases occur during consensual intercourse [296], with penile fracture more likely in certain positions [297]. Penile fracture is caused by rupture of the cavernosal tunica albuginea, and may be associated with subcutaneous haematoma and lesions of the corpus spongiosum or urethra in 10-22% [298-300]. Genital injury is prevalent (42%) after sexual abuse [301]. Although animal bites are common, bites injuring the external genitalia are rare. Wounds are usually minor, but have a risk of wound infection.

Gunshot injuries to the external genitalia are relatively uncommon and are usually not life-threatening; however, they can have a significant impact on quality of life. About 40-60% of all penetrating genito-urinary lesions involve the external genitalia [302, 303], 35% of these are gunshot wounds [285]. In a series of wartime injuries, the majority were caused by improvised explosive devices and other explosive ordinance, while smaller numbers of injuries were due to gunshot injuries [304]. In both males and females, penetrating injuries affect multiple organs in 70% of patients. In males, penetrating scrotal injuries affect both testes in 30% of cases compared with 1% in blunt injuries [285, 305]. Self-mutilation of the external genitalia has also been reported in psychotic patients and transsexuals [306]. Genital burns are rare in isolation and are usually due to industrial flames or chemicals [307]. Both male and female genital piercings increase the risk for unexpected genital trauma [308].

Traumatic dislocation of the testicle rarely occurs and is most common in victims of MVAs [309-312]. Bilateral dislocation of the testes has been reported in up to 25% of cases [310]. Testicular rupture is found in approximately 50% of cases of direct blunt scrotal trauma [313, 314]. It may occur under intense compression of the testis against the inferior pubic ramus or symphysis, resulting in a rupture of the tunica albuginea. A force of approximately 50 kg is necessary to cause testicular rupture [315]. Most penile avulsion injuries are self-inflicted, but some are a result of industrial accidents or assault.

Coital injury of the female genital tract can happen during consensual sexual intercourse. Up to 35% of all genital injuries in women are sustained during their first sexual contact. The most frequently found injuries are lacerations [316]. Blunt trauma to the vulva is rarely reported and usually presents as a large haematoma. The incidence of traumatic vulvar haematomas after vaginal deliveries has been reported as 1 in 310 deliveries [317]. The presence of a vulvar haematoma is closely related to an increased risk of associated vaginal, pelvic or abdominal injuries [318, 319]. Blunt injuries of the vulva and vagina are associated with pelvic trauma in 30%, after consensual intercourse in 25%, following sexual assault in 20%, and other blunt trauma in 15% [320].

4.5.2 Diagnostic evaluation

4.5.2.1 Patient history and physical examination

Penile fracture is associated with a sudden cracking or popping sound, pain and immediate detumescence. Local swelling of the penile shaft develops quickly, due to enlarging haematoma [233]. Bleeding may spread along the fascial layers of the penile shaft and extend to the lower abdominal wall if Buck’s fascia is also ruptured. Sometimes, the rupture of the tunica may be palpable. Less severe penile injuries can be distinguished from penile fracture, as they are not usually associated with detumescence [294].

Testicular rupture is associated with immediate pain, nausea, vomiting, and sometimes fainting. The hemiscrotum is tender, swollen, and ecchymotic. The testis itself may be difficult to palpate. Blunt vulvar or perineal trauma in women may be associated with bleeding, pain and voiding problems, bladder catheterisation is usually required.

In genital trauma, a urinalysis should be performed. The presence of visible haematuria requires a retrograde urethrogram in males. In females, flexible or rigid cystoscopy is recommended to exclude urethral and bladder injury [318, 320]. In women with genital injuries and blood at the vaginal introitus, further gynaecological investigation is needed [318].

4.5.3 Imaging

In cases of suspected penile fracture cavernosography, US or contrast-enhanced MRI [294, 321-323] can identify lacerations of the tunica albuginea in unclear cases [324], or provide reassurance that the tunica is intact. Magnetic resonance imaging is superior to US in diagnosing penile fracture [325]. If a concomitant urethral injury is suspected, manage as outlined in section 4.4.
Ultrasound should be performed to determine intra- and/or extra-testicular haematoma, testicular contusion, or rupture [314, 326-334]. However, the literature is contradictory as to the usefulness of US compared to clinical examination alone. Some studies have reported convincing findings with a specificity of up to 98.6% [335]. Heterogeneous echo pattern of the testicular parenchyma with the loss of contour definition is a highly sensitive and specific radiographic finding for testicular rupture [325]. Others reported poor specificity (78%) and sensitivity (28%) for the differentiation between testicular rupture and haematoma, while accuracy is as low as 56% [327]. Colour Doppler-duplex US may provide useful information when used to evaluate testicular perfusion. If scrotal US is inconclusive, testicular CT or MRI may be helpful [336]; however, these techniques did not specifically increase the detection rates of testicular rupture.

4.5.4 Disease management

4.5.4.1 Animal bites
Local wound management depends on the extent of tissue destruction. Antibiotics should be prescribed in accordance with local resistance patterns [337-339]. The possibility of rabies infection must be considered taking into account the geographical location, animal involved, specific nature of the wound and the type of attack (provoked/unprovoked). Elderly and immunosuppressed patients should be vaccinated with human rabies immunoglobulin and human diploid cell vaccine [340, 341].

4.5.4.2 Human bites
In cases of human bites, apart from wound management, infection should be considered since transmission of viral diseases may occur, Hepatitis B vaccine/immunoglobulin and/or immunodeficiency virus (HIV) post-exposure prophylaxis should be offered. For further details, see Guidelines for the Management of Human Bite Injuries [342].

4.5.4.3 Blunt penile trauma
Blunt trauma to the flaccid penis does not usually cause tearing of the tunica. Subcutaneous haematoma after sexual intercourse, without associated rupture of the cavernosal tunica albuginea, does not require surgical intervention. In these cases, non-steroidal analgesics and ice-packs are recommended [343].

4.5.4.4 Penile fracture
The thickness of the tunica albuginea in the flaccid state (approximately 2 mm) decreases in erection to 0.25-0.5 mm, and is therefore more vulnerable to traumatic injury [335, 344]. When a penile fracture is diagnosed, surgical intervention with closure of the tunica albuginea is recommended; it ensures the lowest rate of negative long-term sequelae and has no negative effect on the psychological wellbeing of the patient [345]. The approach is usually through a circumferential incision proximal to the coronal sulcus which enables complete degloving of the penis. Increasingly, local longitudinal incisions centred on the area of fracture or ventral longitudinal approaches are currently used [257]. A recent systematic review on the management of penile fractures concluded that immediate repair should be within 24 hours of presentation [346]; however, delayed presentation should not prevent exploration [297]. Further localisation may be gained with a flexible cystoscopy performed prior to incision, if urethral trauma is suspected and eventually proven [233]. Surgical closure of the tunica should be carried out using absorbable sutures.

4.5.4.5 Penetrating penile trauma
In penetrating penile trauma non-operative management is recommended for small superficial injuries with intact Buck's fascia [302]. In more significant penetrating penile injuries, surgical exploration and debridement of necrotic tissue is recommended. Even in extended injuries of the penis, primary alignment of the disrupted tissues may allow for acceptable healing because of the robust penile blood supply [306].

The principles of care are debridement of devitalised tissue, with the preservation of as much viable tissues as possible, haemostasis, diversion of urine in selected cases and the removal of foreign bodies. Tissues of questionable viability may be left for subsequent definitive surgery. If a delayed repair is needed, depending on the type of injury and the extent of tissue damage, it usually takes place four to six weeks after the trauma has occurred.

The surgical approach depends upon the site and extent of the injury, but a subcoronal incision with penile degloving usually gives good exposure. Initially, a defect in the tunica albuginea should be closed after copious irrigation. If there has been too much tissue loss, the defect can be repaired either immediately or after delay with a patch (either from an autologous saphenous vein or xenograft).

The elasticity of genital skin means it is usually possible to manage the loss of a moderate amount of penile skin; however, management is more difficult in extensive injuries with significant skin loss. The tissue chosen for reconstruction following trauma needs to provide good coverage and must be suitable for reconstruction. Split-thickness skin grafting provides good coverage and a dependable take that is reproducible and durable. However, split-thickness grafts contract more than full-thickness grafts and their
use on the penile shaft should be kept to a minimum. Skin grafts with thickness of at least 0.4 mm should be used in order to reduce the risk of contraction [306]. Full-thickness skin grafting onto the penile shaft gives less contracture, a better cosmetic appearance and more resistance to trauma during intercourse, when re-established [343]. The donor site may be taken from the abdomen, buttock, thigh or axilla and is chosen according to surgeon’s preference and the pattern of injury. In cases of extensive destruction of deeper tissues, or if later prosthetic placement is being considered, skin flaps, with their secure vascular supply, can be used.

4.5.4.6 Penile avulsion injuries and amputation

Acute management involves resuscitation of the patient, and preparation for surgical re-implantation of the penis if it has been recovered and is not too badly damaged. Surgical re-implantation should be considered for all patients and should be performed within 24 hours of amputation [347].

The severed penis should be washed with sterile saline, wrapped in saline-soaked gauze, placed in a sterile bag and immersed in iced water. The penis must not come into direct contact with the ice. A pressure dressing or a tourniquet should be placed around the penile stump to prevent excessive blood loss. Re-attachment can be achieved in a non-microsurgical way, but gives higher rates of post-operative urethral stricture and more problems with loss of sensation [348]. When operating microscopically, the corpora cavernosa and urethra are firstly aligned and repaired. Subsequently, the dorsal penile arteries, the dorsal vein and the dorsal nerves are anastomosed. The cavernosal arteries are generally too small to anastomose. The fascia and skin are closed in layers and both a urethral and a suprapubic catheter are placed [349].

If the severed penis cannot be found, or is unsuitable for re-attachment, then the end should be closed as it is done in partial penectomy. Later reconstruction may be employed to lengthen the penis (e.g. suspensory ligament division and V-Y plasty, pseudo-glans formation with split-thickness skin grafting, etc.). A delayed major reconstructive procedure, i.e. phalloplasty (either radial artery or pubic), is sometimes required for injuries which leave a very small or non-functioning penile stump [347].

4.5.4.7 Testicular dislocation

It can be either a subcutaneous dislocation with epifascial displacement of the testis or an internal dislocation. In the latter, the testis is positioned in the superficial external inguinal ring, inguinal canal or abdominal cavity. Traumatic dislocation of the testis is treated by manual replacement and secondary orchidopexy. If primary manual reposision cannot be performed, immediate orchidopexy is indicated.

4.5.4.8 Haematocoele

Conservative management is recommended in haematocoeles smaller than three times the size of the contralateral testis [350]. In large haematocoeles, non-operative management can fail, and delayed surgery (more than three days) is often required. Patients with large haematocoeles have a higher rate of orchectomy than patients who undergo early surgery, even in non-ruptured testes [285, 306, 313, 351, 352]. Early surgical intervention results in preservation of the testis in more than 90% of cases compared to delayed surgeries which result in orchectomy in 45-55% of patients [313]. In addition, non-operative management is also associated with prolonged hospital stays. Therefore, large haematocoeles should be treated surgically, irrespective of the presence of testicular contusion or rupture. At the very least, the blood clot should be evacuated from the tunica vaginalis sac to relieve disability and hasten recovery.

4.5.4.9 Testicular rupture

It is essential to surgically explore equivocal patients whenever imaging studies cannot definitively exclude testicular rupture. This involves exploration with evacuation of blood clots and haematoma, excision of any necrotic testicular tubules and closure of the tunica albuginea, usually with running 3.0-absorbable sutures.

4.5.4.10 Penetrating scrotal trauma

Penetrating injuries to the scrotum require surgical exploration with debridement of non-viable tissue. Depending on the extent of the injury, primary reconstruction of the testis and scrotum can usually be performed. In complete disruption of the spermatic cord, re-alignment without vaso-vasostomy may be considered if surgically feasible [353]. Staged secondary microsurgical vaso-vasostomy can be performed after rehabilitation, although only a few cases have been reported [353]. If there is extensive destruction of the tunica albuginea, mobilisation of a free tunica vaginalis flap can be performed for testicular closure. If the patient is unstable or reconstruction cannot be achieved, orchectomy is then indicated. Prophylactic antibiotics are recommended after scrotal penetrating trauma, although data to support this approach are lacking.

Extended laceration of scrotal skin requires surgical intervention for skin closure. Due to the elasticity of the scrotum, most defects can be primarily closed, even if the lacerated skin is only minimally attached to the scrotum [306]. Local wound management with extensive initial wound debridement and washout is important for scrotal convalescence. In the case of extensive loss of genital tissue, e.g. improvised explosive device blast injury, complex and staged reconstructive surgical procedures are often required [304].
### Summary of key points:

#### Penile fracture
- The most common causes of penile fracture are sexual intercourse, forced flexion, masturbation and rolling over.
- Penile fracture is associated with a sudden cracking or popping sound, pain, immediate detumescence and local swelling.
- Magnetic resonance imaging is superior to all other imaging techniques in diagnosing penile fracture.
- Management of penile fracture is surgical intervention with closure of the tunica albuginea.

#### Testicular Trauma
- Blunt testicular injury may occur under intense compression of the testis against the inferior pubic ramus or symphysis, resulting in a rupture of the tunica albuginea.
- Testicular rupture is associated with immediate pain, nausea, vomiting, and sometimes fainting.
- Scrotal ultrasound is the preferred imaging modality for the diagnosis of testicular trauma.
- Surgical exploration in patients with testicular trauma ensures preservation of viable tissue when possible.

### Complications

The possibility of complications from genital trauma, including psychological effects, erectile dysfunction, urethral stricture, and infertility, is high. In patients with a history of penile fracture post-operative complications were reported in up to 20% of cases, development of plaques or nodules following surgery, post-operative curvature formation and erectile dysfunction occur in 13.9%, 2.8% and 1.9% of patients, respectively [294]. Post-surgical erectile dysfunction is more common in patients > 50 years and those with bilateral corporal involvement [354]. Skin necrosis is rare [297]. Conservative management of penile fracture increases complications, such as penile abscess, missed urethral disruption, penile curvature, and persistent haematoma requiring delayed surgical intervention [355]. Late complications after conservative management were fibrosis and angulations in 35% and impotence in up to 62% [296, 356].

Post-operative complications were reported in 8% of patients who underwent testicular repair after penetrating trauma [302]. Despite good management and regular follow-up of external genital gunshot wounds, such wounds are fraught with the possibility of complications such as erectile dysfunction, urethral stricture, and infertility. Delayed complications include chronic pain and testicular atrophy. Haematoceles initially treated non-operatively may eventually need delayed surgery if they develop infection or undue pain. Genital injuries are rarely life threatening, but fertility and testosterone production often become the male trauma patient's chief concern once acute issues are resolved [357].

### Follow-up

In patients with genital trauma follow-up should focus on diagnosis of and therapy for late complications. Erectile dysfunction, urethral stricture and assessment of fertility are the main concerns [300, 358].

1. INTRODUCTION

1.1 Aim
This guideline plays an important role in the process of consolidation and improvement of care for patients with pelvic pain and associated lower abdominal pain. From both literature and daily practice it has become clear that lower abdominal and pelvic pain are areas still under development. This guideline has been recognised as a cornerstone for important developments that have taken place in the past ten years.

This guideline aims to expand the awareness of caregivers in the field of abdominal and pelvic pain and to assist those who treat patients with abdominal and pelvic pain in their daily practice. The guideline is a useful instrument not only for urologists, but also for gynaecologists, surgeons, physiotherapists, psychologists and pain doctors.

It must be emphasised that guidelines present the best evidence available to the experts. However following guideline recommendations will not necessarily result in the best outcome. Guidelines can never replace clinical expertise when making treatment decisions for individual patients, but rather help to focus decisions - also taking personal values and preferences/individual circumstances of patients into account. Guidelines are not mandates and do not purport to be a legal standard of care.

Structure and scope
The panel wishes to take advantage of modern methods of delivering guideline information to clinicians dealing with these patients. In 2016, a stepped information structure was made, in alignment with stepped care protocols, using new digital information sources like websites and apps to aid this process. Furthermore, the guideline was changed according to the template used in all other non-oncology guidelines of the EAU. It was recognised that structuring a guideline on chronic pain is quite different from structuring one on another subject. A multi-disciplinary approach is of utmost importance and demands a broad view. In 2016, the guideline was rewritten to be centred around pain instead of being organ-centred. It is partly theoretical to show the importance of using this pain-centred approach. The biggest part, however, deals with the practical approach to diagnostics, treatment and management of patients with abdominal and pelvic pain.

1.2 Publication history
The EAU Guidelines on Chronic Pelvic Pain were first published in 2003 [1] which formed the basis of a scientific publication in European Urology in 2004 [2]. Also, in the 2003 edition the concept of Chronic Pelvic Pain Syndromes (CPPS) was introduced, which is now referred to as “pain as a disease process”. Partial updates of the Chronic Pelvic Pain Guidelines were published in 2008 and formed the basis for another scientific publication in European Urology in the year 2010 [3, 4]. Two chapters were added at that time: Chapter 5 ‘Gastrointestinal aspects of chronic pelvic pain’ and Chapter 7 ‘Sexological aspects of chronic pelvic pain’. In the 2014 edition minor revisions were made in Chapter 5 ‘Gastrointestinal aspects of chronic pelvic pain’ and Chapter 8 ‘Psychological aspects of chronic pelvic pain’.

For the 2015 edition the panel critically reviewed the sub-chapter on chronic primary bladder pain syndrome (BPS) which is now a comprehensive part of the guideline. The fact that this part was so extensive shows that the roots of talking about abdominal pain and pelvic pain lies in the bladder, where Interstitial Cystitis was one of the first subjects addressed talking about pain in urology. The panel has illustrated this in the publication in European Urology in 2013 [5].

1.3 Available Publications
Alongside the full text version, a quick reference document (Pocket Guidelines) is available in print and as an app for iOS and Android devices. These are abridged versions which may require consultation together with the full text version. This reference document follows the updating cycle of the underlying large texts.

All available material can be viewed at the EAU website. The EAU website also includes a selection of EAU Guideline articles as well as translations produced by national urological associations: uroweb.org/guideline/chronicpelvicpain/.

1.4 Panel composition
The panel of experts responsible for this guideline include five urologists, (one of whom has a sub-specialisation in neuro-urology and one is a sexologist), three consultants in pain medicine, a uro-gynaecologist, a psychologist, a gastroenterologist, a pelvic physiotherapist, health scientist and (clinical) epidemiologist and two patient advocates.
1.5 Terminology

Definitions of chronic pelvic pain terminology

Classification

Much debate over the classification of chronic pelvic pain has occurred, is ongoing and will continue in the future. Classification involves three aspects of defining a condition: phenotyping, terminology and taxonomy.

Phenotyping

Phenotyping is describing the condition. For example, chronic bladder pain may be associated with the presence of Hunner's lesions and glomerulation on cystoscopy, whereas other bladder pain conditions may have a normal appearance on cystoscopy. These are two different phenotypes. The same is true for irritable bowel syndrome (IBS), which may be sub-divided into that associated primarily with diarrhoea or that with constipation. Phenotyping is based upon mechanisms when they are known (e.g., infection, ischaemic, auto-immune, or neuropathic). In the absence of well-defined mechanisms, describing the condition by its symptoms, signs and, where possible, by investigations, has been demonstrated to have clinical and research validity in many situations. When pain is the main symptom and pain as a disease process is considered the cause, the condition is often referred to as a pain syndrome - a well-defined collection of symptoms, signs and investigation results associated with pain mechanisms and pain perception as the primary complaint. The World Health Organization (WHO) International Classification of Diseases 11th Revision (ICD-11) uses the term Chronic Primary Pain to distinguish these conditions from pain associated with another diagnosis that they refer to as Chronic Secondary Pain (see below).

Terminology

Terminology is the word(s) that are used within classification, both to name the phenotype and within the definition of the phenotype. Examples of names for phenotypes associated with the bladder include interstitial cystitis, painful bladder syndrome or BPS. The EAU, the International Society for the study of BPS (known as ESSIC), the International Association for the Study of Pain (IASP) and several other groups have preferred the term BPS. In the pain syndromes, the role of the nervous system in generating the sensations is thought to be pivotal, but the term syndrome is also comprehensive and takes into account the emotional, cognitive, behavioural, sexual and functional consequences of the chronic pain.

When defining the phenotype, the terminology used in that definition must also be clear and if necessary, defined. One of the most important guiding principles is that spurious terminology should be avoided. Terms that end in “itis” should particularly be avoided, unless infection and or inflammation is proven and considered to be the cause of the pain [6]. It must be appreciated that end-organ inflammation may be secondary and neurogenic in origin and not a primary cause of the pain.

Taxonomy

Taxonomy places the phenotypes into a relationship hierarchy. The EAU approach sub-divides chronic pelvic pain into conditions that are pain syndromes with no obvious diagnosis, chronic primary pelvic pain syndromes (CPPPS) (consistent with ICD-11 Chronic Primary Pain) and those that are non-pain syndromes. The latter are conditions that have well-recognised pathology (e.g., infection, neuropathy or inflammation), whereas the former syndromes do not, and pain as a disease process is the mechanism. Other terms for the non-pain syndromes include “classical conditions”, “well-defined conditions” and “confusable diseases” and the ICD-11 Chronic Secondary Pain. Although the EAU approach deals primarily with urological conditions, this approach to classification can be applied to all conditions associated with pain perception within the pelvis; the classification has been developed to include non-urological pain and was accepted by the IASP for publication in January 2012.

Classification of chronic pelvic pain

Importance of classification

It should be obvious to all that a condition cannot be treated unless it is defined. However, the reasons for classifying chronic pelvic pain go far beyond that.

Clues to the mechanism

As a result of systematic phenotypic and taxonomic classifications, similarities and differences between conditions become clear. Drawing comparisons between the phenotypes of different disorders allows comparison between disorders such as bladder and bowel pain syndromes, thus facilitating research and treatment.
Guidelines for best treatment options
As conditions become better defined, more specific treatment approaches can be adopted. In particular, there will be a move away from treatments based upon spurious terms (e.g., antibiotics and non-steroidal antinflammatory drugs for the “-itis” conditions). Generic treatments aimed at groups of conditions will be more commonplace and based upon research evidence.

Research platform
Only by clearly defining the phenotype being investigated can research be valued or applied to the clinical situation.

Patient needs
A diagnosis, or name, for a set of symptoms can provide patients with a sense of being understood, as well as hope for relief. It may therefore help in acceptance of the problem as chronic, resolution of unfounded fears about its implications (if not life-threatening), and engagement in therapeutic endeavours, as well as assists in self-management. However, it may lead to accessing information of variable quality associated with the diagnosis or name, and the possibility of generating new concerns about long-term consequences or about the appropriateness of treatment.

IASP definitions
Sub-dividing pain syndromes
There is much debate on the sub-divisions of the pain syndromes within the hierarchical taxonomy. The EAU has led the way in this regard and the guiding principles are as follows [2]:

1. The pain syndromes are defined by a process of exclusion. In particular, there should be no evidence of infection or inflammation. Investigations by end-organ specialists should therefore be aimed at obtaining a differential diagnosis; repeated, unnecessary investigations are detrimental in the management of chronic pain syndromes.

2. A sub-division phenotype should only be used if there is adequate evidence to support its use. For instance, in non-specific, poorly localised pelvic pain without obvious pathology, only the term chronic primary pelvic pain syndrome (CPPPS) should be used. If the pain can be localised to an organ, then a more specific term, such as rectal pain syndrome, may be used, also potentially with the term primary added. If the pain is localised to multiple organs, then the syndrome is a regional pain syndrome and the term CPPPS should once again be considered. As well as defining the patient by a specific end-organ phenotype, there are several other more general descriptors that need to be considered. These are primarily psychological (e.g., cognitive or emotional), sexual, behavioural and functional. Psychological and behavioural factors are well-established factors which relate to quality of life (QoL) issues and prognosis. A North American research program, the MAPP program (Multi-disciplinary Approach to the study of Chronic Pelvic Pain research) has been devised to investigate the importance of these factors and looks at all types of pelvic pain irrespective of the end-organ where the pain is perceived. It also looks at systemic disorder associations, such as the co-occurrence of fibromyalgia, facial pain, or auto-immune disorders.

3. In 2004 the panel introduced the concept of managing the polysymptomatic nature of CPPPS, since then others have developed their own schemes, such as Nickel’s UPOINT [7], modified by Magri et al. [8]. In light of these and other publications, the symptom classification table has been updated (Table 1).

The debate in relation to sub-dividing the pain syndromes continues. As more information is collected suggesting that the central nervous system (CNS) is involved, and indeed may be the main cause of many CPPPS conditions (e.g., bladder, genitalia, colorectal or myofascial), therefore there is a general tendency to move away from end-organ nomenclature. Only time and good research will determine whether this is appropriate. To enable such research, it is essential to have a framework of classification within which to work. Any hierarchical taxonomy must be flexible to allow change.

ICD classification: purpose and uses
The International Classification of Diseases is the foundation for the identification of health trends and statistics globally, and the international standard for reporting diseases and health conditions. It is the diagnostic classification standard for all clinical and research purposes. It defines the universe of diseases, disorders, injuries and other related health conditions, listed in a comprehensive and hierarchical fashion [9]. The latest version, ICD-11, is available for member states to report with from January 2022.
The ICD-11 classification for the first time included chronic pain (“chronic pain is pain that persists or recurs for longer than three months”) and divided the coding into Chronic Primary Pain (“chronic primary pain is multifactorial: biological, psychological and social factors contribute to the pain syndrome”) and a number of Chronic Secondary Pain conditions (related to cancer, post surgical, musculoskeletal, visceral, neuropathic, headache/orofacial, other).

The significance of the inclusion of Chronic Pain as a condition within the ICD-11 should not be underestimated. There are, however, unresolved issues regarding this classification, such as when a condition ends and pain persists, does that term Chronic Secondary Pain become Chronic Primary Pain? [10, 11]. Similarly, the contents of recent drafted national institute for health and care excellence (NICE) guidelines [12] (https://www.nice.org.uk/guidance/GID-NG10069/documents/draft-guideline), were found to be contentious as the guidelines considered all Chronic Primary Pain as being essentially the same and the ‘biological’ nature of the pain appeared to have been missed. Whereas in the final guidelines this may be corrected, it does illustrate the risk behind the term Chronic Primary Pain.

The panel will change the EAU terminology previously used in the Guidelines to show conformity with ICD 11 definitions. This will include changing terminology used in originally cited works.
The classification has been set up according to the axis system used by IASP.

Pain syndromes
The original EAU classification [2] was inspired by the IASP classification [13] and much work around what has become known as “pain as a disease” and its associated psychological, behavioural, sexual, social and organ function aspects. After ten years of work developing the initial ideas, an updated version was accepted by the IASP Council for publication in January 2012.

EAU Definition of chronic pelvic pain
Chronic pelvic pain is chronic or persistent pain perceived* in structures related to the pelvis of either men or women. It is often associated with negative cognitive, behavioural, sexual and emotional consequences as well as with symptoms suggestive of lower urinary tract (LUT), sexual, bowel, pelvic floor or gynaecological dysfunction. [*Perceived indicates that the patient and clinician, to the best of their ability from the history, examination and investigations (where appropriate) have localised the pain as being discerned in a specified anatomical pelvic area.]

In the case of documented nociceptive pain that becomes chronic/persistent through time, pain must have been continuous or recurrent for at least three months (in accordance with ICD-11). For cyclical pain, a longer period of more than six months may be appropriate. Cyclical pain is included in the classification, particularly if there is evidence of central sensitisation and hence dysmenorrhoea (hormonally dependent) needs to be considered as a chronic pain syndrome, if it is persistent and associated with negative cognitive, behavioural, sexual, or emotional consequences.

Chronic pelvic pain may be sub-divided into conditions with well-defined classical pathology (such as infection or cancer) and those with no obvious pathology but still including biological mechanisms. For the purpose of the EAU's classification, the term “specific disease-associated pelvic pain” has been accepted for the former, and “chronic pelvic pain syndrome” for the latter. In the new ICD-11 these conditions have new names: the former will be called Chronic Secondary Pelvic Pain and the latter Chronic Primary Pelvic Pain.

The following classification only deals with Chronic Primary Pelvic Pain Syndromes.

EAU Definition of chronic primary pelvic pain syndrome
Chronic primary pelvic pain syndrome (CPPPS) is the occurrence of chronic pain when there is no proven infection or other obvious local pathology that may account for the pain. It is often associated with negative cognitive, behavioural, sexual or emotional consequences, as well as with symptoms suggestive of LUT, sexual, bowel or gynaecological dysfunction. Chronic Primary Pelvic Pain Syndrome is a subdivision of chronic pelvic pain. Throughout the text below in the 2021 update, CPPS is replaced with CPPPS if it is appropriate.

Further subdivision of chronic primary pelvic pain syndrome
Pain perception in CPPPS may be focused within a single organ, more than one pelvic organ and even associated with systemic symptoms such as chronic fatigue syndrome (CFS), fibromyalgia (FM) or Sjögren’s syndrome. When the pain is localised to a single organ, some specialists may wish to consider using an end organ term such as BPS (Table 2), also using the term primary. The use of such a phrase with the terminology “syndrome” indicates that, although peripheral mechanisms may exist, CNS neuromodulation may be more important and systemic associations may occur. When the pain is localised to more than one organ site, the generic term CPPPS should be used. Many, including some of the panel members never sub-divide by anatomy and prefer to refer to patients with pain perceived within the pelvis, and no specific disease process, as suffering from CPPPS, sub-divided by psychological and functional symptoms.

Psychological considerations for classification
Many CPPPSs are associated with a range of concurrent negative psychological, behavioural and sexual consequences that must be described and assessed. Examples that need to be considered are depression, anxiety, fears about pain or its implications, unhelpful coping strategies, and distress in relationships. Both anxiety and depression can be significant important concomitant symptoms that are relevant to pain, disability and poor QoL. Catastrophic interpretation of pain has been shown to be a particularly salient variable, predicting patients’ report of pain, disability, and poor QoL, over and above psychosocial variables such as depression or behavioural factors such as self-reported sexual dysfunction. Many of these biopsychosocial consequences are common to other persistent pain problems but may show varying degrees of importance for any one individual suffering from CPPPS. In all patients with CPPPS, these consequences must be clearly described as part of the phenotype (where the term phenotype is used to indicate the observable characteristics of the syndrome) [14].
Functional considerations for classification

Functional disorders, for the purpose of this document, are pathologies that have arisen secondary to changes in the control mechanisms of an organ or system. That is, they are disorders characterised by disturbance of function. As an example, slow colonic transit is a functional disorder of the bowel - the normal function of the bowel is not occurring as a result of changes in the mechanisms that produce defecation, and therefore bowel control is altered. The term is not used in the sense of a psychiatric functional disorder. Many CPPPSs are associated with functional abnormalities at a local and even systemic level. These also need to be defined as a part of the phenotype.

Functional pain disorders may not include significant pathology in the organs that appear responsible for the primary symptoms, but they are associated with substantial neurobiological, physiological and sometimes anatomical changes in the CNS.

Multi-system sub-division

It is recognised that the end-organ where the pain is perceived may not be the centre of pain generation. This classification is based upon the most effective and accepted method of classifying and identifying different pain syndromes, that is, by site of presentation. It is argued that keeping the end-organ name in the classification is inappropriate because, in most cases, there are multi-systemic causes and effects, with the result that symptoms are perceived in several areas. This is an area in which discussions are ongoing, and despite there being strong arguments for both keeping and dispensing with end-organ classification, the panel have not taken the umbrella approach of referring to all pain perceived in the pelvis as CPPS, primary or secondary.

Dyspareunia

Dyspareunia is defined as pain perceived within the pelvis associated with penetrative sex. It tells us nothing about the mechanism and may be applied to women and men. It is usually applied to penile penetration, but is often associated with pain during insertion of any object. It may apply to anal as well as vaginal intercourse. It is classically sub-divided into superficial and deep.

Primary perineal pain syndrome

Primary perineal pain syndrome is a neuropathic-type pain that is perceived in the distribution area of the pudendal nerve, and may be associated with symptoms and signs of rectal, urinary tract or sexual dysfunction. There is no proven obvious pathology. It is often associated with negative cognitive, behavioural, sexual and emotional consequences, as well as with symptoms suggestive of lower urinary tract and sexual dysfunction. Primary perineal pain syndrome should be distinguished from pudendal neuralgia which is a specific disease associated with perineal pain that is caused by nerve damage.

<td><strong>Primary prostate pain syndrome</strong></td>
</tr>
<tr>
<td>Primary prostate pain syndrome (PPPS) is the occurrence of persistent or recurrent episodic pain (which is convincingly reproduced by prostate palpation). There is no proven infection or other obvious local pathology. Primary prostate pain syndrome is often associated with negative cognitive, behavioural, sexual or emotional consequences, as well as with symptoms suggestive of lower urinary tract and sexual dysfunction. The term “chronic prostatitis” continues to be equated with that of PPPS. In the authors’ and others’ opinion, this is an inappropriate term, although it is recognised that it has a long history of use. The National Institutes of Health (NIH) consensus [15] includes infection (types I and II), which the authors feel should not be considered under PPPS, but as specific disease-associated pelvic pain. The term prostadynia has also been used in the past but is no longer recommended by the expert panel. Please note that some of the authors of the IASP document disagree with this term and suggest that CPPPS of the male is used instead of PPPS, which has been agreed by the majority.</td>

<tbody>
<tr>
<td><strong>Primary vulvar pain syndrome</strong></td>
<td>Primary vulvar pain syndrome is the occurrence of persistent or recurrent episodic vulvar pain. There is no proven infection or other local obvious pathology. It is often associated with negative cognitive, behavioural, sexual or emotional consequences, as well as with symptoms suggestive of lower urinary tract, sexual, bowel or gynaecological dysfunction. Although pain perceived in the vulva was included under sexual disorders in the DSM-IV-R manual for classifying psychiatric disorders, there is no scientific basis for this classification, and pain perceived in the vulva is best understood as a pain problem that usually has psychological consequences. There is no evidence for its classification as a psychiatric disorder. The International Society for the Study of Vulvovaginal Disease (ISSVD) has used the term vulvodynia, where we use the term primary vulvar pain syndrome. According to the ISSVD, vulvodynia is vulvar pain that is not accounted for by any physical findings. The ISSVD has defined vulvodynia as “vulvar discomfort, most often described as burning pain, occurring in the absence of relevant visible findings or a specific, clinically identifiable, neurologic disorder”. If physical findings are present, the patient is said to have vulvar pain due to a specified cause. The ISSVD has sub-divided vulvodynia based on pain location and temporal characteristics of the pain (e.g. provoked or unprovoked). The following definitions are based on that approach.</td>
</tr>
<tr>
<td><strong>Primary generalised vulvar pain syndrome</strong></td>
<td>Primary generalised vulvar pain syndrome refers to a vulvar pain syndrome in which the pain/burning cannot be consistently and precisely localised by point-pressure mapping via probing with a cotton-tipped applicator or similar instrument. Rather, the pain is diffuse and affects all parts of the vulva. The vulvar vestibule (the part that lies between the labia minora into which the urethral meatus and vaginal introitus open) may be involved but the discomfort is not limited to the vestibule. This pain syndrome is often associated with negative cognitive, behavioural, sexual or emotional consequences. Previous terms have included “dysesthetic vulvodynia” and “essential vulvodynia”, but these are no longer recommended.</td>
</tr>
<tr>
<td><strong>Primary localised vulvar pain syndrome</strong></td>
<td>Primary localised vulvar pain syndrome refers to pain that can be consistently and precisely localised by point-pressure mapping to one or more portions of the vulva. Clinically, the pain usually occurs as a result of provocation (touch, pressure or friction). Primary localised vulvar pain syndrome can be sub-divided into primary vestibular pain syndrome and primary clitoral pain syndrome.</td>
</tr>
<tr>
<td><strong>Primary vestibular pain syndrome</strong></td>
<td>Primary vestibular pain syndrome refers to pain that can be localised by point-pressure mapping to the vestibule or is well perceived in the area of the vestibule.</td>
</tr>
<tr>
<td><strong>Primary clitoral pain syndrome</strong></td>
<td>Primary clitoral pain syndrome refers to pain that can be localised by point-pressure mapping to the clitoris or is well-perceived in the area of the clitoris.</td>
</tr>
</tbody>
</table>

### Gynaecological system: internal pelvic pain syndromes

<table>
<thead>
<tr>
<th>Syndrome</th>
<th>Description</th>
</tr>
</thead>
<tbody>
<tr>
<td><strong>Endometriosis-associated pain syndrome</strong></td>
<td>Endometriosis-associated pain syndrome is chronic or recurrent pelvic pain in patients with laparoscopically confirmed endometriosis, and the term is used when the symptoms persist despite adequate endometriosis treatment. It is often associated with negative cognitive, behavioural, sexual or emotional consequences, as well as with symptoms suggestive of lower urinary tract, sexual, bowel or gynaecological dysfunction. Many patients have pain above and beyond the endometriotic lesions; this term is used to cover that group of patients. Endometriosis may be an incidental finding, is not always painful, and the degree of disease seen laparoscopically does not correlate with severity of symptoms. As with other patients, they often have more than one end-organ involved. It has been suggested that this phenotype should be removed from the classification because the endometriosis may be irrelevant.</td>
</tr>
<tr>
<td><strong>Chronic primary pelvic pain syndrome with cyclical exacerbations</strong></td>
<td>Chronic primary pelvic pain syndrome with cyclical exacerbations covers the non-gynaecological organ pain that frequently shows cyclical exacerbations (e.g., IBS or PBPS) as well as pain similar to that associated with endometriosis/adenomyosis but where no pathology is identified. This condition is different from dysmenorrhoea, in which pain is only present with menstruation.</td>
</tr>
<tr>
<td><strong>Primary dysmenorrhoea</strong></td>
<td>Primary dysmenorrhoea is pain with menstruation that is not associated with well-defined pathology. Dysmenorrhoea needs to be considered as a chronic primary pain syndrome if it is persistent and associated with negative cognitive, behavioural, sexual or emotional consequences.</td>
</tr>
</tbody>
</table>
Gastrointestinal Pelvic Pain Syndromes

<table>
<thead>
<tr>
<th>Syndrome</th>
<th>Description</th>
</tr>
</thead>
<tbody>
<tr>
<td>Irritable bowel syndrome</td>
<td>Irritable bowel syndrome is the occurrence of chronic or recurrent episodic pain perceived in the bowel, in the absence of proven infection or other obvious local pathology. Bowel dysfunction is frequent. Irritable bowel syndrome is often associated with worry and pre-occupation about bowel function, and negative cognitive, behavioural, sexual or emotional consequences, as well as with symptoms suggestive of lower urinary tract or gynaecological dysfunction. The above classification is based upon the Rome III Criteria [17]: three months of continuous or recurring symptoms of abdominal pain or irritation that may be relieved with a bowel movement, may be coupled with a change in frequency, or may be related to a change in stool consistency. Two or more of the following are present at least 25% of the time: change in stool frequency (&gt; three bowel movements per day or &lt; three per week); noticeable difference in stool form (hard, loose, watery or poorly formed stools); passage of mucus in stools; bloating or feeling of abdominal distension; or altered stool passage (e.g., sensation of incomplete evacuation, straining, or urgency). Extra-intestinal symptoms include: nausea, fatigue, full sensation after even a small meal, and vomiting.</td>
</tr>
<tr>
<td>Chronic primary anal pain syndrome</td>
<td>Chronic primary anal pain syndrome is the occurrence of chronic or recurrent episodic pain perceived in the anus, in the absence of proven infection or other obvious local pathology. Chronic primary anal pain syndrome is often associated with negative cognitive, behavioural, sexual or emotional consequences, as well as with symptoms suggestive of lower urinary tract, sexual, bowel or gynaecological dysfunction.</td>
</tr>
<tr>
<td>Intermittent chronic primary anal pain syndrome</td>
<td>Intermittent chronic primary anal pain syndrome refers to severe, brief, episodic pain that seems to arise in the rectum or anal canal and occurs at irregular intervals. This is unrelated to the need to or the process of defecation. It may be considered a sub-group of the chronic primary anal pain syndromes. It was previously known as “proctalgia fugax” but this term is no longer recommended.</td>
</tr>
</tbody>
</table>

Musculoskeletal System

<table>
<thead>
<tr>
<th>Syndrome</th>
<th>Description</th>
</tr>
</thead>
<tbody>
<tr>
<td>Primary pelvic floor muscle pain syndrome</td>
<td>Primary pelvic floor muscle pain syndrome is the occurrence of persistent or recurrent episodic pelvic floor pain. There is no proven well-defined local pathology. It is often associated with negative cognitive, behavioural, sexual or emotional consequences, as well as with symptoms suggestive of lower urinary tract, sexual, bowel or gynaecological dysfunction. This syndrome may be associated with over-activity of, or trigger points within, the pelvic floor muscles. Trigger points may also be found in several muscles, such as the abdominal, thigh and paraspinal muscles and even those not directly related to the pelvis.</td>
</tr>
<tr>
<td>Primary coccyx pain syndrome</td>
<td>Primary coccyx pain syndrome is the occurrence of chronic or recurrent episodic pain perceived in the region of the coccyx, in the absence of proven infection or other obvious local pathology. Primary coccyx pain syndrome is often associated with negative cognitive, behavioural, sexual or emotional consequences, as well as with symptoms suggestive of lower urinary tract, sexual, bowel or gynaecological dysfunction. The term “coccydynia” was used but is no longer recommended.</td>
</tr>

Chronic Pain Post-Surgery

<table>
<thead>
<tr>
<th>Syndrome</th>
<th>Definition</th>
</tr>
</thead>
<tbody>
<tr>
<td>Chronic post-surgical pain syndrome</td>
<td>The definition of chronic post-surgical pain is chronic pain that develops or increases in intensity after a surgical procedure and persists beyond the healing process, i.e., at least three months after the surgery. There is a separate category for this in the ICD11 classification.</td>
</tr>
</tbody>
</table>

2. METHODOLOGY

2.1 Methods
For each recommendation within the guidelines there is an accompanying strength rating form, the basis of which is a modified GRADE methodology [18]. Each strength rating form addresses a number of key elements namely:
1. the overall quality of the evidence which exists for the recommendation, references used in this text are graded according to a classification system modified from the Oxford Centre for Evidence-Based Medicine Levels of Evidence [19];
2. the magnitude of the effect (individual or combined effects);
3. the certainty of the results (precision, consistency, heterogeneity and other statistical or study related factors);
4. the balance between desirable and undesirable outcomes;
5. the impact of patient values and preferences on the intervention;
6. the certainty of those patient values and preferences.

These key elements are the basis which panels use to define the strength rating of each recommendation. The strength of each recommendation is represented by the words ‘strong’ or ‘weak’ [18]. The strength of each recommendation is determined by the balance between desirable and undesirable consequences of alternative management strategies, the quality of the evidence (including certainty of estimates), and nature and variability of patient values and preferences.

Additional information can be found in the general Methodology section of this print, and online at the EAU website: http://www.uroweb.org/guideline/. A list of associations endorsing the EAU Guidelines can also be viewed online at the above address.

The 2012 full text update was based on a systematic review (SR) of literature using the Embase and Medline databases, the Cochrane Central Register of controlled trials and the PsychINFO and Bandolier databases to identify the best evidence from randomised controlled trials (RCTs) (Level of Evidence 1 [LE: 1]) according to the rating schedule adapted from the Oxford Centre for Evidence-based Medicine Levels of Evidence. Where no LE: 1 literature could be identified the search was moved down to the next lower level on the rating scale.

Extensive use of free text ensured the sensitivity of the searches, resulting in a substantial body of literature to scan. Searches covered the period January 1995 to July 2011 and were restricted to English language publications. In 2017, a scoping search for the previous five years was performed and the guideline was updated accordingly.

In 2021, a new section was included on Post-Surgical Pain Syndrome. In addition, the classifications in the Guideline have been amended to reflect ICD-11 released by WHO. The latest version of ICD-11 will be available for member states to report with as from January 2022. For the 2022 print, a scoping search for the previous three years was performed and the guideline was updated accordingly.

2.2 Review
This document was subject to peer review prior to publication in 2021.

3. EPIDEMIOLOGY, AETIOLOGY AND PATHOPHYSIOLOGY

3.1 Chronic visceral pain
Definition of pain
Pain is defined as an unpleasant sensory and emotional experience associated with actual or potential tissue damage, or described in terms of such damage (IASP Taxonomy).

Introduction to chronic pelvic primary pain syndromes
Over the years much of the focus for CPPPS has been on peripheral-end-organ mechanisms, such as inflammatory or infective conditions. However, both animal and clinical research have indicated that many of the mechanisms for the CPPPSs are based within the CNS. Although a peripheral stimulus such as infection may initiate the start of a CPPPS condition, the condition may become self-perpetuating as a result of CNS modulation. As well as pain, these central mechanisms are associated with several other sensory, functional, behavioural and psychological phenomena. It is this collection of phenomena that forms the basis of the pain syndrome diagnosis and each individual phenomenon needs to be addressed in its own right through multi-specialty and multi-disciplinary care. Although ongoing peripheral organ pathology can produce persistent and chronic pain, the main focus of these guidelines is on CPPPSs in which no peripheral ongoing pathology (such as infection or neoplastic disease) is detected. The main exception is when pain is due to peripheral nerve damage.
3.1.1 Incidence
No adequate data on incidence were found.

3.1.2 Prevalence
Across the world [20] chronic pain is prevalent, seriously affecting the quality of people's social, family, and working lives, with differences between countries attributable to multiple causes, including study methodology. A UK study found a prevalence of chronic pelvic pain of 14.8% in women over 25 years [21].

3.1.3 Influence on Quality of Life
Assessing QoL in pelvic pain patients is challenging due to the complex pathology, the multi-faceted nature of the complaints and the overlap between the different pelvic pain syndromes [22, 23]. Pelvic pain syndromes have an impact in terms of QoL [24, 25], depression, anxiety, impaired emotional functioning, insomnia and fatigue [24, 26]. If these aspects are identified and targeted early in the diagnostic process, the associated pain symptoms may also improve. Addressing comorbidities will help in further improving QoL [27]. Quality of life assessment is therefore important in patients with pelvic pain and should include physical, psychosocial and emotional tools, using standardised instruments where possible [25]. Chronic pain is, in many countries, the leading cause of years lost to disability [20], although these figures are dominated by musculoskeletal pain and headache. Chronic pain is often associated with depression and other psychological problems; with loss or reduction of work and of ability to carry out domestic tasks; and, with substantial use of healthcare, often with disappointing outcomes.

3.1.4 Costs
No adequate data on costs were found.

3.1.5 Risk Factors and underlying causes

3.1.5.1 Risk factors
Risk factors include many different factors from various areas, including genetic, psychological state, recurrent physical trauma and endocrine factors.

The endocrine system is involved in visceral function. Significant life events, and in particular, early life events may alter the development of the hypothalamic-pituitary-adrenal axis and the chemicals released. Increased vulnerability to stress is thought to be partly due to increased corticotrophin-releasing hormone (CRH) gene expression. Up-regulation of CRH has been implicated in several pain states such as rectal hypersensitivity to rectal distension. This model suggests an action of CRH on mast cells. A range of stress-related illnesses have been suggested, e.g., IBS and BPS. There is evidence accumulating to suggest that the sex hormones also modulate both nociception and pain perception. Stress can also produce long-term biological changes which may form the relation between chronic pain syndromes and significant early life and adverse life events [28]. Asking the patient about these events is important as they have an effect on a patient's psychological wellbeing [29, 30].

Genetics also play a role in assessing the risk of developing chronic pain. An individual who has one chronic pain syndrome is more likely to develop another. Family clusters of pain conditions are also observed and animals can be bred to be more prone to apparent chronic pain state. A range of genetic variations have been described that may explain the pain in certain cases; many of these are to do with subtle changes in transmitters and their receptors. However, the picture is more complicated in that developmental, environmental and social factors also influence the situation. Evidence that PBPS may have a genetic component has been presented in several identical twin studies, but genetics may contribute to less than one third of total variation in susceptibility to PBPS [31, 32].

Studies about integrating the psychological factors of CPPPSs are few but the quality is high. Psychological factors are consistently found to be relevant in the maintenance of persistent pelvic and urogenital pain [33]. Beliefs about pain contribute to the experience of pain [34] and symptom-related anxiety and central pain amplification may be measurably linked, as in IBS [35], and catastrophic thinking about pain and perceived stress predict worsening of urological chronic pain over a year [33, 36]. Central sensitisation has been demonstrated in symptomatic endometriosis [37] and central changes are evident in association with dysmenorrhoea and increasingly recognised as a risk for female pelvic pain [38]. The various mechanisms of CNS facilitation, amplification and failure of inhibition mean that there is no simple relationship between physical findings, pain experience and resulting distress and restriction of activities. Division of aetiology into organic vs. psychogenic is unscientific. Diagnoses that assign women's pain to psychological origins due to scepticism about the reality or severity of their pain [39, 40] undermines any therapeutic relationship [41]. Pelvic
pain and distress may be related [42] in both men and women [43]; as are painful bladder and distress [36]. In a large population based study of men, CPPPS was associated with prior anxiety disorder [44]. The only SR [45] of risk factors for chronic non-cyclical pelvic pain in women included, as well as medical variables: sexual or physical abuse (Odds Ratio (OR): 1.51-3.49); psychological problems such as anxiety (OR: 2.28; 95% Confidence Interval (CI): 1.41-3.70) and depression (OR: 2.69; 95% CI: 1.86-3.88); multiple somatic problems (OR: 4.83; 95% CI: 2.50-9.33 and OR: 8.01; 95% CI: 5.16-12.44).

Many studies have reported high rates of childhood sexual abuse in adults with persistent pain, particularly in women with pelvic pain [46]. It is hard to establish a causal role for sexual abuse or trauma history, anxiety or depression in women with CPPPS [47, 48], as the attribution of current pain to past sexual or physical abuse is associated both with current depression [49] and with current overall physical health [50]. There is some evidence for a specific relationship between rape and CPPPS (and with fibromyalgia and functional gastrointestinal disorders) [51]; and, recent sexual assault may prompt presentation of pelvic pain [46, 52]. Few studies have been found of sexual or physical abuse in childhood and pelvic pain in men, although it has known adverse effects on health [51], but men who reported having experienced sexual, physical or emotional abuse had increased odds (3.3 vs. 1.7) for symptoms suggestive of CPPPS [53]. Both sexes should be screened for sexual abuse when presenting with symptoms suggestive of CPPPS, and clinicians should inquire about pelvic pain in patients who have experienced abuse [53].

3.1.5.2 Underlying causes
The mechanisms that serve as an underlying cause for chronic pelvic pain are:

1. Ongoing acute pain mechanisms [54] (such as those associated with inflammation or infection), which may involve somatic or visceral tissue.
2. Chronic pain mechanisms, which especially involve the CNS [6].
3. Emotional, cognitive, behavioural and sexual responses and mechanisms [55-57].

Symptoms and signs of neuropathic pain appear to be common in CPPPS patients and assessment of neuropathic pain should be considered in that group of patients. The presence or absence of endometriosis does not seem to change this [58].

Chronic pain mechanisms may include altered resting state neuromotor connectivity, for instance in men with chronic prostatitis/CPPPS [59].

Table 3 illustrates some of the differences between the somatic and visceral pain mechanisms. These underlie some of the mechanisms that may produce the classical features of visceral pain; in particular, referred pain and hyperalgesia.

**Ongoing peripheral pain mechanisms in visceral pain**

In most cases of chronic pelvic pain, ongoing tissue trauma, inflammation or infection is absent [60, 61]. However, conditions that produce recurrent trauma, infection or ongoing inflammation may result in chronic pelvic pain in a small proportion of cases. For example, out of a large cohort with acute bacterial prostatitis, 10.5% ended up with a state of CPPPS [62]. It is for this reason that the early stages of assessment include looking for these pathologies [16]. Once excluded, ongoing investigations for these causes are rarely helpful and indeed may be detrimental.

When acute pain mechanisms are activated by a nociceptive event, as well as direct activation of the peripheral nociceptor transducers, sensitisation of those transducers may also occur; therefore, magnifying the afferent signalling. Afferents that are not normally active may also become activated by the change, that is, there may be activation of the so-called silent afferents. Although these are mechanisms of acute pain, the increased afferent signalling is often a trigger for the chronic pain mechanisms that maintain the perception of pain in the absence of ongoing peripheral pathology (see below) [63].

There are a number of mechanisms by which the peripheral transducers may exhibit an increase in sensibility:

1. Modification of the peripheral tissue, which may result in the transducers being more exposed to peripheral stimulation.
2. There may be an increase in the chemicals that stimulate the receptors of the transducers [64].
3. There are many modifications in the receptors that result in them being more sensitive.
In general, the effect of 1 and 2 above is to lower the threshold and the effect of 3 above is to increase responsiveness to external stimuli. Some of the chemicals responsible for the above changes may be released from those cells associated with inflammation, but the peripheral nervous system may also release chemicals in the positive and inhibitory loops [65, 66].

Central sensitisation as a mechanism in visceral pain
It is important to appreciate that nociception is the process of transmitting information to centres involved in perception of a stimulus that has the potential to cause tissue damage. Pain is far more complex and involves activation of the nociceptive pathways but also the emotional response. The brain may affect the modulation of pain pathways at the spinal cord level.

Neuronal sensitisation is responsible for a decrease in threshold and an increase in response duration and magnitude of dorsal horn neurons. It is associated with an expansion of the receptive field. As a result, sensitisation increases signalling to the CNS and amplifies what we perceive from a peripheral stimulus. For example, for cutaneous stimuli, light touch would not normally produce pain, however, when central sensitisation is present, light touch may be perceived as painful (allodynia). In visceral hyperalgesia (so called because the afferents are primarily small fibres), visceral stimuli that are normally sub-threshold and not usually perceived, may be perceived. For instance, with central sensitisation, stimuli that are normally sub-threshold may result in a sensation of fullness and a need to void or to defecate. Non-noxious stimuli may be interpreted as pain and stimuli that are normally noxious may be magnified (true hyperalgesia) with an increased perception of pain. As a consequence, one can see that many of the symptoms of PBPS and IBS may be explained by central sensitisation. A similar explanation exists for the muscle pain in FM.

It is now well accepted that there are both descending pain-inhibitory and descending pain-facilitatory pathways that originate from the brain [67]. Several neurotransmitters and neuromodulators are involved in descending pain-inhibitory pathways. The main ones are the opioids, 5-hydroxytryptamine and noradrenaline.

The autonomic nervous system also plays a role in sensitisation. There is good evidence that damaged afferent fibres may develop a sensitivity to sympathetic stimulation, both at the site of injury and more centrally, particularly in the dorsal horns. In visceral pain, the efferent output of the CNS may be influenced by central changes (again, those changes may be throughout the neuraxis), and such modification of the efferent message may produce significant end-organ dysfunction. These functional abnormalities can have a significant effect on QoL and must be managed as appropriate.

Psychological mechanisms in visceral pain
Psychological processes of emotions, thought and behaviour involve networks rather than distinct centres. Some of these processes are sophisticated and others fundamental in evolutionary terms, and their interaction with pain processing is complex.

Various psychological processes affect pain neuromodulation at a higher level. Inhibiting or facilitating both the strength of the nociceptive signal reaching the consciousness and appraisal and interpretation of that signal, will also modulate the response to the nociceptive message and hence the pain experience. Further, descending pathways represent cognitive, emotional and behavioural states at spinal and peripheral levels. The psychological modulation of visceral pain probably involves multiple pathways: for instance, mood and attentional focus probably act through different areas of the brain when involved in reducing pain [68].

This psychological modulation may act to reduce nociception within a rapid time frame but may also result in long-term vulnerability to chronic visceral pain, through long-term potentiation. This involvement of higher centre learning may be at both a conscious and subconscious level, and is clearly significant in the supratentorial neuroprocessing of nociception and pain. Long-term potentiation [69] may occur at any level within the nervous system, so that pathways for specific or combinations of stimuli may become established, resulting in an individual being vulnerable to feeling pain from sensations that would not normally be experienced as painful.

An important review [28] of chronic pelvic pain in women dismantled the notion that women without relevant physical findings differ in psychological characteristics from women with relevant physical findings. Women with pelvic pain often have other non-pain somatic symptoms and current or lifetime anxiety and depression disorder [21]; they may have a history of physical or sexual abuse in childhood; but this is of unclear significance. Studies should avoid interpreting the absence of physical findings as evidence for psychological origins of the complaint (‘psychosomatic’ or ‘somatoform’ disorders). Pain studies describe multiple processes
by which pain may spread across sites, or in time, including central sensitisation (see previous section), viscer-visceral cross sensitisation in relation to multiple pain sites [70], activation of the hypothalamic-pituitary axis and dysregulation of serotonergic pathways [71] that can render pain levels responsive to stress. Some pain problems which affect sexual activity are diagnosed as sexual problems (e.g., ‘dyspareunia’) when pain is the central problem and is not contingent on sexual activity alone [72]. Better integration of sexology and mainstream psychology for pelvic pain in both men and women is needed, building on a biopsychosocial formulation [73, 74].

The term psychosomatic symptoms can best be understood as multiple somatic symptoms not associated with, or indicative of, any serious disease process. Medical and surgical history may also be important [75].

**Understanding the psychological components of pain**

Psychological processes of emotions, thought and behaviour involve distributed networks, whose interactions with pain processing are complex, producing inhibition and facilitation of signal processing, appraisal, and response. Models that integrate psychological factors involved in maintaining persistent pelvic and urogenital pain with current neurobiological understanding of pain are few, but the quality is high (see Section 3.1.5.1).

There is no evidence that women with CPPPS without physical findings are primarily presenting a psychological problem [28]. Anxiety and post-traumatic stress symptoms are common in some women with CPPPS [40, 76] and with vulvar pain [77], and may account for substantial variance in health status, treatment use and treatment outcome; for instance, women’s expectations about vulvar pain on penetration predicted pain, sexual function and sexual satisfaction [78]. Negative investigative findings do not necessarily resolve women’s anxieties about the cause of pain [79, 80] and anxiety often focuses on what might be ‘wrong’. Depression may be related to pain in various ways, as described above. Until measures are available that are adequately standardised in patients with pain, assessment of anxiety and distress requires questions about the patient’s beliefs about the cause of pain, the hope that diagnosis will validate pain, the struggle with unpredictability, and the implications of pain for everyday life [81, 82]. Reference to the studies of the IMMPACT group [83] is recommended for guidance on outcome measures suitable for pain trials.

Stress can modify the nervous system to produce long-term biological changes. These structural changes may be responsible for significant early life and adverse life events which are associated later with chronic pain syndromes [30]. The patient should be asked about adverse life events that may produce these biological responses and affect general psychological well-being [30, 84].

### 3.1.5.3 Clinical paradigms in visceral pain

**Referred pain**

Referred pain is frequently observed and its identification is important for diagnosis and treatment. Referral is usually somatic to somatic, or visceral to somatic. However, there is no reason why pain cannot also be perceived within the area of an organ with the nociceptive signal having arisen from a somatic area. Referred pain may occur as a result of several mechanisms but the main theory is one of convergence-projection. In the convergence-projection theory, afferent fibres from the viscera and the somatic site of referred pain converge onto the same second order projection neurons. The higher centres receiving messages from these projection neurons are unable to separate the two possible sites from the origin of the nociceptive signal [63].

Hyperalgesia refers to an increased sensitivity to normally painful stimuli. In patients that have passed a renal stone, somatic muscle hyperalgesia is frequently present, even a year after expulsion of the stone. Pain to non-painful stimuli (allodynia) may also be present in certain individuals. Somatic tissue hyperaesthesia is associated with urinary and biliary colic, IBS, endometriosis, dysmenorrhoea, and recurrent bladder infections. Primary vulvar pain syndromes are examples of cutaneous allodynia that, in certain cases, may be associated with visceral pain syndromes, such as BPS. Referred pain with hyperalgesia is thought to be due to central sensitisation of the converging viscero-somatic neurons. Central sensitisation also stimulates efferent activity that could explain the trophic changes that are often found in the somatic tissues.

**Musculo-skeletal system and pelvic pain**

In the urogenital pain syndromes, muscle tenderness and trigger points may be implicated as a source of pain. Central mechanisms are of great importance in the pathogenesis of this muscle hyperalgesia. The muscles involved may be a part of the spinal, abdominal or pelvic complex of muscles. It is not unknown for adjacent muscles of the lower limbs and the thorax to become involved. Pain may be localised to the trigger points but it is more often associated with classical referral patterns. As well as trigger points, inflammation of the ligaments and tendons to the bones (enthesitis) and of the bursa (bursitis) may be found [85]. Certain postures affect the
different muscles in different ways, and as a consequence, may exacerbate or reduce the pain. Stress has been implicated as both an initiator of pelvic myalgia and as a maintenance factor. As a result, negative sexual encounters may also have a precipitating effect [28].

**Visceral hyperalgesia**

The increased perception of stimuli in the viscera is known as visceral hyperalgesia, and the underlying mechanisms are thought to be responsible for IBS, PBPS and dysmenorrhoea. The mechanisms involved are often acute afferent input (e.g., due to infection) followed by long-term central sensitisation. Viscero-visceral hyperalgesia is thought to be due to two or more organs with converging sensory projections and central sensitisation. For instance, overlap of bladder and uterine afferents or uterine and colon afferents.

### 3.2 Pelvic pain

#### 3.2.1 Incidence

No adequate data on incidence were found.

#### 3.2.2 Prevalence

##### 3.2.2.1 Primary prostate pain syndrome

There is only limited information on the true prevalence of PPPS in the population. As a result of significant overlap of symptoms with other conditions (e.g., benign prostatic enlargement and PBPS), purely symptom based case definitions may not reflect the true prevalence of PPPS [86, 87]. In the literature, population-based prevalence of prostatitis symptoms ranges from 1-14.2% [88, 89]. The risk of prostatitis increases with age (men aged 50-59 years have a 3.1-fold greater risk than those aged 20-39 years).

##### 3.2.2.2 Primary bladder pain syndrome

Reports of PBPS prevalence have varied greatly, along with the diagnostic criteria and populations studied. Recent reports range from 0.06-30% [90-99]. There is a female predominance of about 10:1 [96] but possibly no difference in race or ethnicity [86, 100, 101]. The relative proportions of Hunner's lesion and non-lesion disease are unclear. Incidence in studies has ranged from 5-50% [102-105]. There is increasing evidence that children under eighteen may also be affected, although prevalence figures are low; therefore, PBPS cannot be excluded on the basis of age [106].

##### 3.2.2.3 Sexual pain syndrome

In the 1980s, an association between chronic pelvic pain and sexual dysfunction was postulated. In a review the relationship between Primary Prostate Pain Syndrome and health status, with influence on sexual activity, was addressed [107]. In a Chinese study of men with chronic pelvic pain, 1,768 males completed the questionnaires. The overall prevalence of sexual dysfunction was 49%. Erectile dysfunction (ED) is the most investigated sexual dysfunction in PPPS patients. The reported prevalence of ED ranges from 15.1-48%, varying with evaluation tools and populations [108, 109]. Erectile dysfunction was prevalent in 27.4% of Italian men aged 25-50 [110], 15.2% among Turkish men (significantly higher than in the control group) [111] and 43% among Finnish men with PPPS [112]. The prevalence of ED was found to be higher in young men with PPPS than in the general population. According to other studies, men with pelvic pain had a higher chance of suffering from ED [113]. A significant correlation between “chronic prostatitis”, chronic pelvic pain symptoms (measured by NIH-CPSI) and ED (measured by International Index of Erectile Function [IIEF]) was confirmed [114], while other studies using the same questionnaires were not able to confirm such a correlation [74, 115]. Some studies also report ejaculatory dysfunction, mainly premature ejaculation [108, 109, 116, 117].

In community-based studies in the UK [118], New Zealand [119] and Australia [120], a substantially larger proportion of the women with chronic pelvic pain reported dyspareunia (varying between 29-42%) than women without chronic pelvic pain (varying between 11-14%). Only a few studies have investigated sexual problems within clinical populations [121]. Another study showed that all of the sexual function domains (desire, arousal, lubrication, orgasm, satisfaction, and pain) were significantly lower in women with chronic pelvic pain than in women without chronic pelvic pain [121]. In line with the results of these community based studies, patients with chronic pelvic pain reported more sexual problems such as dyspareunia, problems with desire or arousal and lubrication than women without chronic pelvic pain [121, 122]. One study of patients enrolled in chronic pain treatment programs in England has reported that 73% had pain-related sexual problems [123].

##### 3.2.2.4 Myofascial pain syndromes

The relationship between muscular dysfunction (especially over-activity) and pelvic pain has been found in several studies [124]. Rectal pain treated with pelvic floor muscle therapy is only relieved when patients learn to relax their pelvic floor muscles [125, 126]. The vast majority (92.2%) of men visiting a tertiary centre for pelvic
Chronic pelvic pain is a complex condition often associated with dysfunction of the pelvic floor muscles. This finding was true regardless of evidence of inflammation (prostatitis or cystitis) [127]. This relationship has been found in chronic prostatitis [128], PBPS [129] and vulvar pain [130]. Dysfunction of the pelvic floor directly affects function of the pelvic viscera and vice versa. Both systems can act as the primary signal to the spinal cord, with a cascade of reactions ascending to the CNS as a result. The muscle itself ends up shortened, leading to restrictions even in a relaxed state.

3.2.3 Influence on Quality of Life
Data on the influence on QoL will be included in a future version of the guidelines.

3.2.4 Costs
No adequate data on costs were found.

3.2.5 Risk factors and underlying causes
The risk factors are unspecific for most of the pain syndromes in the pelvic area. They are described in Section 3.1.5.1. The underlying causes, including the mechanisms for the different clinical pain syndromes are described here.

3.2.5.1 Primary prostate pain syndrome
Pain is the main symptom in PPPS. As a common feature of primary chronic pain syndromes, no single aetiological explanation has been found. One explanation is that the condition probably occurs in susceptible men exposed to one or more initiating factors, which may be single, repetitive or continuous. Several of these potential initiating factors have been proposed, including infectious, genetic, anatomical, neuromuscular, endocrine, immune (including autoimmune), or psychological mechanisms. These factors may then lead to a peripheral self-perpetuating immunological, inflammatory state and/or neurogenic injury, creating acute and then chronic pain. A study showed that chronic but not acute histological inflammation of the prostate was significantly associated with symptomatic progression [131]. Based on the peripheral and the CNS, sensitisation involving neuroplasticity may lead to a centralised neuropathic pain state [132]. This could also explain why tissue damage is not usually found in PPPS. There is growing evidence for a neuropathic origin and association with CNS changes of pain in PPPS, and anxiety appears to be a risk factor for its development [44].

3.2.5.2 Primary bladder pain syndrome
An initial unidentified insult to the bladder, leading to urothelial damage, neurogenic inflammation and pain is thought to be a trigger of PBPS. However, PBPS might be a local manifestation of a systemic disorder. No infection has as yet been implicated. Nevertheless, urinary infections are significantly more frequent during childhood and adolescence, in patients with PBPS in adulthood [133]. Experimental induction of chronic pelvic pain by O-antigen deficient bacterial strains supports the bacterial hypothesis [134]. Pancystitis, with associated perineural inflammatory infiltrates, and mast cell count increase is an essential part of PBPS type 3 C [135], but is rare in non-lesion PBPS [30, 68, 136, 137]. Cystoscopic and biopsy findings in both lesion and non-lesion PBPS are consistent with defects in the urothelial glycosaminoglycan (GAG) layer, which might expose submucosal structures to noxious urine components [138-144] and a consequent cytotoxic effect [145, 146]. Basic and clinical studies indicate that autonomic dysfunction with sympathetic predominance may be implicated in PBPS [147, 148].

An association has been reported between PBPS and non-bladder syndromes such as FM, CFS, IBS, vulvodynia, depression, panic disorders, migraine, sicca syndrome, temporomandibular joint disorder, allergy, asthma and systemic lupus erythematosus [149-153].

Risk of PBPS correlates with a number of non-bladder syndromes in each patient [154]. Recent work showing non-lesion PBPS to have significantly more FM, migraine, temporomandibular joint disorder and depression than PBPS type 3 C patients, which emphasises, the need for subtyping [155].

3.2.5.3 Primary scrotal pain syndrome
Often scrotal pain is not associated with any specific pathology. Pain is perceived in the testes, epididymis, or the vas deferens. The ilioinguinal, genitofemoral and the pudendal nerves innervate the scrotum [156]. Any pathology or intervention at the origin or along the course of these nerves may result in pain perceived in the scrotum [157].

Two special forms of scrotal pain syndrome can be described. The first is post-vasectomy scrotal pain syndrome which occurs following vasectomy. The mechanisms are poorly understood, and for that reason it is considered by some a special form of primary scrotal pain syndrome. Incidence of post-vasectomy pain is 2-20% among all men who have undergone a vasectomy [158]. In men with post-vasectomy pain, 2-6% have
a Visual Analogue Scale (VAS) score > 5 [159]. In a large cohort study of 625 men, the likelihood of scrotal pain after six months was 14.7%. The mean pain severity on a VAS score was 3.4/10. In the pain group, 0.9% had quite severe pain, noticeably affecting their daily life. In this cohort, different techniques were used to perform the vasectomy. The risk of post-vasectomy pain was significantly lower in the no-scalpel vasectomy group (11.7% vs. the scalpel group 18.8%) [160].

The second special form of scrotal pain is post-inguinal hernia repair pain. It is seen as a complication of hernia repair, but in trials it is seldom reported, or it is put under the term chronic pain (not specified). In studies that have explicitly mentioned scrotal pain, there was a difference in incidence between laparoscopic and open hernia repair. In almost all studies, the frequency of scrotal pain was significantly higher in the laparoscopic than in the open group [157, 161]. In one particular study, there was no difference at one year but after five years, the open group had far fewer patients with scrotal pain [162]. Inguinal hernia repair can lead to chronic post-surgical pain (CPSP) in up to 10% of patients at six months [163] and may present with groin and/or scrotal pain. Testicular injury is uncommon (< 1%) but if associated with pain, orchidectomy can lead to symptomatic relief in 2/3 of patients [164]. Careful identification and preservation of nerves has been found to be associated with a reduced risk of chronic pain.

3.2.5.4 Primary urethral pain syndrome
Several mechanisms for the development of primary urethral pain syndrome have been proposed. The intimate relationship of the urethra with the bladder (both covered with urothelium) suggests that primary urethral pain syndrome may be a form of PBPS. Mechanisms thought to be basic for PBPS may also apply to the urethra. This means that the specific testing with potassium has been used to support the theory of epithelial leakage [165, 166]. Another possible mechanism is neuropathic hypersensitivity following urinary tract infection [167]. The relationship with gynaecological and obstetric aspects is unclear. In a small group of patients with urethral pain, it has been found that grand multi-parity and delivery without episiotomy were more often seen in patients with urethral syndrome, using univariate analysis [168].

3.2.5.5 Primary vaginal and vulvar pain syndromes
Pain in the vagina or the female external genital organs is often due to infection or trauma, as a consequence of childbirth or surgery. Pain is usually a precedent to dyspareunia. When the pain persists for more than three months, it can be diagnosed as primary vulvar pain syndrome previously known as “vulvodynia” or “chronic vaginal pain” with no known cause. It is still a poorly understood condition, and therefore difficult to treat.

There are two main sub-types of primary vulvar pain syndrome: generalised, where the pain occurs in different areas of the vulva at different times; and focal, where the pain is at the entrance of the vagina. In primary generalised vulvar pain syndrome, the pain may be constant or occur occasionally, but touch or pressure does not initiate it, although it may make the pain worse. In primary focal vulvar pain syndrome, the pain is described as a burning sensation that comes on only after touch or pressure, such as during intercourse.

The possible causes of primary vulvar pain syndrome are many and include:
• history of sexual abuse;
• history of chronic antibiotic use;
• hypersensitivity to yeast infections, allergies to chemicals or other substances;
• abnormal inflammatory response (genetic and non-genetic) to infection and trauma;
• nerve or muscle injury or irritation;
• hormonal changes.

3.2.5.6 Chronic pelvic pain and prolapse/incontinence mesh
Continence and prolapse mesh implants were developed as simple flexible polypropylene plastic acting as a scaffold to treat stress urinary incontinence (SUI) and uterovaginal prolapse, respectively. They were deemed easy to insert, but no credence was given as to how safe they were, whether they could be removed should they cause complications, or what to do should they not be effective [169, 170]. Most meshes took less than an hour to implant surgically and most patients were treated as day cases, allowing women to leave hospital quickly and get on with their lives. Therefore, rather than undergo complex traditional surgery, women were offered permanent mesh implants, particularly in the treatment of SUI where they were considered to be the gold standard [171, 172]. However, over the last few years the insertion of mesh has come with significant ‘health and safety warnings’ [173, 174].
For many, mesh was initially seen not just as an effective treatment but as a permanent one. Complications were not thought to be a significant issue and the figure of 1-3% was often quoted. However, we now know the complication rate was closer to 10% [175]. They included chronic pain [176, 177], as well as chronic infections [178], erosion into the surrounding organs including the vagina, urethra and bladder, as well as nerve and musculoskeletal damage affecting mobility [176, 177, 179, 180]. All had a significant impact on the patients’ QoL.

It is as a result of severely debilitating complications following mesh implantation [176], that the field of mesh removal medicine and surgery has emerged [181].

Early recognition of possible mesh complications is very important. It is normal to wake up in some degree of discomfort after any surgery. However, if the pain after the operation is very severe and much more than expected after this type of surgery, it can be a sign that there was added trauma to the surrounding organs during the procedure. Most pain is often managed with analgesia, but some women might not fully respond to therapy. If the pain is difficult to treat and does not improve over time, it may become necessary to remove the mesh. Leaving a painful mesh in the pelvis, can lead to chronic pelvic pain. The precise mechanism is unknown but it is thought to be a ‘neuro-inflammatory’ process [182], as has been proposed in hernia mesh neuralgia. The impact of the mesh, regardless of site, appears to be similar.

3.2.5.7 Chronic post-surgical pain

Chronic post-surgical pain may develop following surgical procedures and has a significant impact on the individual. The ICD-11 has recently classified chronic post-surgical pain (CPSP) as a chronic pain condition. The definition of CPSP is chronic pain that develops or increases in intensity after a surgical procedure and persists beyond the healing process, i.e., at least three months after the surgery [183].

Chronic post-surgical pain may occur in a significant number of patients, and is more prevalent following some operations rather than others. Procedures with a higher risk of CPSP include limb amputation (30-85%), thoracotomy (5-65%) and mastectomy (11-57%) [184].

Risk factors for CPSP include a number of pre-, peri- and post-operative factors. Younger age, female gender, chronic pain pre-operatively elsewhere, higher number of previous operations, use of opioids and a higher post-operative pain score have been found to be associated with a higher risk of CPSP in a prospective cohort of patients undergoing laparoscopy and laparotomies. Older age, malignant indication for surgery, a higher pre-operative mental health score and the use of epidural analgesia in addition to general anaesthesia were protective [185, 186].

There are a number of procedures specific to the abdomen and pelvis that are associated with an increased risk of chronic pain post-surgery, including bariatric procedures, inguinal hernia repair, vasectomy, hysterectomy and caesarean section. Adhesions are a common cause of chronic abdominal pain but despite this, a SR identified only low level evidence to help guide management of affected individuals [187].

The estimated prevalence of CPSP following bariatric surgery is 30% [188]. In affected individuals careful assessment that may include laparoscopy could identify a treatable cause (such as adhesions, mesenteric defect or cholecystitis) and lead to a significant reduction in post-operative pain [189].

Inguinal hernia repair can lead to CPSP in up to 10% of patients at six months [163] and may present with groin and/or scrotal pain.

The incidence of post vasectomy pain ranges from 2-20% [158, 159]. The risk is significantly lower following the no scalpel technique [160].

The incidence of post-surgical pain following hysterectomy is difficult to determine as pain is a common indication for the operation. When defined as CPSP, rates are estimated at 28-30% [190, 191]. Careful case selection and management of patient expectation is therefore important.

The frequency of caesarean section has increased over time. A meta-analysis has shown a significant incidence of CPSP both at three months and at more than twelve months (15% and 11% respectively) [192], therefore careful counselling is needed in non-emergency cases.
3.2.5.8  Associated conditions in pelvic pain syndromes

Nerve damage

Spinal pathology and any pathology along the course of the nerve involved may result in neuropathic pain in the distribution of these nerves. Neoplastic disease, infection, trauma, surgical incisions and post-operative scarring may result in nerve injury [193].

Pudendal neuralgia is the most often mentioned form of nerve damage in the literature. Anatomical variations may pre-dispose the patient to developing pudendal neuralgia over time or with repeated low-grade trauma (such as sitting for prolonged periods of time or cycling) [194, 195].

The pudendal nerve may be damaged at the level of:

1. The piriformis muscle. For example, as part of a piriformis syndrome: in some cases, the nerve may pass through the muscle and hence be trapped; or in other cases, muscle hypertrophy or spasm is implicated.
2. The sacrospinal/sacrotuberous ligaments, possibly accounting for 42% of cases.
3. Within Alcock’s canal (medial to the obturator internus muscle, within the fascia of the muscle), possibly accounting for 26% of cases.
4. Multiple levels in 17% of cases.
5. The site of injury determines the location of perceived pain and the nature of associated symptoms (e.g., the more distal the damage, the less likely the anal region will be involved).

The clinical presentation depends on different factors. There is a wide age range, as one would expect, with a condition that has so many potential causes. It is suggested that, the younger the patient, the better the prognosis. Essentially, the sooner the diagnosis is made, as with any compression nerve injury, the better the prognosis, and older patients may have a more protracted problem [196-198]. Six out of ten cases are observed in women. Some special situations can be listed:

- In orthopaedic hip surgery, pressure from the positioning of the patient, where the perineum is placed hard against the brace, can result in pudendal nerve damage [199, 200]. The surgery itself may also directly damage the nerve. Pelvic surgery such as sacrospinous fixation is clearly associated with pudendal nerve damage in some cases [201, 202]. In many types of surgery, including colorectal, urological and gynaecological, pudendal nerve injury may be implicated.
- Fractures of the sacrum or pelvis may result in pudendal nerve/root damage and pain. Falls and trauma to the gluteal region may also produce pudendal nerve damage if associated with significant tissue injury or prolonged pressure.
- Tumours in the pre-sacral space must be considered. Tumours invading the pudendal nerve may occur and there may also be damage from surgery for pelvic cancer [203].
- The pudendal neuralgia of birth trauma is thought to resolve in most cases over a period of months. However, rarely, it appears to continue as painful neuropathy. Multiple pregnancies and births may predispose to stretch neuropathy in later life. This is more difficult to be certain about [204];
- Child birth and repeated abdominal straining associated with chronic constipation [205] are thought to pre-dispose elderly women to post-menopausal pelvic floor descent and stretching of the pudendal nerve with associated pain. Changes in the hormone status may also be a factor. In Urogenital Pain Management Centres, the commonest associations with pudendal neuralgia appear to be: history of pelvic surgery; prolonged sitting (especially young men working with computer technology); and postmenopausal older women.

Sexual dysfunction

Chronic pelvic pain is a clinical condition that results from complex interactions of physiological and psychological factors and has a direct impact on the social, personal and professional lives of men and women.

Men

Chronic pain as well as its treatment can impair our ability to express sexuality. In an England study, 73% of patients with any chronic pain had some degree of sexual problems as a result of the pain [123]. These problems can occur because of several factors. Psychological factors like decrease in self-esteem, depression and anxiety can contribute to loss of libido. Physiological factors like fatigue, nausea and pain itself can cause sexual dysfunction. Pain medications (opioids, and the selective serotonin re-uptake inhibitors [SSRIs]) can also decrease libido [206] and delay ejaculation. The number of studies on the effects of CPPPS on sexual function is limited. Sexual dysfunction is often ignored because of a lack of standardised measurements. At present, the most commonly used tool is the IIEF questionnaire [145].
The presence of pelvic pain may increase the risk for ED independent of age [207]. On the other hand, cross-sectional data suggest no improvement of lower urinary tract symptoms (LUTS) by an increased frequency of ejaculation [208]. Although mental distress and impaired QoL related to illness could contribute to sexual dysfunction observed in patients with PPPS, the presence of erectile and ejaculatory disorders is more frequently related to symptoms suggestive of a more severe inflammatory condition [117]. These arguments are important for the understanding of the close relationship between CPPPS symptoms, disturbed sexuality, impact on QoL, and psychological implications including depression and more failure anticipation thoughts [107-109, 208-210]. Sexual dysfunction heightens anger, frustration and depression, all of which place a strain on the patients’ relationships. The female partners of men with sexual dysfunction and depression often present with similar symptoms including pain upon intercourse and depressive symptoms. Men with CPPPS have reported a high frequency of sexual relationship dissolution and psychological symptoms, such as depression and suicidal thinking [107, 211]. Primary Prostate Pain Syndrome patients reported substantial sexual and relationship problems [107, 211]. On the other hand, it was found that men with PPPS did not report significantly decreased sexual satisfaction compared to controls [212]. There is consensus that therapeutic strategies reducing symptoms of pelvic pain are of relevance in relation to changes in sexual function. Also intimacy and having sex can yield positive experiences that will reduce the pain. The CNS plays an important role in this mechanism.

Women
Chronic pelvic pain leads to substantial impairment in QoL and several sexual dysfunctions [119, 213-215]. It seems reasonable to expect that pain, extreme fatigue, depressive mood and pain drugs will affect women’s sexuality. Women with CPPPS reported significantly more pain, depression, and anxiety symptoms and were physically more impaired than women in the control group. In comparison with controls, women with CPPPS reported significantly more sexual avoidance behaviour, non-sensuality, and complaints of “vaginismus” [216]. Patients with CPPPS reported more sexual problems than women with any other type of chronic pain problem [217]. The quality of intimate relationships is closely connected with sexual function [218]. Satisfaction with sexual relationships appears to be associated with higher marital functioning [219]. In addition sexual dissatisfaction is related to sexual dysfunction. When one partner suffers from chronic pain, the ability of both partners to cope with the pain and the extent to which partners are supportive of the chronic pain sufferer have been found to be a predictor of sexual functioning [219].

Approximately two-thirds of patients in another study reported reduced frequency in their sexual relations as a result of CPPPS [220]. One study demonstrated that CPPPS patients reported worse sexual function with regard to desire, arousal, lubrication, orgasm, satisfaction, and more frequent and severe pain with vaginal penetration than women without CPPPS [221]. In an interview with 50 chronic pain sufferers and their spouses, 78% of the pain sufferers and 84% of partners described deterioration, including cessation of their sex life [222]. In a study in patients with back pain, half reported decreased frequency of sex since the onset of chronic pain [123]. The Female Sexual Function Index (FSFI) has been developed as a brief, multi-dimensional self-report instrument for assessing the key dimensions of sexual function in women, which includes desire, subjective arousal, lubrication, orgasm, satisfaction, and pain. Using the FSFI, women with CPPPS reported worse sexual function in all subscales and total score than women without CPPPS. The largest differences between women with CPPPS and without CPPPS, were seen for the domains of pain and arousal. The total score and the subscales of the FSFI had high levels of internal consistency and test-retest reliability when assessed in a sample of women with CPPPS. The FSFI also showed good ability to discriminate between women with and without CPPPS [221].

Myofascial pain
Myalgia is too often overlooked as a form of chronic pelvic pain. The pelvic floor and adjacent muscles are used in an abnormal way. Studies in the field of chronic prostatitis support the idea that patients with CPPPS have more muscle spasm and increased muscle tone and report pain when the pelvic floor muscles are palpated [223]. Learning pelvic floor muscle relaxation can diminish spasm and pain [224]. Repeated or chronic muscular overload can activate trigger points in the pelvic floor muscles. A report from the Chronic Prostatitis Cohort Study showed that 51% of patients with prostatitis and only 7% of controls had any muscle tenderness. Tenderness in the pelvic floor muscles was only found in the CPPPS group [128].

The first ideas about the neurological aspects of the pelvic floor muscles in relation to chronic pelvic pain were published in 1999. The possibility of CNS changes in the regulation of pelvic floor function was suggested as a mechanism for development of CPPPS. Of the patients presenting with pelvic pain, 88% had poor to absent pelvic floor muscle function [127]. Animal studies on the role of neurogenic inflammation have also elucidated some important phenomena. Irritation of the prostate, bladder and pelvic floor muscles results in expression
of C-fos-positive cells in the CNS. There appears to be convergence of afferent information onto central pathways. Once the central changes have become established, they become independent of the peripheral input that initiated them [225].

Repeated or chronic muscular overload can activate trigger points in the muscle. Trigger points are defined as hyper-irritable spots within a taut band. Other criteria for trigger points are recognition of the pain as ‘familiar’, and pain on stretching the muscle. Apart from pain point, trigger points prevent full lengthening of the muscle, thereby restricting the range of movement. Pain as a result of these trigger points is aggravated by specific movements and alleviated by certain positions. Positions and movements in which the shortened muscle is stretched are painful. Patients know which activities and postures influence pain. Trigger points can be located within the pelvic floor muscles and in adjacent muscles such as the abdominal, gluteal and iliopsoas muscles. Pain is aggravated by pressure on the trigger point (e.g., pain related to sexual intercourse). Pain also worsens after sustained or repeated contractions of pelvic floor muscles (e.g., pain related to voiding or defecation).

3.3 Abdominal aspects of pelvic pain

3.3.1 Incidence

Epidemiological data on IBS and CPPPS are scarce [226]. Chronic Pelvic Pain has been shown to be one of the most common functional disorders in women of reproductive age. The monthly incidence rate of CPPPS published by Zondervan et al. was 1.58/1000 [227].

3.3.2 Prevalence

Using a vague definition of continuous or episodic pain situated below the umbilicus over six months, one study reported that CPPPS was one of the most common diagnoses in primary care units in Great Britain [227]. The monthly prevalence rate of CPPPS in this study was 21.5/1,000, with an annual prevalence of 38.3/1,000. The prevalence rates increase significantly with older age and vary significantly between regions in the UK. The overall prevalence of anorectal pain in a sample of USA householders was 6.6% and was more common in women [228]. Irritable bowel syndrome is associated with common gynaecologic problems (endometriosis, dyspareunia, and dysmenorrhoea) [229]. Fifty per cent of women who presented with abdominal pain to the gynaecologic clinic or were scheduled for laparoscopy due to CPPPS had symptoms of IBS [230]. In a survey from Olmsted county, 20% of women reported CPPPS and 40% of those met the criteria for IBS [22]. This overlap of CPPPS and IBS was associated with an increased incidence of somatisation. Not gynaecological surgical procedures but only psychosocial variables predict pain development without a different incidence of IBS in a prospective and controlled study [231]. Clinical features of pelvic floor dysfunction, gynaecological and psychological features, are related to disordered anorectal function in IBS patients, but do not predict physiological anorectal testing.

3.3.3 Influence on Quality of Life

There is little known on health related quality of life (HRQoL) in patients with CPPPS. There is a need to develop validated disease specific HRQoL instruments for CPPPS in addition to sound measurement properties. More data are available in patients with IBS treated at referral centres who have comparable HRQoL scores as patients with other common disorders such as diabetes, end-stage renal disease, and inflammatory bowel disease [232]. Sub-groups of IBS with predominance of diarrhoea or constipation show no difference in HRQoL. Multi-variate analysis shows that HRQoL in patients with IBS is affected by sex and psychological conditions.

3.3.4 Costs

Costs combine direct health-care costs and societal costs (productivity loss) such as under-performance and absenteeism from work. The annual costs to society can be calculated by using the average population earnings. In Germany direct care costs are estimated at €791 and societal costs €995 per patient with IBS per year which may be comparable to patients with CPPPS [233].

3.3.5 Risk factors & underlying causes

Risk factors are covered in Section 3.1.5.

3.4 Summary of evidence and recommendations: CPPPS and mechanisms

<td>CPPPS mechanisms are well defined and involve mechanisms of neuropasticity and neuropathic pain.</td>
<td>2</td>
</tr>
<tr>
<td>The mechanisms of neuropasticity and neuropathic pain result in increased perception of afferent stimuli which may produce abnormal sensations as well as pain.</td>
<td>1</td>
</tr>
</tbody>
</table>
End-organ function can also be altered by the mechanisms of neuroplasticity so that symptoms of function can also occur.

The diagnosis of a CPPPS as a pain syndrome is essential as it encourages a holistic approach to management with multi-specialty and multi-disciplinary care.

4. DIAGNOSTIC EVALUATION

4.1 General evaluation

4.1.1 History

History is very important for the evaluation of patients with chronic pelvic pain. Pain syndromes are symptomatic diagnoses, which are derived from a history of pain perceived in the region of the pelvis, and absence of other pathology, for a minimum of three months. This implies that specific disease-associated pelvic pain caused by bacterial infection, cancer, drug-induced pathology (e.g., ketamine use) [234], primary anatomical or functional disease of the pelvic organs, and neurogenic disease must be ruled out.

4.1.1.1 Anxiety, depression, and overall function

Distress is best understood in the context of pain and of the meaning of pain to the individual and is best assessed ideographically rather than normatively. Almost all diagnostic measures and standardised instruments of anxiety and depression are designed for people without significant physical problems, so are difficult to interpret in chronic pelvic pain [235].

Anxiety about pain often refers to fears of missed pathology (particularly cancer) as the cause of pain [34], or to uncertainties about treatment and prognosis. These can drive healthcare seeking behaviour. The question: “What do you believe or fear is the cause of your pain?” has been suggested [236]. Anxiety may also concern urinary urgency and frequency that are problematic in social settings.

Depression or depressed moods are common in chronic pain [237], often related to losses consequent to chronic pain (work, leisure activities, social relationships, etc.). Due to the lack of suitable assessment instruments, it is better to ask a simple question such as “How does the pain affect you emotionally?” If the answer gives cause for concern about the patient’s emotional state, further assessment should be undertaken by an appropriately qualified colleague.

Most measures of restricted function are designed primarily for musculoskeletal pain and may emphasise mobility problems rather than the difficulties of the individual with pelvic or urogenital pain. A promising specific measure, UPOINT, was introduced and in a later version the sexological aspects were added [238]. However, it may underassess relevant psychological variables [43]. Generic QoL measures are helpful. If such an instrument is not already used in the clinic, the Brief Pain Inventory [239] provides a broad and economical assessment of interference of pain with various aspects of life, and is available in multiple languages. (For further suggested instruments see [240]).

4.1.1.2 Urological aspects

Pain may be associated with urological symptoms. A detailed history of LUT functions should be taken. Dysfunctions of the LUT may exacerbate symptoms, as pain may interfere with the function of the LUT. Micturition in all its aspects should be addressed. Special attention should be paid to the influence of micturition on the experience of pain.
Primary prostate pain syndrome

Primary prostate pain syndrome is diagnosed from a history of pain perceived in the region of the prostate (convincingly reproduced by prostate palpation), and absence of other LUT pathology, for a minimum of three months. As mentioned above, specific disease-associated pelvic pain must be ruled out. A thorough history is an important first step in the evaluation of PPPS. It should include type of pain and localisation. Pain is often reported in other pelvic areas outside the prostate such as perineum, rectum, penis, testicles and abdomen [49]. In addition, associated LUT symptoms, sexual function, psychological, social and economic factors should be addressed. Determination of the severity of disease, its progression and treatment response can be assessed only by means of a validated symptom-scoring instrument (see Section 4.2.3). These subjective outcome measures are recommended for the basic evaluation and therapeutic monitoring of patients in urological practice.

Primary bladder pain syndrome

Primary bladder pain syndrome should be diagnosed on the basis of pain, pressure or discomfort associated with the urinary bladder, accompanied by at least one other symptom, such as daytime and/or night-time increased urinary frequency, the exclusion of confusable diseases as the cause of symptoms, and if indicated, cystoscopy with hydrodistension and biopsy (Table 4) [16].

The nature of pain is key to disease definition:
1. pain, pressure or discomfort perceived to be related to the bladder, increasing with increasing bladder content;
2. located suprapublically, sometimes radiating to the groins, vagina, rectum or sacrum;
3. relieved by voiding but soon returns [241, 242];
4. aggravated by food or drink [242].

Primary bladder pain syndrome type 3 can lead to a small capacity fibrotic bladder with or without upper urinary tract outflow obstruction.

4.1.1.3 Gynaecological aspects

A detailed medical history outlining the nature, frequency and site of pain; its relationship to precipitating factors and the menstrual cycle, may help define the aetiology. A menstrual and sexual history, including a history of sexually transmitted diseases, vaginal discharge, as well as previous sexual trauma is mandatory as well as up to date cervical cancer screening. A history of obstetric and/or gynaecological surgery is also warranted, particularly if devices such as synthetic mesh were used.

4.1.1.4 Gastrointestinal aspects

The predominant symptoms that patients are interviewed about are discomfort or pain in relation to their bowel habits, daily activities, and eating. A precise history of dysfunctional voiding or defecation should be asked, ideally applying symptom questionnaires for urinary and anorectal symptoms (e.g., Rome III criteria for anorectal pain). Excessive straining at most defecations, anal digitations in dyssynergic defecation, and a sensation of anal blockage may be found in patients with chronic anal pain. History of anxiety and depression with impaired QoL is often encountered in anorectal functional disorders and should be evaluated.

Diagnostic criteria for primary chronic anal pain syndrome (chronic proctalgia) according to the Rome III criteria are as follows and must include all of the following: chronic or recurrent rectal pain or aching, episodes last at least twenty minutes and exclusion of other causes of rectal pain such as ischaemia, inflammatory bowel disease, cryptitis, intramuscular abscess and fissure, haemorrhoids, prostatitis, and Coccyx Pain Syndrome. These criteria should be fulfilled for the past three months with symptom onset at least six months before diagnosis [243, 244].

The primary chronic anal pain syndrome includes the above diagnostic criteria and exhibits exquisite tenderness during posterior traction on the puborectalis muscle (previously called “Levator Ani Syndrome”). Pathophysiology of pain is thought to be due to over-activity of the pelvic floor muscles.

Primary intermittent chronic anal pain syndrome (proctalgia fugax) consists of all the following diagnostic criteria, which should be fulfilled for three months: recurrent episodes of pain localised to the anus or lower rectum, episodes last from several seconds to minutes and there is no anorectal pain between episodes. Stressful life events or anxiety may precede the onset of the intermittent chronic anal pain syndrome. The attacks may last from a few seconds to as long as 30 minutes. The pain may be cramping, aching or stabbing and may become unbearable. However, most patients do not report it to their physicians and pain attacks occur less than five times a year in 51% of patients.

CHRONIC PELVIC PAIN - LIMITED UPDATE MARCH 2022 29
4.1.1.5 Peripheral nerve aspects
A proportion of patients will be able to relate the onset of pain to an acute event such as surgery, sepsis or trauma, and occasionally, cycling for a prolonged period. Chronic injury is more frequent, such as associated with sitting for prolonged periods over time. Many will be idiopathic.

The pain is classically perceived in the perineum from anus to clitoris/penis. However, less-specific pain distribution may occur, and this may be due to anatomical variation, involvement of branches of the nerve rather that the main nerve, CNS central sensitisation, and consequently, the involvement of other organs and systems in a regional pain syndrome. Other nerves in the vicinity may also be involved, for example, inferior cluneal nerve and perineal branches of the posterior femoral cutaneous nerve. The musculoskeletal system may become involved, confusing the pain picture as aches and pain developing in the muscles due to immobility and disability, possibly magnified by the CNS changes.

Burning is the most predominant adjective used to describe the pain. Crushing and electric may also be used, indicating the two components - a constant pain often associated with acute sharp episodes. Many patients may have the feeling of a swelling or foreign body in the rectum or perineum, often described as a golf or tennis ball. The term pain has different meanings to patients and some would rather use the term discomfort or numbness.

Aggravating factors include any type of pressure being applied, either directly to the nerve or indirectly to other tissue, resulting in pudendal traction. Allodynia is pain on light touch due to involvement of the CNS, and may make sexual contact and the wearing of clothes difficult. These patients often remain standing, and as a consequence, develop a wide range of other aches and pains. Soft seats are often less well-tolerated, whereas sitting on a toilet seat is said to be much better tolerated. If unilateral, sitting on one buttock is common. The pain may be exacerbated by bowel or bladder evacuation.

Pudendal nerve damage may be associated with a range of sensory phenomena. In the distribution of the nerve itself, as well as unprovoked pain; the patient may have paraesthesia (pins and needles); dysaesthesia (unpleasant sensory perceptions usually but not necessarily secondary to provocation, such as the sensation of running cold water); allodynia (pain on light touch); or hyperalgesia (increased pain perception following a painful stimulus, including hot and cold stimuli). Similar sensory abnormalities may be found outside of the area innervated by the damaged nerve, particularly for visceral and striated muscle hyperalgesia.

The cutaneous sensory dysfunction may be associated with superficial dyspareunia, but also irritation and pain associated with clothes brushing the skin. There may also be a lack of sensation and pain may occur in the presence of numbness. Visceral hypersensitivity may result in an urge to defecate or urinate. This is usually associated with voiding frequency, with small amounts of urine being passed. Pain on visceral filling may occur. Anal pain and loss of motor control may result in poor bowel activity, with constipation and/or incontinence. Ejaculation and orgasm may also be painful or reduced.

Many of those suffering from pudendal neuralgia complain of fatigue and generalised muscle cramps, weakness and pain. Being unable to sit is a major disability, and over time, patients struggle to stand and they often become bedbound. The immobility produces generalised muscle wasting, and minimal activity hurts. As a consequence of the widespread pain and disability, patients often have emotional problems, and in particular, depression. Patients with chronic pelvic pain are also often anxious and have the tendency to catastrophise. Depression, catastrophising and disability are all poor prognostic markers. Cutaneous colour may change due to changes in innervation but also because of neurogenic oedema. The patient may describe the area as swollen due to this oedema, but also due to the lack of afferent perception.

4.1.1.6 Myofascial aspects
When taking a history from a patient with pelvic pain, it is important to address the function of all the organs in the pelvic area. The following items certainly should be addressed: lower urinary tract function, anorectal function, sexual function, gynaecological items, presence of pain and psychosocial aspects. One cannot state that there is a pelvic floor dysfunction based only on the history. But there is a suspicion of pelvic floor muscle dysfunction when two or more pelvic organs show dysfunction, for instance a combination of micturition and defecation problems.

4.1.2 Physical Evaluation
The clinical examination often serves to confirm or refute the initial impressions gained from a good history. The examination should be aimed at specific questions where the outcome of the examination may change
management. Prior to an examination, best practice requires the medical practitioner to explain what will happen and what the aims of the examination are to the patient. Consent to the examination should occur during that discussion and should cover an explanation around the aim to maintain modesty as appropriate and, if necessary, why there is a need for rectal and/or vaginal examination. Finally, the risk of exacerbating the pain should form a part of that request. A record of the discussion should be noted. The possibility of the presence of a chaperone should be discussed with the patient. As well as a local examination, a general musculoskeletal and neurological examination should be considered an integral part of the assessment and undertaken. Following the examination, it is good practice to ask the patient if they had any concerns relating to the conduct of the examination and that discussion should be noted.

There is no specific diagnostic test for CPPPS, therefore, procedures are on the one hand directed towards identification and exclusion of specific diseases associated with pelvic pain, and on the other hand may be used for phenotypic description. Abdominal and pelvic examination to exclude gross pelvic pathology, as well as to demonstrate the site of tenderness is essential. It is important to look for abnormalities in muscle function.

Examination of the external genitalia is a part of the evaluation. In patients with scrotal pain, gentle palpation of each component of the scrotum is performed to search for masses and painful spots. The penis and urethra may be palpated in a similar way. Many authors recommend that one should assess cutaneous allodynia along the dermatomes of the abdomen (T11-L1) and the perineum (S3), and the degree of tenderness should be recorded. The bulbocavernosus reflex in the male may also provide useful information concerning the intactness of the pudendal nerves. Clinical pelvic examination should be a single digit examination if possible. The usual bi-manual examination can generate severe pain so the examiner must proceed with caution. A rectal examination is done to look for prostate abnormalities in male patients including pain on palpation and to examine the rectum and the pelvic floor muscles regarding muscle tenderness and trigger points as well as the ability to contract and relax these muscles.

At clinical examination, perianal dermatitis may be found as a sign of faecal incontinence or diarrhoea. Fissures may be easily overlooked and should be searched for thoroughly in patients with an anal pain. A rectal digital examination findings may show high or low anal sphincter resting pressure, a tender puborectalis muscle in patients with the Levator Ani Syndrome, and occasionally increased perineal descent. The tenderness during posterior traction on the puborectalis muscle differentiates between Levator Ani Syndrome and unspecified Functional Anorectal Pain and is used in most studies as the main inclusion criterion. Dyssynergic (paradoxical) contraction of the pelvic muscles when instructed to strain during defecation is a frequent finding in patients with pelvic pain. Attention should be paid to anal or rectal prolapse at straining, and ideally during combined rectal and vaginal examination to diagnose pelvic organ prolapse.

A full clinical examination of the musculo-skeletal, nervous and urogenital systems is necessary to aid in diagnosis of pudendal neuralgia, especially to detect signs indicating another pathology. Often, there is little to find in pudendal neuralgia and frequently findings are non-specific. The main pathognomonic features are the signs of nerve injury in the appropriate neurological distribution, for example, allodynia or numbness. Tenderness in response to pressure over the pudendal nerve may aid the clinical diagnosis. This may be elicited by per rectal or per vaginal examination and palpation in the region of the ischial spine and/or Alcock's canal. Muscle tenderness and the presence of trigger points in the muscles may confuse the picture. Trigger points may be present in a range of muscles, both within the pelvis (levator ani and obturator internus muscles) or externally (e.g., the piriformis, adductors, rectus abdominis or paraspinal muscles).

### 4.2 Supplemental evaluation

If history is suggestive of lower urinary tract, gynaecological, anorectal or other disease of known aetiology, diagnostic work-up should follow respective guidelines.

#### 4.2.1 Assessing pelvic pain and related symptoms

Determination of the severity of pain and associated symptoms, its progression and treatment response can be assessed only by means of a reliable and validated symptom-scoring instrument. These subjective outcome measures are recommended for the basic evaluation and therapeutic monitoring of patients. Pain should always be assessed at presentation and (see below) to identify progression and treatment response. As well as doing this in the clinic, the patient can keep a daily record (pain diary). This may need to include other relevant variables such as voiding, sexual activity, activity levels, or analgesic use.
Increased attention to patient reported outcomes gives prominence to patients' views on their disease and pain diaries, in patients' own environments, improve data quality.

Quality of life should also be measured because it can be very poor compared to other chronic diseases [245, 246]. In a study more pain, pain-contingent rest, and urinary symptoms were associated with greater disability (also measured by self-report), and pain was predicted by depression and by catastrophising (helplessness subscale) [57].

Where the primary outcome of treatment is pain relief, it is useful before starting treatment to agree a clinically useful level of relief [247]. The most reliable methods are:

- a five point verbal scale: none, mild, moderate, severe, very severe pain;
- a VAS score from one to ten;
- an eleven point numerical scale (as below).

<table>

<td></td>
<td></td>
<td></td>
<td></td>
<td></td>
<td></td>
<td></td>
<td></td>
<td></td>
<td>extreme pain</td>
</tr>
</tbody>
</table>

Pain assessment ratings are not independent of cognitive and emotional variables [56]. Target outcomes of pain severity, distress and disability co-vary only partly, and improvement in one does not necessarily imply improvement in the others. When the primary outcome is pain its meaning should be anchored in discussion of clinically important difference [247].

**Primary prostate pain syndrome**

Reliable, valid indices of symptoms and QoL are the NIH-CPSI [248] and the International Prostate Symptom Score (I-PSS) [249].

**Primary bladder pain syndrome**

Symptom scores may help to assess the patient and act as outcome measures. The O’Leary-Sant Symptom Index, also known as the Interstitial Cystitis Symptom Index (ICSI) was validated in a large study [250].

**Gastrointestinal questionnaire**

Functional ano rectal pain disorders (ano rectal pelvic pain) are defined and characterised by duration, frequency, and quality of pain. More complex questionnaires are used in the setting of IBS. The validated IBSSymptom Severity Scale (IBS-SSS) includes the broadest measurement of pain-related aspects [251, 252]. However, as different instruments measure different endpoints of chronic abdominal pain in IBS, a comparison of published studies is often impossible.

**Sexual function assessment**

In males the most frequent effects on sexual function are ED and premature ejaculation. These can be evaluated by proper questionnaires namely IIEF and PEDT (Premature Ejaculation Diagnostic Tool). In comparison with controls, women with chronic pelvic pain reported significantly more sexual avoidance behaviour, non-sensuality, and complaints of “vaginismus” [205]. The Female Sexual Function Index (FSFI) has been developed as a brief, multi-dimensional self-report instrument for assessing the key dimensions of sexual function in women, which includes desire, subjective arousal, lubrication, orgasm, satisfaction, and pain. The corresponding evidence in men is lacking.

4.2.2 **Focused myofascial evaluation**

Pelvic floor muscle testing can be done by the medical doctor but a consultation of the pelvic floor by a physiotherapist is a good alternative, but either should have had appropriate training in pelvic assessment. A vaginal or rectal examination is performed to assess the function of the pelvic floor muscles, according to the International Continence Society (ICS) report. This assessment has been tested and shows satisfactory validity and intra-observer reliability. It can therefore be considered suitable for use in clinical practice [253]. Rectal examination is a good way to test the pelvic floor function in men [254]. There is a growing number of reports on the use of ultrasound (US) in establishing the function of the pelvic floor muscles. The exact place in the diagnostic setting needs to be addressed in the future [255]. In a cohort study of 72 men with chronic pelvic pain, the relationship between the locations of the trigger point and the referred pain was examined. Ninety percent of the patients showed tenderness in the puborectalis muscle and 55% in the abdominal wall muscles. Of the patients in whom trigger points were found in the puborectalis, 93% reported pain in the penis and 57% in the suprapubic region. Patients with trigger points in the abdominal muscles reported pain in the penis
(74%), perineum (65%) and rectum (46%) [256]. In addition, a broad musculoskeletal (tender point) evaluation, including muscles outside the pelvis, helps to diagnose the myofascial pain aspects of the pelvic pain in phenotyping pelvic pain patients [257, 258].

4.2.3 **Neurological Injections**
An injection of local anaesthetic and steroid at the site of nerve injury may be diagnostic. Differential block of the pudendal nerve helps to provide information in relation to the site where the nerve may be trapped [259, 260]. Infiltration at the ischial spine requires the use of a nerve stimulator/locator. Both motor (anal contraction) and sensory endpoints may be noted. The anatomical target may be localised by fluoroscopy, computed tomography (CT) guidance, or the use of US. Ultrasound avoids any form of radiation, whereas CT guidance involves a significant amount of radiation. Currently, fluoroscopy is probably the imaging technique most frequently used because it is readily available to most anaesthetists that perform the block. Currently, infiltration of the pudendal nerve within Alcock’s canal is primarily undertaken with the use of CT. As well as injecting around the pudendal nerve, specific blocks of other nerves arising from the pelvis may be performed.

**Electrophysiological studies**
These may reveal signs of perineal denervation, increased pudendal nerve latency, or impaired bulbocavernosus reflex [196, 199, 261-263]. However, for an abnormality to be detected, significant nerve damage is probably necessary. Pain may be associated with limited nerve damage, therefore, these investigations are often normal.

4.2.4 **Imaging**
Ancillary studies should be performed according to appropriate guidelines for exclusion of diseases with known aetiology presenting with symptoms identical to those of CPPS. Once the latter diagnosis is established, studies can be useful to assess functional abnormalities and phenotype conditions such as PBPS, and primary chronic anal pain syndrome.

**Ultrasound**
Ultrasound has limited value but may reassure patients. However, over-investigating may be detrimental.

**MRI**
Magnetic resonance neurography has been increasingly used in specialised centres for the diagnosis of the location (proximal vs. peripheral) and degree (total vs. partial) of nerve injury in the peripheral nervous system, earlier and with higher specificity than conduction studies. This may show benefits for CPPPS in the coming years.

**MR defecating proctogram**
Magnetic resonance imaging in conjunction with MR defecography has become the most valuable imaging technique to assess anorectal function dynamically. Magnetic resonance imaging studies simultaneously outline the anatomy of the pelvic floor and visualise different structural and functional pathologies, by applying dynamic sequences after filling of the rectum with a viscous contrast medium (e.g., US gel). The following pathologies can be visualised: pelvic floor descent, an abnormal anorectal angle while squeezing and straining, rectal intussusception, rectocele, enterocele and cystocele. However, limitations of MR defecography are the left lateral position and the limited space for the patient, which may reduce the ability to strain and thereby reduce the sensitivity of the method, underestimating the size of entero- and rectoceles as well as the amount of intussusception.

**Functional neuroimaging**
Functional neuroimaging, functional magnetic resonance imaging (fMRI) is currently being re-evaluated as a research tool and some groups have raised issues around over interpretation [264]. With regards to pain, fMRI findings may represent a pain matrix or may represent non-specific threat processing [265]. Currently this panel cannot recommend fMRI as a clinical tool.

4.2.5 **Laboratory Tests**

**Microbiology tests**

**Primary prostate pain syndrome**
Laboratory diagnosis of prostatitis has been classically based on the four-glass test for bacterial localisation [266]. Besides sterile pre-massage urine (voided bladder urine-2), PPPS shows < 10³ cfu/mL of uropathogenic bacteria in expressed prostatic secretions and insignificant numbers of leukocytes or bacterial growth in
ejaculates. However, this test is too complex for use by practising urologists. Diagnostic efficiency may be enhanced cost-effectively by a simple screening procedure, that is, the two-glass test or pre-post-massage test (PPMT) [267, 268]. Overall, these tests help only a little in the diagnosis of PPPS, because 8% of patients with suggested PPPS have been found to have positive prostatic localisation cultures, similar to the percentage of asymptomatic men [269].

**Primary bladder pain syndrome**

Urine dipstick and urine culture (including culture for Tuberculosis if sterile pyuria) are recommended in all patients suspected of having PBPS. Urine cytology is also recommended in risk groups.

**Gynaecological aspects of chronic pelvic pain**

Vaginal and endocervical swabs to exclude infection are recommended. In specific cases, imaging may be required to help rule out a defined pathology such as sacral neuropathy in endometriosis [270].

### 4.2.6 Invasive tests

#### Anorectal pain

Anorectal manometry with sensory testing (pressure volume measurement: barostat) may be useful to diagnose dyssynergic defecation and hypersensitivity of the rectum which are typical for patients with CPPPS and IBS. Flexible rectosigmoidoscopy or colonoscopy should be considered in patients with anorectal pain to rule out coincidental colorectal pathology.

#### Laparoscopy for females

Laparoscopy is perhaps the most useful invasive investigation to exclude gynaecological pathology [271, 272] and to assist in the differential diagnosis of CPPPS in women [273, 274]. Often, it is combined with cystoscopy [275, 276] and/or proctoscopy to help identify the site of multi-compartment pain.

#### Psychological considerations around laparoscopy

Three very different studies of laparoscopy suggest that it can improve pain through resolving concerns about serious disease [277]. Integrating somatic and psychological assessment from the start rather than dealing with psychological concerns only after excluding organic causes of pelvic pain is helpful [278].

#### Cystoscopy and bladder biopsy

Despite controversy on the diagnostic and follow-up value of cystoscopy in PBPS [279-283], the panel believes that objective findings are important for diagnosis, prognosis and ruling out other treatable conditions (a standardised scheme of diagnostic criteria will also contribute to uniformity and comparability of different studies) [284]. Endoscopically, PBPS type 3 displays reddened mucosal areas often associated with small vessels radiating towards a central scar, sometimes covered by a small clot or fibrin deposit – the Hunner’s lesion [241]. The scar ruptures with increasing bladder distension, producing a characteristic waterfall type of bleeding. There is a strong association between PBPS type 3 and reduced bladder capacity under anaesthesia [285]. Non-lesion disease displays a normal bladder mucosa at initial cystoscopy. The development of glomerulations after hydrodistension is considered to be a positive diagnostic sign although they can be observed without PBPS [286]. Biopsies are helpful in establishing or supporting the clinical diagnosis of both classic and non-lesion types of the disease [139, 165, 284, 287, 288]. Important differential diagnoses to exclude, by histological examination, are carcinoma in situ and tuberculous cystitis.

4.4 Other painful conditions without a urological cause

**Dysmenorrhoea**
Menstrual pain or ‘dysmenorrhoea’ may be primary or secondary. Primary dysmenorrhoea classically begins at the onset of ovulatory menstrual cycles and tends to decrease following childbirth [273]. Secondary dysmenorrhoea suggests the development of a pathological process, such as endometriosis [272], adenomyosis or pelvic infection, which need to be excluded.

**Infection**
In pre-menopausal women, a history of Pelvic Inflammatory Disease (PID) must be excluded. A patient's sexual history should be taken along with swabs to exclude chlamydia and gonorrhoea infection. Bacterial and viral genital tract pathogens should also be excluded [289], as they can cause severe pelvic/vaginal/vulvar pain [290] and are associated with ulcerating lesions and inflammation, which may lead to urinary retention [291]. If there is any doubt about the diagnosis, laparoscopy may be helpful, as one of the differential diagnoses is endometriosis.

**Endometriosis and adenomyosis**
The incidence of endometriosis is rising in the developed world. It has widespread impact on women’s lives [292], with pain more important than physical findings in determining QoL [293]. The precise aetiology is unknown, but an association with infertility is recognised [294]. A diagnosis is usually made when a history of secondary dysmenorrhoea and/or dyspareunia exists [295]. On examination, there is often tenderness in the lateral vaginal fornices, reduced uterine mobility, tenderness in the recto-vaginal septum, and on occasion, adnexal masses. Laparoscopy is the most useful diagnostic tool [296-298]. Adenomyosis is associated with augmented pain during menses [299]. It is diagnosed by an US scan of the uterus, which often shows cystic dilatation of the myometrium [300].

**Gynaecological malignancy**
The spread of gynaecological malignancy of the cervix, uterine body or ovary will cause pelvic pain depending on the site of spread.

**Injuries related to childbirth**
Trauma occurring at the time of childbirth may lead to chronic pelvic pain related to the site of injury [298]. Female sexual dysfunction is perhaps the commonest presenting problem [301], though increasingly women are reporting other symptoms such as pelvic girdle pain and other genito-pelvic pain of different aetiology [302]. There is often a transient problem with oestrogen deficiency in the post-partum period and during breastfeeding, which can compound this situation. Denervation of the pelvic floor can similarly compound the situation [303].
Pain associated with pelvic organ prolapse and prolapse surgery
Pelvic organ prolapse is often asymptomatic, unless it is so marked that it causes back pain, vaginal pain and skin excoriation [304]. Prolapse is often a disease of older women, and it is often associated with postmenopausal oestrogen deficiency, which may lead to pain associated with intercourse. Prolapse surgery has entailed the use of non-absorbable mesh (usually in the form of “mesh kits”). Although they may have a role in supporting the vagina, they are also associated with several complications including bladder, bowel and vaginal trauma [305], chronic pain [306] and neuropathy [307]. Patients need to be fully evaluated and may need specialised imaging, using contrast mediums if necessary, to make a diagnosis of the possible cause of the pain [308-311].

Haemorrhoids
Chronic pelvic pain is rare in haemorrhoidal disease because endoscopic and surgical treatment is mostly effective in acute disease. The most frequent aetiology of pain without significant bleeding is thrombosed external haemorrhoids or an anal fissure. Haemorrhoidal pain on defecation associated with bleeding is usually due to prolapse or ulceration of internal haemorrhoids. Anaemia from haemorrhoidal bleeding is rare but may arise in patients on anti-coagulation therapy, or those with clotting disorders.

Anal fissure
Anal fissures are tears in the distal anal canal and induce pain during and after defecation. The pain can last for several minutes to hours. Persistence of symptoms beyond six weeks or visible transversal anal sphincter fibres define chronicity. Fissures located off the midline are often associated with specific diseases such as Crohn’s disease or anal cancer. Internal anal sphincter spasms and ischaemia are associated with chronic fissures.

Proctitis
Abdominal and pelvic pain in patients with inflammatory bowel disease and proctitis are often difficult to interpret. Faecal calprotectin may help to differentiate between inflammation and functional pain, to spare steroids.

Irritable bowel syndrome
Although IBS can be associated with pelvic pain, the panel consider a full discussion of this topic beyond the scope of these guidelines. A number of high quality clinical guidelines address this topic [243, 312].

5. MANAGEMENT

The philosophy for the management of chronic pelvic pain is based on a bio-psychosocial model. This is a holistic approach with patients’ active involvement. Single interventions rarely work in isolation and need to be considered within a broader personalised management strategy, including self-management. Pharmacological and non-pharmacological interventions should be considered with a clear understanding of the potential outcomes and endpoints. These may well include: psychology, physiotherapy, drugs and more invasive interventions.

**Treatment philosophy**

Providing information that is personalised and responsive to the patient’s problems, conveying belief and concern, is a powerful way to allay anxiety [313]. Additional written information or direction to reliable sources of information is useful; practitioners tend to rely on locally produced material or pharmaceutical products of variable quality while endorsing the need for independent materials for patients [314].

5.1  **Conservative management**

5.1.1  **Pain education**

It is always valuable to include education about the causes of pain, including eliciting from patients their anxieties about undiscovered pathology and addressing them. Information improves adherence to treatment and underpins self-management, as shown in bladder pain syndrome and in many other painful and non-painful disorders [319].

5.1.2  **Physical therapy**

The physiotherapist is part of the pain management team; (including doctors, psychologists and nurses). The therapeutic options for physiotherapists may not be the same in every country. Physiotherapists can either
specifically treat the pathology of the pelvic floor muscles, or more generally treat myofascial pain if it is part of the pelvic pain syndrome. In most studies that have been done looking at the effect of physiotherapy in pelvic pain, the treatment of the pelvic floor is only part of the pain management. In a review about physiotherapy in women with pelvic pain, it was concluded that recommendations for physiotherapy should be given with caution [316]. The review found six RCTs, of which three showed level 1b evidence with low-risk of bias. One of these three found that Mensendieck somatocognitive therapy showed a pain reduction after one year follow-up of 64%. This approach consists of myofascial relaxation and tension, improving posture and movement in combination with cognitive behaviour therapy (CBT) [317].

Pelvic floor muscle pain
Treating pelvic floor over-activity and myofascial trigger points should be considered in the management of chronic pelvic pain. Treatment should be done by specialised physiotherapists who are trained not only in the musculoskeletal aspects of pain, but also in the psychological mechanisms and the role of the CNS in chronic pain.

For patients with chronic pelvic pain and dysfunction of the pelvic floor muscles, it is very helpful to learn how to relax the muscles when the pain starts. By doing this, the circle of pain-spasm-pain can be interrupted. In the case of shortened muscles, relaxation alone is not enough. Stretching of the muscle is mandatory to regain length and function. Studies on physical therapy for pelvic floor pain syndrome have been sparse. A single blinded RCT with myofascial physical therapy and general body massage was carried out in patients with prostate or bladder pain. The global response rate (RR) to treatment with massage was significantly better in the prostate than in the bladder pain group (57% vs. 21%). In the prostate pain group, there was no difference between the two treatment arms. In the bladder pain group, myofascial treatment did significantly better than massage. Massage only improved complaints in the prostate pain group. The fact that gender distribution was different in each group is mentioned as a possible confounding factor [318].

Myofascial trigger point release
Treatment of myofascial trigger points can be done by manual therapy, dry needling and wet needling. The evidence for all the different treatments is weak, with most studies showing no significant difference between these techniques, though most studies were small and heterogeneous with regards to the patients and methods. There is no evidence that manual techniques are more effective than no treatment [319]. Most studies of dry needling have compared with wet needling. Different SRs have come to the conclusion that, although there is an effect of needling on pain, it is neither supported nor refuted that this effect is better than placebo [320].

Physiotherapy in PBPS
Transvaginal manual therapy of the pelvic floor musculature (Thiele massage) in PBPS patients with high-tone dysfunction of the pelvic floor significantly improved several assessment scales [321]. The role of specific levator ani trigger point injections in women with chronic pelvic pain has been studied [322]. Each trigger point was identified by intravaginal palpation and injected with bupivacaine, lidocaine and triamcinolone. Seventy-two percent of women improved with the first trigger point injection, with 33% being completely pain-free. Efficacy and safety of pelvic floor myofascial physical therapy has been compared with global therapeutic massage in women with PBPS; global response assessment (GRA) rate was 59% and 26%, respectively. Pain, urgency and frequency ratings, and symptoms decreased in both groups during follow-up, and did not differ significantly between the groups. This suggests that myofascial physical therapy is beneficial in women with PBPS [323].

Primary Anal Pain Syndrome
An RCT demonstrated that biofeedback treatment was superior to electrogalvanic stimulation and massage of the Levator muscle for treating chronic primary anal pain syndrome [125]. One hundred and fifty-seven patients who had at least weekly rectal pain were investigated, but only patients with tenderness on traction of the pelvic floor showed a significant treatment benefit. In patients with tenderness of the puborectalis muscle (Rome II: “Highly likely Levator Ani Syndrome”), 87% reported adequate relief after one month of biofeedback vs. 45% for electrogalvanic stimulation, and 22% for massage. These results were maintained at twelve months with adequate relief after nine sessions of biofeedback in 58% of the whole group (Rome II: “Highly likely” and “Possible Levator Ani Syndrome”), after galvanic stimulation in 27% and massage in 21% of patients. As previously described in dyssynergic defecation, the ability to expel a 50 mL water filled balloon and to relax pelvic floor muscles after biofeedback treatment were predictive of a favourable therapeutic outcome [125]. The pathophysiology of the chronic primary anal pain syndrome is therefore similar to that of dyssynergic defecation, and this favours the role of the pelvic floor muscles in the pathophysiology of both conditions. Other treatment modalities have been less successful.
Treatment of sexual dysfunctions and chronic pelvic pain

Couples often benefit from early referral for relationship and sexual counselling during their treatment course [324]. It needs to be remembered that sexual difficulties will arise as a result of pelvic pain syndromes as well as those disorders potentially being primary. Specific behavioural strategies for women who have urogenital complaints and female sexual dysfunction often include exploring alternatives to sexual intercourse (manual or oral pleasuring), different coital positions (female superior or side lying), and pacing, such as limiting the activity to less than that which causes pain. Planning for the time of intercourse is important, and scheduling a clinic visit after intercourse might be useful to identify specific sites and causes of post-coital flares. The corresponding evidence in men is lacking, but similar principles would apply. Other behavioural changes involve pre- and post-coital voiding, application of ice packs to the genital or suprapubic area [324, 325], and increased use of vaginal dilators, fingers or sex toys. Lubricants can also be used and women with signs of vulvovaginal atrophy may benefit from oestrogen cream [326]. Optimising the pelvic floor muscle is indicated when dysfunction is present and will relieve the pain [327-329].

Other physical therapy interventions

Electromagnetic therapy. A small, sham-controlled, double-blind study of four weeks showed a significant, sustained effect over a one-year period for CPPPS [330].

Microwave thermotherapy. In uncontrolled studies significant symptomatic improvement has been reported from heat therapy, for example, transrectal and transurethral thermotherapy [331, 332].

Extracorporeal shockwave therapy. A small sham-controlled double-blind study of four times weekly perineal extracorporeal shockwave therapy (n=30) in men with CPPPS showed significant improvement in pain, QoL, and voiding compared to the control group (n=30), over twelve weeks [333]. Two other randomised shamcontrolled studies, have been published more recently, one comparing ten treatment sessions over two weeks (n=40 vs. n=40) [334], another with four times weekly treatments (n=20 vs. n=20) [335]. Both concluded there was a significant effect in terms of total NIH-CPSI score and pain at twelve weeks. Unfortunately, no long term effects at 24 weeks could be shown in a published follow-up study of the second [336]. A Cochrane review of non-pharmacological interventions for chronic pelvic pain reported a reduction in symptoms following treatment compared with control and concluded that extracorporeal shockwave therapy may improve symptoms without an increase in adverse events [337]. In addition, a recent SR and meta-analysis concluded that extracorporeal shockwave therapy is effective for the improvement of pain and quality of life, but long-term efficacy was non-significant [338]. Recent publications show a potential role for external shock wave lithotripsy applied to the bladder. In a RCT enrolling 54 patients, improvement in the VAS > 3 was 57.1% vs. 19.0% (ESWT vs. placebo; P =.011), at 12 weeks post treatment. However, primary endpoint did not reach significance [339].

Acupuncture. In a small three-arm RCT of CPPPS in men, electro-acupuncture was superior to sham treatment and advice and exercise alone [340]. Another RCT comparing acupuncture (n=50) vs. sham-controlled (n=50), once weekly treatment for six weeks showed significant long lasting improvement at 24 weeks in terms of RR and overall symptom scores [341]. Another RCT showed a significant effect for a follow-up of 32 weeks [342]. Two SRs and meta-analyses were published in 2016 analysing seven RCTs on a total of 471 participants comparing acupuncture to sham control or oral medical treatment [343, 344]. Both came to the conclusion that acupuncture was effective and safe, significantly reducing total NIH-CPSI scores compared to sham or medical treatment, and should be considered as a treatment option. This is in line with the conclusion of a recent Cochrane review [337] on non-pharmacological treatment options. However, the durability of this effect is not known.

Posterior tibial nerve stimulation. See section 5.3.2, Neuromodulation.

Transcutaneous electrical nerve stimulation. See section 5.3.2, Neuromodulation.

5.1.3 Psychological therapy

Psychological interventions may be directed at pain itself or at adjustment to pain in terms of function and mood and reduced health-care use, with or without pain reduction. Ideally, treatment follows general principles and practice in the field of chronic pain [345, 346] but these have been neglected in pelvic pain. Two SRs and meta-analyses of the few heterogeneous trials of psychologically based treatment for pelvic pain [347, 348] found benefits for pain comparable to those from pharmacotherapy over a few months, but this was not sustained at follow-up. Exposure to pain-related fears in women with chronic pelvic pain proved superior to manual therapy in reducing those fears and overall pain disability, albeit assessed only by self-report [349]. The importance of multi-disciplinary treatment is emphasised by several reviews [43, 350, 351] of intervention for diverse chronic pains, but standard multi-component psychologically-based programmes for pelvic pains are mostly in the pilot stages [352], with mixed findings so far [353]. For less disabled and distressed patients treatment can be delivered remotely [354].
5.1.4 **Dietary treatment**
Scientific data are limited and dietary restriction alone does not produce significant symptomatic relief; however, consider the involvement of a dietician.

5.2 **Pharmacological management**

5.2.1 **Drugs for chronic primary pelvic pain syndrome**
In this section the evidence available for specific CPPPSs is presented. Where there is no evidence the reader is directed to the section on analgesics below (Section 5.2.2) where more generic use is discussed. There is a large discrepancy in the treatment effects reported in case series and controlled trials that results from a large placebo effect or publication bias. As a result of the multifactorial origin of for example PPPS, one reason for treatment failure in some large placebo-controlled RCTs, may be the heterogeneity of the patient population [355]. One strategy for improving treatment effects may be stratification of patient phenotypes. A prospective series of phenotypically directed treatment for CPPPS has shown significant improvement of symptoms and QoL [356]. Monotherapeutic strategies for the treatment of CPPPS may fail [357], therefore, most patients require multimodal treatment aimed at the main symptoms, and taking comorbidity into account. In the past ten years, results from RCTs have led to advances in standard and novel treatment options.

5.2.1.1 **Mechanisms of action**
Mechanisms of action are discussed as appropriate under the drugs headings below.

5.2.1.2 **Comparisons of agents used in pelvic pain syndromes**

**Primary Prostate Pain Syndrome (PPPS)**

**Anti-inflammatory drugs**

For non-steroidal anti-inflammatory agents (NSAIDs), a trial with celecoxib reported that the pain sub-score, QoL sub-score, and total NIH-CPSI score were in favour of the treatment arm vs. placebo, but effects were limited to the duration of therapy [358]. In a meta-analysis, two studies of NSAIDs [269, 358] and one with prednisolone [359] were pooled. Anti-inflammatory drugs were 80% more likely to have a favourable response than placebo. In an updated network meta-analysis with more restrictive inclusion criteria regarding documented outcome measures but a wider spectrum of drugs (including glycosaminoglycans, phytotherapy and tanezumab), a significant effect on total NIH-CPSI scores and treatment response rates could be demonstrated. Overall, a moderate treatment effect has been shown for anti-inflammatory drugs, but larger studies are needed for confirmation, and long-term side-effects have to be taken into account.

**α-blockers**

Positive results from RCTs of α-blockers, i.e. terazosin [360, 361], alfuzosin [362], doxazosin [363, 364], tamsulosin [365, 366], and silodosin [367] have led to widespread use of α-antagonists in the treatment of PPPS in recent years. Whereas one SR and meta-analysis has not reported a relevant effect of α-blockers due to study heterogeneity [368], another network meta-analysis of α-blockers [367] has shown significant improvement in total symptoms, pain, voiding, and QoL scores. In addition, they had a higher rate of favourable response compared to placebo [relative risk (RR): 1.4; 95% CI: 1.1-1.8, p=0.013]. However, treatment responsiveness, i.e., clinically perceptive or significant improvement, may be lower than expected from the change in mean symptom scores. Overall, α-blockers seem to have moderate but significant beneficial effects. This probably is not the case for long-standing PPPS patients [369]. Future studies should show if longer duration of therapy or some sort of phenotypically directed (e.g., patients with PPPS and relevant voiding dysfunction) treatment strategies will improve treatment outcomes.

**Antibiotic therapy**

Empirical antibiotic therapy is widely used because some patients have improved with antimicrobial therapy. Patients responding to antibiotics should be maintained on medication for four to six weeks or even longer. Unfortunately, culture, leukocyte and antibody status of prostate-specific specimens do not predict antibiotic response in patients with PPS [370], and prostate biopsy culture findings do not differ from those of healthy controls [371]. The only placebo-controlled RCTs of sufficient quality have been done for oral antibiotic treatment with ciprofloxacin (six weeks) [372], levofloxacin (six weeks) [373], and tetracycline hydrochloride (twelve weeks) [374]. The studies have been analysed in meta-analyses [367, 375]. Although direct meta-analysis has not shown significant differences in outcome measures, network meta-analysis has suggested significant effects in decreasing total symptom, pain, voiding, and QoL scores compared with placebo. Combination therapy of antibiotics with α-blockers has shown even better outcomes in network meta-analysis.
Despite significant improvement in symptom scores, antibiotic therapy did not lead to statistically significant higher response rates [375]. In addition, the sample sizes of the studies were relatively small and treatment effects only modest, mostly below clinical significance. It may be speculated that patients profiting from treatment had some unrecognised uropathogens. If antibiotics are used, other therapeutic options should be offered after one unsuccessful course of a quinolone or tetracycline antibiotic over six weeks. In addition, it is very important that unnecessary antibiotic use is avoided and local resistance patterns are considered. In this regard, the relevant recommendations of the EAU Guidelines on Urological Infections should be followed [376].

5-α-reductase inhibitors

Although a few small pilot studies with 5-α-reductase inhibitors supported the view that finasteride may improve voiding and pain, the first RCT published in a peer-reviewed journal did not support this, although the study lacked power [377]. In another RCT, finasteride provided better amelioration of symptoms compared to saw palmetto over a one-year period, but lacked a placebo-control arm [378]. A six-month placebo-controlled study showed a non-significant tendency towards better outcome in favour of finasteride, possibly because of a lack of statistical power [366]. The NIH-CPSI scores decreased significantly in a subgroup of men enrolled in a prostate cancer risk reduction study treated with dutasteride compared to placebo [367]. Patients (n=427, age 50 to 75, with elevated prostate-specific antigen [PSA]) were included if they had significant “prostatitis-like” symptoms at baseline. Based on the evidence, 5-α-reductase inhibitors cannot be recommended for use in PPPS in general, but symptom scores may be reduced in a restricted group of older men with an elevated PSA [367].

Phytotherapy

Phytotherapy applies scientific research to the practice of herbal medicine. An adequately powered placebo-controlled RCT of a pollen extract (Cernilton) showed clinically significant symptom improvement over a twelve week period in inflammatory PPPS patients (NIH Cat. IIIA) [379]. The effect was mainly based on a significant effect on pain. Another pollen extract (DEPROX 500) has been shown to significantly improve total symptoms, pain and QoL compared to ibuprofen [380]. In an RCT of patients treated with pollen extract suppositories (n=70) vs. oral ibuprofen (n=71) over a period of ten days, the authors could find a clinically significant effect up to six months of follow-up including fewer adverse events in the pollen extract group [381]. A SR and meta-analysis of pollen extract for the treatment of PPPS showed significant improvement in overall QoL [382]. Quercetin, a polyphenolic bioflavonoid with documented antioxidant and anti-inflammatory properties, improved NIH-CPSI scores significantly in a small RCT [383]. In contrast, treatment with saw palmetto, most commonly used for “benign prostatic hyperplasia”, did not improve symptoms over a one-year period [378]. In a SR and meta-analysis, patients treated with phytotherapy were found to have significantly lower pain scores than those treated with placebo [367]. In addition, overall RR in network meta-analysis was in favour of phytotherapy (RR: 1.6; 95% CI: 1.1-1.6).

Pregabalin is an anti-epileptic drug that has been approved for use in neuropathic pain. In an adequately powered placebo-controlled RCT, which was the only report included in a published Cochrane review [384], a six-week course of pregabalin (n=218) compared to placebo (n=106) did not result in a significant reduction of NIH-CPSI total score [385].

Pentosane polysulphate is a semi-synthetic drug manufactured from beech-wood hemicellulose. One study using oral high-dose (3 x 300 mg/day) demonstrated a significant improvement in clinical global assessment and QoL over placebo in men with PPPS, suggesting a possible common aetiology [386].

Muscle relaxants (diazepam, baclofen) are claimed to be helpful in sphincter dysfunction or pelvic floor/perineal muscle spasm, but there have been few prospective clinical trials to support these claims. In one RCT, a triple combination of a muscle relaxant (thiocholchicoside), an anti-inflammatory drug (ibuprofen) and an α-blocker (doxazosin) was effective in treatment-naïve patients, but not superior to an α-blocker alone [364].

Botulinum toxin type A (BTX-A) for the treatment of CPPPS is an off-label use, but a recent SR identified two RCTs and one non-randomised comparative study assessing intraprostatic BTX-A injections (100-200 units) for treatment of PPPS [387]. All three papers used the NIH-CPSI to score pain. Although two of the studies reported a statistically significant reduction in pain, incomplete data and differences in dose and study methodology precluded calculation of a summary effect estimate for BTX-A-related improvement in pain. No definitive conclusions could be drawn from the review.
Zafirlukast, a leukotriene antagonist, and prednisone in two low-power placebo-controlled studies failed to show a benefit [359, 388]. More recently, a placebo-controlled phase Ila study of tanezumab, a humanised monoclonal antibody that specifically inhibits the pain mediating neurotrophin, nerve growth factor, failed to demonstrate significant effect [389] and should only be used in clinical trials.

Allopurinol
There is insufficient evidence for the use of allopurinol in PPPS [390, 391].

Primary Bladder Pain Syndrome (PBPS)

Treatments of significant value for PBPS

Anti-histamines
Mast cells may play a role in PBPS. Histamine is one of the substances released by mast cells. Histamine receptor antagonists have been used to block the H1 [392] and H2 [393] receptor subtypes, with variable results. A prospective placebo-controlled RCT of hydroxyzine or oral pentosane polysulphate did not show a significant effect [394].

Amitriptyline
Amitriptyline is a tricyclic antidepressant. Several reports have indicated improvement of PBPS symptoms after oral amitriptyline [395]. Amitriptyline has been shown to be beneficial when compared with placebo plus behavioural modification [396]. Drowsiness is a limiting factor with amitriptyline, nortriptyline is sometimes considered instead.

Pentosane polysulphate
Pentosan polysulphate is a semi-synthetic drug manufactured from beech-wood hemicellulose. Subjective improvement of pain, urgency, frequency, but not nocturia, has been reported [397, 398]. Pentosane polysulphate had a more favourable effect in PBPS type 3 C than in non-lesion disease [399]. Response was not dose dependent but related more to treatment duration. At 32 weeks, about half the patients responded. Combination therapy showed a RR of 40% compared to 13% with placebo. For patients with an initial minor response to pentosane polysulphate, additional subcutaneous heparin was helpful [400, 401].

Immunosuppressants
Azathioprine treatment has resulted in disappearance of pain and urinary frequency [402]. Initial evaluation of cyclosporin A (CyA) [403] and methotrexate [404] showed good analgesic effect but limited efficacy for urgency and frequency. Corticosteroids are not recommended in the management of patients with PBPS because of a lack of evidence.

Intravesical Treatments
Intravesical drugs are administered due to poor oral bio-availability establishing high drug concentrations within the bladder, with few systemic side-effects. Disadvantages include the need for intermittent catheterisation which can be painful in PBPS patients, cost and risk of infection [405].

- Local anaesthetics
There are sporadic reports of successful treatment of PBPS with intravesical lidocaine [406, 407]. Alkalisation of lidocaine improves its pharmacokinetics [408]. Combination of heparin, lidocaine and sodium bicarbonate gave immediate symptom relief in 94% of patients and sustained relief after two weeks in 80% [409]. Intravesical instillation of alkalised lidocaine or placebo for five consecutive days resulted in significantly sustained symptom relief for up to one month [410].

- Hyaluronic acid and chondroitin sulphate
These are described to repair defects in the GAG layer. Despite the fact that intravesical GAG replenishment has been in use for about twenty years for PBPS/IC, most of the studies are uncontrolled and with a small number of patients. Based on the studies available there are differences by virtue of substance classes, whether they are natural GAG layer components, dosage formulations, or concentrations. A recent RCT seems to reinforce the case for GAG layer replenishment, however it lacks a placebo arm [411]. A meta-analysis confirms usefulness of GAG layer replenishment. However most retrieved studies are non-randomised and with scarce numbers [412].
• **Intravesical heparin**
  Primary bladder pain syndrome patients were treated with heparin for three months, and over half had control of symptoms, with continued improvement after one year of therapy [413]. Kuo reported another trial of intravesical heparin for three months in women with frequency-urgency syndrome and a positive potassium test. Symptomatic improvement was reported in 80% of PBPS patients [414]. Intravesical heparin plus peripheral neuromodulation in patients with refractory PBPS was studied and it was shown that voiding frequency, pain score and maximum cystometric capacity were significantly better after two and twelve months [415].

• **Hyperbaric oxygen**
  This has a moderate effect on a small subgroup of PBPS patients. Disadvantages include high cost, limited availability of treatment sites, and time-consuming treatment [400].

### Treatments of limited value for PBPS

**Cimetidine**
There are limited data to suggest that cimetidine improves symptoms of PBPS in the short-term. Compared with placebo for three months, cimetidine significantly improved symptom scores, pain and nocturia, although the bladder mucosa showed no histological changes in either group [416].

**Prostaglandins**
Misoprostol is a prostaglandin that regulates various immunological cascades. After three months of treatment with misoprostol, fourteen out of 25 patients had significantly improved, with twelve showing a sustained response after a further six months [417]. The incidence of adverse drug effects was 64%.

**L-Arginine**
Oral treatment with the nitric oxide (NO) synthase substrate L-arginine decreases PBPS-related symptoms [418, 419]. Nitric oxide is elevated in patients with PBPS [420]. However, others have not demonstrated symptomatic relief or changes in NO production after treatment [421, 422].

**Oxybutynin** is an anti-cholinergic drug used in overactive detrusor dysfunction. Intravesical oxybutynin combined with bladder training improves functional bladder capacity, volume at first sensation, and cystometric bladder capacity [423]. However, an effect on pain has not been reported.

**Duloxetine** (a serotonin-noradrenaline re-uptake inhibitor antidepressant with a licence for the management of neuropathic pain) did not significantly improve symptoms of PBPS [424]. Administration was safe, but tolerability was poor due to nausea. Based on these preliminary data, duloxetine cannot be recommended for treatment of PBPS.

### Primary Scrotal Pain Syndrome (PSPS)
  Treatment of primary scrotal pain syndrome is based on the principles of treating chronic pain syndromes, as described throughout these guidelines.

In men with pain post inguinal hernia repair, there is limited evidence from case series showing that neurectomy of the damaged nerves can lead to symptomatic benefit [192, 425].

For scrotal pain post vasectomy, affected men may find that reversal of vasectomy can cure symptoms especially in those in whom patency is achieved [426]. In a prospective RCT, pulsed radio-frequency to the ilioinguinal and genitofemoral nerves is associated with high rates of symptomatic improvement (80%) but follow up was limited to three months [427]. The evidence for epididymectomy is poor but if considered, is less likely to provide benefit if the epididymis has a normal sonographic appearance [428].

### Chronic gynaecological pain
  It is difficult to compare the wide variation of drugs from an efficacy and safety perspective as they have such diverse uses/indications. In those gynaecological patients where chronic pelvic pain is unrelated to any of the well-defined conditions, it is often difficult to determine a therapeutic pathway other than a multi-disciplinary chronic abdomino-pelvic pain management plan. A Cochrane review suggests there may be some evidence (moderate) supporting the use of progestogens [347]. Though efficacious, physicians need to be knowledgeable of progestogenic side effects (e.g., weight gain, bloatedness - the most common adverse effects) which can stop some patients from accepting such medication. Gonadotropin-releasing hormone
(GnRH), such as goserelin, are also thought to help such pain. However, when compared with progestogens, their efficacy remains limited. The quality of evidence is generally low and drawn from single studies [347]. Gonadotropin-releasing hormone on the other hand binds to specific receptors on pituitary gonadotrophs, leading to desensitisation and consequently to suppressed gonadotropin secretion. By contrast, GnRH antagonists compete with GnRH for receptors thus gonadotrophin secretion, which may be beneficial in certain clinical applications, such as reducing the size of fibroids, endometrial bleeding and endometriosis [429].

**Pelvic Floor, Abdominal and Chronic Anal Pain**

**Botulinum toxin type A (pelvic floor)**

Pelvic floor muscle over-activity plays a role in CPPPS. Botulinum toxin type A, as a muscle relaxant, can be used to reduce the resting pressure of the pelvic floor muscles and injection of the puborectalis and pubococcygeus muscles has been used to treat spasm of the levator ani A pilot study of 12 women with pelvic floor muscle overactivity as defined by a vaginal resting pressure > 40 cm H₂O on vaginal manometry reported a reduction in resting pressure with improvement in dyspareunia and dysmenorrhoea, but no significant changes in non-menstrual pelvic pain scores [430]. A recent SR including three RCTs comparing BTX-A with saline injections into the pelvic floor found no benefit in pain scores at six months follow-up despite a reduction in pelvic floor pressure [387].

Botulinum toxin type A has been injected into trigger points. It is more expensive than lidocaine and has not been proven to be more effective [431]. Reviews do not support the injection of BTX-A into trigger points [432].

Botulinum toxin type A can also be injected at the sphincter level to improve urination or defecation. Relaxation of the urethral sphincter alleviates bladder problems and secondarily the spasm. In a cohort study of thirteen patients with CPPPS, BTX-A was injected into the external urethral sphincter. Subjectively, eleven patients reported a substantial change in pain symptoms, from a score of 7.2 to 1.6 on a VAS [433].

**Intermittent chronic primary anal pain syndrome**

Due to the short duration of the episodes, medical treatment and prevention is often not feasible. Inhaled β₂ adrenergic agonist salbutamol was effective in an RCT in patients with frequent symptoms and shortened pain duration [434]. Other treatment options are topic diltiazem and BTX-A [435]. However, there is still some controversy regarding the duration of pain of intermittent chronic and chronic primary anal pain syndrome. Randomised controlled trials often use different definitions, extending the pain duration (with a shift to chronic pain) in order to include more patients and to better evaluate the study-drug action.

**Abdominal pain associated with Irritable Bowel Syndrome**

Linaclotide, a minimally absorbed peptide guanylate cyclase-C agonist at a dose of 290 μg once daily significantly improved abdominal pain (48.9% vs. 34.5% placebo-treated) and bowel symptoms associated with IBS with constipation over 26 weeks of treatment [436]. Diarrhoea was the most common adverse event in patients treated with linaclotide (4.5%). Although it is known to overlap with IBS pelvic pain, effect on the latter was not assessed in this study.

Delta-9-tetrahydrocannabinol (THC) shows only equivocal evidence of analgesic effects in chronic primary abdominal pain. In a recently published phase II trial, no difference was found between THC tablet and a placebo tablet in reducing pain outcome in patients with chronic abdominal pain [437].

5.2.2 **Analgesics**

If the use of simple analgesics fails to provide adequate benefit, then consider using neuropathic agents, and if there is no improvement, consider involving a specialist pain management centre with an interest in pelvic pain. Chronic pelvic pain is well defined and involves multiple mechanisms as described in previous sections.

The management requires a holistic approach with biological, psychological and social components. Few studies have specifically looked at medications used in CPPPS [438], therefore, a wider look at the literature has been undertaken and further specific research is required. The agents concerned are divided for ease of description. Combinations often provide a greater benefit than individual agents [439]. They may also allow lower individual dosages and thus minimise side-effects. The aim of using these drugs is to allow patients to improve their QoL. This is best measured by assessing their function as well as pain severity. If the use of these agents does not allow this, then they should be withdrawn. Unfortunately, the failure of one agent does not exclude potential benefit of an alternative. If the benefit is limited by side-effects, then the lowest effective dose should be found (by dose titration). Sometimes, patients will prefer a higher level of pain and have fewer side-effects.
5.2.2.1  Mechanisms of action
Mechanisms of action are discussed as appropriate under the drug headings below.

5.2.2.2  Comparisons within and between groups in terms of efficacy and safety

Paracetamol (acetaminophen)
Paracetamol is a well-tolerated analgesic in a class of its own. This is an antipyretic analgesic with a central mechanism of action [440]. It is often available over the counter without prescription. A review questions its routine use as a first-line analgesic based on inadequate evidence of efficacy in many pain conditions including dysmenorrhoea [441]. It will not be effective for all patients and individual responses should be reviewed when deciding on longer term use.

Non-steroidal anti-inflammatory agents
These agents are anti-inflammatory, antipyretic analgesics that act by inhibiting the enzyme cyclooxygenase (COX). They have a peripheral effect, hence their use in conditions involving peripheral or inflammatory mechanisms. They are commonly used for pelvic pain; many are available over the counter and are usually well-tolerated. There is insufficient evidence to suggest one NSAID over another for pelvic pain. Guidelines for use of NSAIDs and COX-2 selective agents have been developed. They have more side-effects than paracetamol, including indigestion, headaches and drowsiness.

The evidence for their benefit in chronic pelvic pain is weak or non-existent and is often limited by side-effects. For pelvic pain in which inflammatory processes are considered important, such as dysmenorrhoea [442], NSAIDs are more effective than placebo and paracetamol, but with a higher incidence of side-effects. For pelvic pain in which central mechanisms may be incriminated, such as endometriosis [443] then the evidence is lacking for NSAIDs despite their common use.

At a practical level, if NSAIDs are considered for use, they should be tried (having regard for the cautions and contraindications) and the patient reviewed for improvement in function as well as analgesia. If this is not achieved, or side-effects are limiting, then they should be withdrawn.

Neuromodulators
These agents are not simple analgesics but used to modulate neuropathic or centrally mediated pain. There are several classes commonly used with recognised benefits in pain medicine. They are taken on a regular basis and all have side-effects that may limit their use and have the potential to be dependance-forming. In the UK, NICE has reviewed the pharmacological management of neuropathic pain [444]. The evidence for treatment of CPPPS is lacking but is present for other painful conditions. For this chapter, most of the evidence is from non-pelvic pain sources. The general method for using these agents is by titrating the dose against benefit and side-effects. The aim is for patients to have an improvement in their QoL, which is often best assessed by alterations in their function. It is common to use these agents in combination but studies comparing different agents against each other, or in combination, are lacking. Some of these agents are also used for specific conditions. Early identification of neuropathic pain with a simple questionnaire could facilitate targeted therapy with neuromodulators [58].

Antidepressants
Tricyclic antidepressants
The tricyclic antidepressants (TCAs) have multiple mechanisms of action and are frequently limited by their side-effects. Tricyclic antidepressants have a long history of use in pain medicine and have been subjected to a Cochrane review [445], suggesting that they are effective for neuropathic pain. Amitriptyline is the most commonly used at doses from 10-75 mg/day (sometimes rising to 150 mg/day). This is titrated against benefit or side-effects and should be taken at night [444]. Nortriptyline and imipramine are used as alternatives.

Other Antidepressants
Duloxetine is a SNRI antidepressant licensed for use in depression, SUI and neuropathic pain. There is evidence of benefit in diabetic neuropathy and fibromyalgia at a dose of 60 mg/day [446, 447]. Side-effects are common and may result in its discontinuation.

Anticonvulsants
Anticonvulsants are commonly used in the management of neuropathic pain. There are general studies and some looking more particularly at pelvic pain. Individual agents have been systematically reviewed. Their use is suggested in the NICE Neuropathic Pain Guidelines [444].
Carbamazepine has a long history of use in neuropathic pain. Evidence exists for its benefit [448]. Trials tend to be of short duration, showing only moderate benefit. There are side-effects; some of which may be serious. It is no longer a first choice agent. Other anticonvulsant agents are available with fewer serious side-effects.

**Gabapentinoids**

There is a growing awareness and evidence of the risk for dependence and misuse of gabapentinoids [449]. A formal assessment of efficacy against benefit and side-effects (both pain and QoL) is required with the patient in order to determine the lowest effective dose and if longer-term treatment is to be used.

**Gabapentin** is commonly used for neuropathic pain and has been systematically reviewed [450, 451]. This demonstrates good evidence for postherpetic neuralgia and diabetic neuropathy but evidence for other neuropathies is limited. A double-blind RCT looking at PCPPS in women with no obvious pathology demonstrated no benefits but higher levels of side effect [451].

**Pregabalin** is a commonly used neuromodulator with good evidence of efficacy in some neuropathic conditions [452]. The dose for benefit is in the range of 300-600 mg/day. Evidence for central neuropathic pains is inadequate. Some patients do gain moderate to significant benefit but most will gain no benefit and then the drug should be discontinued. Other agents can be used in the management of neuropathic pain but they are best administered by specialists in the management of pain whom are familiar with their use. They tend to be considered after the standard options have been exhausted. As with all good pain management, they are used as part of a comprehensive multi-dimensional management plan.

**Opioids**

Over recent years opioids have been used extensively for managing chronic non-cancer pain. There is increasing evidence that their role is limited in this population but may be beneficial for a small number of patients at a low dose in a managed setting [453]. There is clear evidence of harm and significant professional, public and political interest. Their use is beneficial for both acute pain and for cancer pain management particularly towards the end of life.

Often patients will stop taking oral opioids due to side effects or insufficient analgesic effect [454]. There is clear evidence of harm including effects on the endocrine and immune systems as well as a growing understanding of opioid-induced hyperalgesia [455]. There is limited guidance on the best method for tapering the dose of opioids with the aim of stopping or finding the lowest effective dose [456].

Opioids should only be used in conjunction with a management plan with consultation between clinicians experienced in their use. It is suggested that a pain management unit should be involved along with the patient and their primary care physician. Ensure there are arrangements for formal monitoring, follow-up and review. If opioids are used and the pain remains, then they are not working and should be stopped even if there is no alternative [455].

The risk of harm increases substantially at doses above 120 mg/day morphine equivalence [455] and guidance suggests regular (at least annual) review for patients with over 50 mg/day morphine equivalence and pain specialist involvement above 90 mg/day morphine equivalence [457].

There are well-established guidelines for the use of opioids in pain management as well as considering the potential risks [455, 457]. Opioid reduction and optimisation should be undertaken where opioids are not providing clear measurable benefit. There is also information available online for patients [455]. Opioids Aware is a web-based resource for patients and healthcare professionals, jointly produced by the Faculty of Pain Medicine of Royal College of Anaesthetists and Public Health England, to support prescribing of opioid medicines for pain. [https://fpm.ac.uk/opioids-aware](https://fpm.ac.uk/opioids-aware).

**Cannabinoids**

There has been increasing interest and changes in national regulations regarding the use of cannabinoids for medicinal use. Regarding pain the evidence base for the use of cannabinoids is weak [458-460] and further well conducted clinical trials are necessary. This is an area where further guidance and research is likely in the coming years.
5.3 Further management

5.3.1 Nerve blocks
Nerve blocks for pain management are usually carried out by specialists in pain medicine as part of a broader management plan [461]. They may have a diagnostic or therapeutic role. Textbooks have been written on the subject and practitioners using them should be trained in appropriate patient selection, indications, risks and benefits. Many such interventions also require understanding and expertise in using imaging techniques to perform the blocks accurately. Diagnostic blocks can be difficult to interpret due to the complex mechanisms underlying the painful condition or syndrome. Sustained but limited benefit may lead to more permanent procedures (e.g., radiofrequency procedures). There is a weak evidence base for these interventions for chronic non-malignant pain [462].

Pudendal Neuralgia
The role of injections may be divided into two. First, an injection of local anaesthetic with or without steroids at the sight of nerve injury may produce a therapeutic action [463, 464]. The second possible benefit is diagnostic. It has already been indicated that when the pudendal nerve is injured there are several sites where this may occur. Differential block of the pudendal nerve helps to provide information in relation to the site where the nerve may be trapped [260, 465-472].

Infiltration at the ischial spine requires the use of a nerve stimulator/locator. Both motor (anal contraction) and sensory endpoints may be noted. The anatomical endpoint may be localised by fluoroscopy, CT guidance, or the use of US, the latter avoids any radiation, whereas CT guidance involves a significant amount of radiation. Currently, fluoroscopy is probably the imaging technique most frequently used because it is readily available to most anaesthetists that perform the block. Currently, infiltration of the pudendal nerve within Alcock’s canal is primarily undertaken with the use of CT. As well as injecting around the pudendal nerve, specific blocks of other nerves arising from the pelvis may be performed. Pulsed radio frequency stimulation has been suggested as a treatment [473]. Pulsed radio frequency lesioning for pudendal neuralgia is being developed with a paper demonstrating potential benefit. Follow-up is short term and further research is required to better elucidate its place in management [474].

5.3.2 Neuromodulation
The role of neuromodulation in the management of pelvic pain should only be considered by specialists in pelvic pain management. These techniques are used as part of a broader management plan and require regular follow-up. The research base is developing and the techniques broadening (e.g., spinal cord stimulation, sacral root stimulation, dorsal root ganglion stimulation or peripheral nerve stimulation). These are expensive interventional techniques for patients refractory to other therapies. Neuromodulation is still finding its role in pelvic pain management. There has been growing evidence but more detailed, high quality research is required [475]. Its role in overactive bladder (OAB) and faecal incontinence is more robust but is limited for pain. Two SRs have evaluated neuromodulation techniques for CPPS [476, 477]. Both studies concluded that neuromodulation may be effective in reducing pain and improving QoL in patients with CPPS; however, studies were of a low quality and long-term results were needed.

Transcutaneous Electrical Nerve Stimulation
Transcutaneous electrical nerve stimulation (TENS) is a non-invasive technique used in many pain conditions. A SR identified twelve studies of TENS in chronic pelvic pain conditions including four RCTs [476]. All RCTs demonstrated a significant reduction in pain following twelve weeks of treatment for pain conditions including dysmenorrhoea and CPPPS. Pain was also found to improve following TENS for provoked vestibular pain. There was conflicting data with regard to improvement of QoL following TENS; where validated questionnaires were used, no significant improvement was found, whereas in trialist-defined studies, an improvement was seen in TENS for dysmenorrhoea and CPPPS. The beneficial effects of a course of TENS may be sustained; one study demonstrating a persistent benefit at 43 months in 73% of men with CPPPS and another demonstrating a prolonged significant improvement in women with provoked vestibular pain at ten months post-treatment. Where reported there were no adverse events recorded. Transcutaneous electrical nerve stimulation could offer an effective non-invasive treatment option for patients with CPPPS.

Percutaneous Tibial Nerve Stimulation
Percutaneous tibial nerve stimulation (PTNS) is a minimally invasive technique that can be use in an outpatient setting. Two SRs have shown that PTNS is effective in reducing pain in patients with CPPPS [476, 477]. Three RCTs identified showed a significant improvement in pain scores and QoL as measured by validated questionnaires. Where recorded, adverse events were rare and minor including temporary slight pain at application site and haematoma.
**Sacral Nerve Stimulation**

Sacral nerve stimulation (SNS) is an invasive technique requiring sedation or general anaesthesia for implantation of a device following trial stimulation. A SR review identified ten studies of SNS in CPPPS, either retrospective case series or prospective cohort studies and no RCTs. Where reported, a mean of 69% of participants progressed to implantation of device following test stimulation (range 52-91%). All studies reported an improvement in pain, statistically significant in five studies. Quality of Life was measured in three studies and a significant improvement demonstrated in two of three studies. There was a large variation in adverse events reported ranging from 0-50%. Complications not requiring surgical intervention included pain, failure of device, wound infection and seroma. Re-operation rate ranged between 11-50% for complications including lead migration, systemic infection, intrathecal implantation, loss of efficacy and erosion. In clinical practice, a patient should be appropriately counselled regarding the need for a period of trial stimulation and whilst there may be an improvement in symptoms, this should be weighed against a notable complication rate.

A SR review in 2018 identified fourteen studies. In all, 403 patients had undergone percutaneous nerve evaluation and/or SNM stage 1 and 54.8%) had progressed to the permanent implantation stage, which is similar to that reported previously. The cause of pain was reported to be IC/BPS in 170 cases (42.2%). Visual Analogue Scale pain scores were available pre- and post-SNM in 210 patients and overall improvement in pain scores was significant. Sacral nerve stimulation is a promising treatment option for refractory chronic pelvic pain. This is mainly supported by level 2b studies. Randomised prospective studies are warranted to compare SNS vs. other modalities for chronic pelvic pain treatment. Further studies are needed to compare antegrade vs. retrograde approaches [478].

**Other neuromodulation techniques**

A variety of other techniques of neuromodulation for patients with CPPPS were identified by SRs [476, 479]. These techniques include intravaginal electrical stimulation for women with CPPPS, pudendal nerve stimulation for CPPPS, spinal cord stimulation for pudendal neuralgia, transcutaneous interferential electrical stimulation for IBS, electrical acupuncture for dysmenorrhoea and electrical stimulation/biofeedback and electromagnetic stimulation for men with CPPPS. Whilst an improvement in pain has been reported in these studies, it is noted that they are largely of low quality and further work is needed in this area to enable robust clinical recommendations to be made. Neuromodulation in combination with hormonal treatment in deep endometriosis may have some benefit [480].

### 5.3.3 Surgery

**Primary Bladder Pain Syndrome (PBPS)**

**Bladder distension**

Although bladder hydrodistension is a common treatment for PBPS, the scientific justification is scarce. It can be part of the diagnostic evaluation, but has limited therapeutic role.

**Hydrodistension and Botulinum toxin type A**

Botulinum toxin type A may have an anti-nociceptive effect on bladder afferent pathways, producing symptomatic and urodynamic improvements [481]. Treatment with hydrodistension and hydrodistension plus intravesical BTX-A has been compared [482]. There was symptomatic improvement in all patients. However, in the hydrodistension-only group, 70% returned to their previous symptoms after one month, while in the BTX-A-treated patients, VAS score and functional and cystometric bladder capacity improved at three months. Botulinum toxin type A trigonal-only injection seems effective and long-lasting as 87% of patients reported improvement after three months follow-up [483]. Over 50% reported continued benefit nine months after the first treatment. When re-treatment was needed, similar results were obtained. Adverse effects of BTX-A administration for IC/PBPS were significantly less than for OAB syndrome, namely in increased post-void residual volumes and decreased voiding efficiency [484]. Recent RCTs have reported benefits and long efficacy of BTX-A administration [485-488], but a summary estimate for overall change in pain following BTX-A injections was not possible in a recent SR [387]. Conflicting data on results hinders issuance of a clear guideline for the use of Botox in PBPS phenotypes. Despite this, the American Urological Association (AUA) guidelines panel has upgraded BTX-A treatment from fifth to a fourth line treatment [489].

Results of treatment with intravesical plasma rich (PRP) injections are also being explored. A recent prospective trial, showed that patients with GRA (global response assessment) ≥ 2, had success rates at one month and at three months after the 4th PRP injection, of 70.6% and 76.7%, respectively. The VAS pain score, frequency, and nocturia showed a significant decrease (all p < 0.05). However further studies are needed to validate findings [490].
Transurethral resection, coagulation and laser ablation
Endourological destruction of bladder tissue aims to eliminate urothelial Hunner lesions. Since the 1970s, resection and fulguration have been reported to achieve symptom relief, often for more than three years [491-493]. Prolonged amelioration of pain and urgency has been described for transurethral laser ablation as well [494].

Open Surgery for PBPS
Primary bladder pain syndrome is benign and does not shorten life, thus operative procedures rank last in the therapeutic algorithm. There is no evidence that it relieves pain. Surgery for PBPS is only appropriate as a last resort for patients with refractory disease. Major surgery should be preceded by thorough pre-operative evaluation, with an emphasis on determining the relevant disease location and subtype. If surgery is considered, the panel’s advice is to refer the patient to a specialist centre experienced in managing CPPPS with a multi-disciplinary team approach.

Four major techniques are common:
1. Urinary diversion without cystectomy is performed to minimise the duration and complexity of surgery, but complications related to the retained bladder commonly occur. Reports that un-resected PBPS bladders cease to induce symptoms after loss of contact with urine are scarce [103, 495].
2. Supratrigonal cystectomy with bladder augmentation represents the most favoured continence-preserving surgical technique particularly in younger patients [496]. Various intestinal segments have been used [497-499]. After orthotopic bladder augmentation, bladder emptying may be incomplete so intermittent self-catheterisation may be required. A study on female sexuality after cystectomy and orthotopic ileal neobladder showed pain relief in all patients and improvement in sexual function items in women who remained sexually active [500]. Pregnancies with subsequent lower-segment Caesarean section have been reported after ileocystoplasty [501].
3. Subtrigonal or simple cystectomy refers to removal of the entire bladder at the level of the bladder neck. This approach has the benefit of removing the trigone as a possible disease site, but at the cost of requiring ureteric re-implantation. Trigonal disease is reported in 50% of patients and surgical failure has been blamed on the trigone being left in place [502], especially in patients with non-lesion type disease [503, 504]. However, in a previous study all patients were rendered symptom-free by supratrigonal resection compared to 82% of those undergoing subtrigonal cystectomy. Voiding dysfunction is most likely to occur following trigonal resection and patients considering augmentation and especially substitution procedures must be capable of accepting, performing and tolerating self-catheterisation [505].
4. Cystectomy with formation of an ileal conduit is considered for patients with PBPS who develop recurrent pain in the augmented bladder, continent pouch after enterocystoplasty or continent urinary diversion. Re-tubularisation of a previously used bowel segment to form a urinary conduit has been recommended [506].

Primary Prostate Pain Syndrome
There is no evidence for surgical management, including transurethral incision of the bladder neck, radical transurethral resection of the prostate or, in particular, radical prostatectomy in the management of chronic pain in patients with PPPS. A large Chinese RCT of circumcision combined with a triple oral therapy (ciprofloxacin, ibuprofen, tamsulosin) vs. oral therapy alone has been published for patients with PPPS (total n=774) [507]. It is hypothesised that there may be some immunological interaction via pathogenic antigen presenting cells in the foreskin with CD4+ T cells causing auto-immunity to the prostate gland. They reported an improvement in total NIH-CPSI score and subdomain scores at twelve weeks. However, despite a large cohort, the study results are questionable because of the weak theoretical background, and a potential large placebo effect lacking a sham control. In addition, no long-term effectiveness has been reported. Before having an impact on recommendations, the results of this study have to be independently confirmed and the treatment effect must persist.

Primary Testicular Pain Syndrome
Microsurgical denervation of the spermatic cord can be offered to patients with testicular pain. In a long-term follow-up study, patients who had a positive result on blocking the spermatic cord were found to have a good result following denervation [508, 509].

Chronic Primary Anal and Abdominal Pain Syndrome
Chronic primary anal pain syndrome after stapled procedures, such as hemorrhoidopexy or stapled transanal rectal resection may respond to excision of the scarred staple line as shown in 21 consecutive patients with
an overall improvement of pain in 85.7% of patients undergoing scar excision surgery [510]. An early scar excision before three to six months after pain onset was associated with better pain relief. Adhesiolysis is still in discussion in the pain management after laparotomy/laparoscopy for different surgical indications in the pelvis and entire abdomen. An RCT has shown, that adhesiolysis is associated with an increased risk of operative complications, and additional operations and increased health care costs as compared to laparoscopy alone [511].

**Primary Urethral Pain Syndrome**

There is no specific treatment that can be advised. Management should be multi-disciplinary and multi-modal [512]. Laser therapy of the trigonal region may be a specific treatment. One trial comparing two forms of laser reported good results, but did not compare with sham treatment [513]. The majority of publications on treatment of primary urethral pain syndrome have come from psychologists [167, 514].

**Presumed intra-abdominal adhesions**

In gynaecological patients with CPPPS and presumed adhesions, there is no consensus as to whether adhesiolysis should be performed to improve pain [514].

Extensive surgery for endometriosis is challenging and is still considered to be controversial, as there is at least one RCT showing no benefit in pain relief after the removal of early extensive endometriosis vs. sham surgery [272, 515]. Increasingly treatment algorithms are being developed using a multi-disciplinary approach, although none have thus far been proven clinically [516]. In patients with adenomyosis, the only curative surgery is hysterectomy but patients can benefit from hormonal therapy and analgesics (see Section 5.2.2).

**Pudendal neuralgia and surgery**

Decompression of an entrapped or injured nerve is a routine approach and probably should apply to the pudendal nerve as it applies to all other nerves. There are several approaches and the approach of choice probably depends upon the nature of the pathology. The most traditional approach is transgluteal; however, a transperineal approach may be an alternative, particularly if the nerve damage is thought to be related to previous pelvic surgery [198, 260, 517-520]. Currently, there has been only one prospective RCT (transgluteal approach) [519]. This study suggests that, if the patient has had the pain for less than six years, 66% of patients will see some improvement with surgery (vs. 40% if the pain has been present for more than six years). Surgery is not the answer for all patients. On talking to patients that have undergone surgery, providing the diagnosis was clear-cut, most patients were grateful to have undergone surgery but many still have symptoms that need management.

**Chronic Pelvic Pain and Prolapse/Incontinence Mesh**

Removing an existing mesh is a complex procedure [521]. Each patient is approached on an individual basis depending on the type of mesh and extent of complications [522]. The complexity of surgery often involves removal of dense scar tissue, reformation of inflamed vaginal skin and surgical reconstruction of the urethra and bladder [523]. Such surgery requires specialist skills, best provided within a multi-disciplinary tertiary setting. Possible complications as a result of this surgical removal include bleeding, infection, damage to surrounding organs as well as LUTS, persistent chronic pain and recurrent SUI, which occurs after mesh removal [524].

Removal of mesh, whilst complex, does have beneficial outcomes generally, which are also durable particularly for chronic pain [525]. However, the long-term consequences after the mesh is removed still can include, not only chronic persistent pain but also autoimmune responses and complex neuropathies affecting the pelvis and lower limbs [526, 527]. Some of these can be treated effectively using a multi-disciplinary pain medicine approach [528]. In other cases, the residual symptoms may require the input of an immunologist, rheumatologist or other symptom-defined specialist.

The alternative to continence and prolapse mesh surgery is dependent on the clinical findings at the time. They include behavioural change, physiotherapy (for SUI and Grade I-II uterovaginal prolapse) or traditional surgical techniques. Studies have shown that over 70% who committed to physiotherapy for SUI often did not need any further intervention [529]. Many clinicians are reverting to conservative measures first, before re-considering surgery. Clinicians are also now retraining in traditional continence surgical techniques, which existed in the pre-mesh era, such as the Burch colposuspension and autologous fascial sling; as well as traditional utero-vaginal prolapse techniques such as vaginal hysterectomy, sacrospinous fixation and fascial repair of vaginal wall prolapse.

Recommendations | Strength rating
--- | ---
Offer subtype and phenotype-oriented therapy for the treatment of Primary Bladder Pain Syndrome (PBPS). | Strong
Always consider offering multimodal behavioural, physical and psychological techniques alongside oral or invasive treatments of PBPS. | Strong
Offer dietary advice. | Weak
Administer amitriptyline for treatment of PBPS. | Strong
Offer oral pentosane polysulphate for the treatment of PBPS. | Strong
Offer oral pentosane polysulphate plus subcutaneous heparin in low responders to pentosane polysulphate alone. | Weak
Do not recommend oral corticosteroids for long-term treatment. | Strong
Offer intravesical hyaluronic acid or chondroitin sulphate before more invasive measures. | Weak
Offer intravesical lidocaine plus sodium bicarbonate prior to more invasive methods. | Weak
Offer intravesical heparin before more invasive measures alone or in combination treatment. | Weak
Consider submucosal bladder wall and trigonal injection of botulinum toxin type A plus hydrodistension if intravesical instillation therapies have failed. | Strong
Offer neuromodulation before more invasive interventions. | Weak
Only undertake ablative and/or reconstructive surgery as the last resort and only by experienced and PBPS-knowledgeable surgeons, following a multi-disciplinary assessment including pain management. | Strong
Offer transurethral resection (or coagulation or laser) of bladder lesions, but in PBPS type 3 C only. | Strong

5.4.3 Management of scrotal pain syndrome

Summary of evidence | LE
--- | ---
Microsurgical denervation of the spermatic cord is an effective therapy for primary scrotal pain syndrome. | 2b
Vasovasostomy is effective in post-vasectomy pain. | 2b

Recommendations | Strength rating
--- | ---
Inform about the risk of post-vasectomy pain when counselling patients planned for vasectomy. | Strong
Do open instead of laparoscopic inguinal hernia repair, to reduce the risk of scrotal pain. | Strong
In patients with testicular pain improving after spermatic block, offer microsurgical denervation of the spermatic cord. | Weak

5.4.4 Management of primary urethral pain syndrome

6. EVALUATION OF TREATMENT RESULTS

6.1  Evaluation of treatment

For patients with chronic primary visceral pain, a visit to the clinician is important because they can ask questions, talk about how the process is going and have some time with the caregiver who understands the nature of their pain. First evaluation should take place after about six weeks to see if the treatment has been successful or not. When necessary adaptations are made and a next evaluation is planned.

6.1.1  Treatment has not been effective

6.1.1.1  Alternative treatment

In cases where the treatment initiated did not have enough effect, an alternative approach is advised. The first thing to do is a thorough evaluation of the patients’ or care providers’ adherence to the treatment that was initiated. Ask the patient if they have taken the medication according to the prescription, if there were any side effects and if there were any changes in pain and function. Adjustment of medication or dose schemes might help. Another important thing to do is to read the reports of other caregivers, for example, the physiotherapist and the psychologist. Has the therapy been followed until the end, what was the opinion of the therapist about the changes that were observed? In cases where the sessions had been terminated by the patient, ask the patient why they made that decision. Check if the patient has understood the idea behind the therapy that had been prematurely stopped.

6.1.1.2  Referral to next envelope of care

If patients and doctors conclude that none of the therapies given showed enough effect, then referral to a next envelope of care is advised. Unfortunately, the terminology used to describe the nature and specialisation level of centres providing specialised care for visceral pain patients is not standardised and is country-based. This does not facilitate easy referral schemes. It is advised that patients are referred to a centre that is working with a multi-disciplinary team and nationally recognised as specialised in pelvic pain. Such a centre will re-evaluate what has been done and when available, provide specialised care.

6.1.1.3  Self-management and shared care

Patients who find themselves confronted with CPPPS, for which there is no specific treatment option available, will have to live with their pain. They will need to manage their pain, meaning that they will have to find a way to deal with the impact of their pain on daily activities in all domains of life. Self-help programmes may be advised
and can be of help. The patient may also benefit from shared care, which means that a caregiver is available for supporting the self-management strategies. Together with this caregiver, the patient can optimise and use the management strategies.

6.1.2 **Treatment has been effective**

In cases where treatment has been effective, the caregiver may pay attention to fall-back prevention. If the patient feels the same pain again, it helps to start at an early stage with the self-management strategies that he/she has learned during the former treatment. By doing so they will have the best chance of preventing the re-development of pelvic pain syndromes.

8. CONFLICT OF INTEREST

All members of the EAU Chronic Pelvic Pain Guidelines working panel have provided disclosure statements on all relationships that they have that might be perceived to be a potential source of conflict of interest. This information is publicly accessible through the European Association of Urology website https://uroweb.org/guidelines/.

This document was developed with the financial support of the European Association of Urology. No external sources of funding and support have been involved. The EAU is a non-profit organisation and funding is limited to administrative assistance and travel and meeting expenses. No honoraria or other reimbursements have been provided.

9. CITATION INFORMATION

The format in which to cite the EAU Guidelines will vary depending on the style guide of the journal in which the citation appears. Accordingly, the number of authors or whether, for instance, to include the publisher, location, or an ISBN number may vary.

The compilation of the complete Guidelines should be referenced as:

If a publisher and/or location is required, include:

References to individual guidelines should be structured in the following way:
**Contributors’ names. Title of resource. Publication type. ISBN. Publisher and publisher location, year.**

6. CITATION INFORMATION
1. INTRODUCTION

1.1 Aim and objectives
The European Association of Urology (EAU) Renal Transplantation Guidelines aim to provide a comprehensive overview of the medical and technical aspects relating to renal transplantation. It must be emphasised that clinical guidelines present the best evidence available to the experts but following guideline recommendations will not necessarily result in the best outcome. Guidelines can never replace clinical expertise when making treatment decisions for individual patients, but rather help to focus decisions - also taking personal values and preferences/individual circumstances of patients into account. Guidelines are not mandates and do not purport to be a legal standard of care.

1.2 Panel Composition
The EAU Renal Transplantation Guidelines panel consists of an international multidisciplinary group of urological surgeons, a nephrologist and a pathologist. All experts involved in the production of this document have submitted potential conflict of interest statements which can be viewed on the EAU website: http://www.uroweb.org/guideline/renal-transplantation/.

1.3 Available publications
A quick reference document, the Pocket Guidelines, is available in print and as an app for iOS and Android devices. These are abridged versions which may require consultation together with the full text version. All are available through the EAU website: http://www.uroweb.org/guideline/renal-transplantation/.

1.4 Publication history

2. METHODS

2.1 Introduction
For the 2021 Renal Transplantation Guidelines, new and relevant evidence was identified, collated and appraised through a structured assessment of the literature. Broad and comprehensive literature searches, covering the Renal Transplantation Guidelines were performed, covering a time frame between May 31st 2018 and 1st April 2020. A total of 1,202 unique records were identified, retrieved and screened for relevance. Databases searched included Medline, EMBASE, and the Cochrane Libraries. Detailed search strategies are available online: http://www.uroweb.org/guideline/renal-transplantation/.

For each recommendation within the guidelines there is an accompanying online strength rating form, the bases of which is a modified GRADE methodology [1, 2]. Each strength rating form addresses a number of key elements namely:

1. the overall quality of the evidence which exists for the recommendation, references used in this text are graded according to a classification system modified from the Oxford Centre for Evidence-Based Medicine Levels of Evidence [3];
2. the magnitude of the effect (individual or combined effects);
3. the certainty of the results (precision, consistency, heterogeneity and other statistical or study related factors);
4. the balance between desirable and undesirable outcomes;
5. the impact of patient values and preferences on the intervention;
6. the certainty of those patient values and preferences.

These key elements are the basis which panels use to define the strength rating of each recommendation. The strength of each recommendation is represented by the words ‘strong’ or ‘weak’ [4]. The strength of each recommendation is determined by the balance between desirable and undesirable consequences of alternative management strategies, the quality of the evidence (including certainty of estimates), and nature and variability of patient values and preferences.
Additional information can be found in the general Methodology section of this print, and online at the EAU website; [http://www.uroweb.org/guideline/](http://www.uroweb.org/guideline/). A list of associations endorsing the EAU Guidelines can also be viewed online at the above address.

### 2.2 Review and future goals

This document was subject to independent peer review prior to publication in 2017. Publications ensuing from systematic reviews have all been peer reviewed.

The results of ongoing systematic reviews will be included in the 2022 update of the Renal Transplantation Guidelines. Ongoing systematic reviews include:

1. What is the best treatment for symptomatic obstructive benign prostatic enlargement in renal transplantation patients [5]?
2. For patients with kidney graft stones, does surgical treatment provide better stone free rates than external shock wave lithotripsy [6]?

### 3. THE GUIDELINE

#### 3.1 Organ retrieval and transplantation surgery

##### 3.1.1 Living-donor nephrectomy

The endoscopic (laparoscopic) approach is the preferred technique for living-donor nephrectomy in established kidney transplant programmes [7]. Nevertheless, open surgery, preferably by a mini-incision approach, can still be considered a valid option, despite increased pain in the post-operative period [8].

Endoscopic living-donor nephrectomy (ELDN) includes:

- Pure or hand-assisted transperitoneal laparoscopy;
- Pure or hand-assisted retroperitoneal approach;
- Laparo-Endoscopic Single Site Surgery (LESS);
- Natural Orifice Transluminal Endoscopic Surgery-assisted (NOTES);
- Laparo-Endoscopic Single Site Surgery and robotic-assisted transperitoneal or retroperitoneal approach.

There is strong evidence in support of laparoscopic living-donor nephrectomy (LLDN), including several systematic reviews and meta-analysis, which have compared its safety and efficacy to open donor nephrectomy. Laparoscopic living-donor nephrectomy is associated with similar rates of graft function and rejection, urological complications and patient and graft survival. However, measures related to analgesic requirements, pain, hospital stay, and time to return to work are significantly better for laparoscopic procedures [9-12].

Standard LLDN is usually done through 5 and 12 mm ports, but has also been done with 3 or 3.5 mm ports [13]. According to a recent meta-analysis, hand-assisted LLDN is associated with shorter operative time and warm ischaemia, but equivalent safety and overall results [14]. Laparoscopic living-donor nephrectomy can also be performed with robotic assistance, with equivalent results according to a systematic review [15]. However, the numbers are still low and recent studies, including a meta-analysis, have reported higher complication rates for this approach [16, 17].

Laparo-endoscopic single site surgery nephrectomy allows the surgeon to work through a single incision (usually the umbilicus) with a multi-entry port. The same or a separate incision is then used for kidney withdrawal. Several retrospective and at least three prospective randomised trials demonstrated equivalent safety and results, with a trend towards less pain and better cosmetic results [18, 19]. However, LESS is considered a more technically demanding procedure when compared with classic LLDN and its role is yet to be defined.

Natural orifice transluminal endoscopic surgery-assisted transvaginal nephrectomy avoids the abdominal incision needed for kidney extraction, aimed at minimising scaring and pain. Initial reports suggest that this approach is safe, however experience with this technique is still highly limited [20].

Right LLDN has been considered more difficult, yielding inferior results. However, both left and right LLDN can be performed with equivalent safety and efficacy according to large retrospective studies, systematic reviews and meta-analysis [21, 22].
Laparoscopic living-donor nephrectomy has brought attention to potential failures of different devices such as, endoscopic staplers and locking and non-locking clips, used to secure the renal hilum [21]. There is no scientific evidence that one device is safer than another for securing the renal artery [23-25]. However, the U.S. Food and Drug Administration (FDA) and the manufacturers of locking clips have issued a contraindication against their use in securing the artery during LLDN.

#### 3.1.2 Organ preservation

In kidneys donated after cardiac death (DCD) evidence suggests that warm ischemia contributes to worse graft outcome. Donor haemodynamic parameters (systolic blood pressure, oxygen saturation and shock index: heart rate divided by systolic blood pressure) may be predictors of delayed graft function (DGF) and graft failure; however, further studies are required to validate this [26]. The duration of asystolic warm ischaemia during procurement in DCD donors is associated with increased risk of graft failure. Overall five year graft failure (including primary graft non-function) was associated with longer asystolic warm ischaemia times [27]. Extraction time (beginning with aortic cross-clamp and ending with placement of the kidneys on ice), is an important factor for DGF. Incidents of DGF were 27.8% and 60% at up to 60 minutes and 120 minutes extraction time, respectively [28].

A retrospective study of 64,024 living donor kidney transplants found that cold ischaemia time (CIT), human leukocyte antigen (HLA) mismatch, donor age, panel reactive antibody, recipient diabetes, donor and recipient body mass index (BMI), recipient race and gender, right nephrectomy, open nephrectomy, dialysis status, ABO incompatibility, and previous transplants were independent predictors of DGF in living donor kidney transplants [29]. Five-year graft survival among living donor kidney transplant recipients with DGF was significantly lower than in those without DGF. Delayed graft function increased the risk of graft failure by more than two-fold [29].

#### 3.1.2.1 Kidney storage solutions and cold storage

There are two main sources for kidney graft injury: ischaemia (warm and cold), and reperfusion injury. The aims of modern kidney storage solutions include: control of cell-swelling during hypothermic ischaemia; maintenance of intra- and extra-cellular electrolyte gradient during ischaemia; buffering of acidosis; provision of energy reserve; and minimisation of oxidative reperfusion injury. There is no agreement on which of the mechanisms is most important for post-ischaemic renal graft function [30]. No storage solution seems to combine all mechanisms. Previously, Euro-Collins was widely used, but is no longer recommended.

Presently, University of Wisconsin (UW), and histidine-tryptophan-ketoglutarate (HTK) solution are equally effective and are standard for multi-organ or single kidney harvesting procedures. The characteristics of HTK are its low viscosity, low potassium concentration and low cost. University of Wisconsin solution has been the standard static cold preservation solution for the procurement of liver, kidney, pancreas, and intestine [31]. University of Wisconsin, HTK, and Celsior solutions have provided similar allograft outcomes in most clinical trials; however, some differences have become apparent in recent studies and registry reports [32, 33]. Marshall’s hypertonic citrate solution (MHCS) is also suitable for use in the preservation of human kidneys before transplantation [34]. In experimental studies of kidney preservation, HTK and UW retained a greater capacity to preserve endothelial structure and pH buffering function during warm ischaemia in comparison to MHCS and Celsior, especially in uncontrolled DCD donors [35]. In the absence of a cost-utility analysis, the results of the meta-analysis from the randomised controlled trials (RCTs) comparing UW with Celsior and MHSC in standard cadaver donors, indicate that these cold storage solutions are equivalent [36].
For living donors, in whom immediate kidney transplantation is planned, perfusion with crystalloid solution is sufficient. Kidneys coming from DCD donors, especially those uncontrolled, are high-risk marginal organs due to prolonged warm ischaemia periods, and require specific measures in order to diminish the rate of non-function or DGF. More than 60% of kidney grafts currently come from Expanded Criteria Donors (ECD) (any donor aged > 65 years and/or donor aged > 55 years with any of the following: acute renal dysfunction, stroke or arterial hypertension) [37].

Summary of evidence

| University of Wisconsin and HTK solution are equally effective and are standard for multi-organ or single kidney harvesting procedures. | LE 1b |
| A meta-analysis of RCTs indicated that UW and Celsior solution are equivalent in standard cadaver donors. | LE 1a |

Recommendations

| Use either University of Wisconsin or histidine tryptophane ketoglutarate preservation solutions for cold storage. | Strength rating Strong |
| Use Celsior or Marshall’s solution for cold storage if University of Wisconsin or histidine tryptophane ketoglutarate solutions are not available. | Strength rating Strong |

3.1.2.2 Duration of organ preservation

Cold ischaemia time should be as short as possible. Kidneys from ECDs after brain death (DBD) and DCD donors are more sensitive to ischaemia than standard criteria donors. Kidneys from DBD donors should ideally be transplanted within a 18 to 21 hour time period; there is no significant influence on graft survival within a 18 hour CIT [36, 38, 39]. Kidneys from DCD donors should ideally be transplanted within 12 hours [40], whilst kidneys from ECDs should ideally be transplanted within 12 to 15 hours [41, 42].

3.1.2.3 Methods of kidney preservation: static and dynamic preservation

Whichever method is used, cold storage is critical. The use of cold preservation as a therapeutic window to deliver pharmacological or gene therapy treatments could, from an investigational point of view, improve both short- and long-term graft outcomes [43]. Cooling reduces the metabolic rate of biological tissue minimising continuous cellular processes that lead to depletion of ATP and accumulation of metabolic products. Reperfusion with oxygenated blood invokes ischaemia-reperfusion injury. Hypothermic perfusion does not enable normal cellular metabolic function or prevent depletion of energy stores [44]; however, it prevents the deleterious effects of simple cooling, especially in the setting of prolonged warm-ischaemic time in uncontrolled DCD donors. Two meta-analyses suggest that hypothermic machine perfusion (HMP) reduces DGF compared with static cold storage [45, 46]. Outcomes for primary non-function (PNF) are less clear, but one meta-analysis limited to high quality studies suggests a reduction in PNF rates with HMP [46]. A Cochrane systematic review and meta-analysis showed that HMP reduced the risk of DGF when compared to static cold storage (CS) for kidneys from both DCD and DBD donors [47].

The increased demand for organs has led to the increased use of “higher risk” kidney grafts. Kidneys from DCD donors or grafts coming from ECDs are more susceptible to preservation injury and have a higher risk of unfavourable outcomes [48, 49].

Dynamic, instead of static, preservation could allow for organ optimisation, offering a platform for viability assessment, active organ repair and resuscitation. Ex situ machine perfusion and in situ regional perfusion in the donor are emerging as potential tools to preserve vulnerable grafts. Preclinical findings have driven clinical organ preservation research that investigates dynamic preservation, in various modes (continuous, pre-implantation) and temperatures (hypothermal, sub-, or normothermic) [44].

There are several methods of kidney preservation including:

- Initial flushing with cold preservation solution followed by ice storage. However, the limitations of static CS in preserving marginal organs such as ECD kidneys has led to the increased use of dynamic methods.
- Current dynamic preservation strategies entering clinical practice and the different modalities of their use are: HMP, hypothermic regional perfusion, normothermic machine perfusion, normothermic regional perfusion, sub-normothermic machine perfusion and sub-normothermic regional perfusion [44].
- Continuous pulsatile HMP seems to be a good preservation method for marginal organs, either initially or after a period of simple CS (shipping of suboptimal kidneys) [50].
• Some evidence shows that hypothermic dynamic preservation should be controlled by pressure and not flow, using low pressures to avoid pressure-related injury. The perfusion solutions used are specific, and are qualitatively different to CS solutions [33].

• Nonoxygenated HMP of the kidney at low perfusion pressures (20-30 mmHg) has been shown to reduce DGF [45]. The largest RCT comparing simple CS with HMP of deceased donor kidneys showed an overall reduced risk of DGF and a survival benefit, most pronounced in ECD kidneys [51]. Hypothermic machine perfusion of kidneys from type III DCD donors decreased DGF with no impact on graft survival [48].

• Hypothermic machine-perfusion reduces the risk of DGF in standard criteria DBD donor kidneys regardless of CIT [52].

• Increased vascular resistance and high perfusate injury marker concentrations are risk factors for DGF; however, they do not justify discarding the kidney. The flow perfusion value seems to be an indicator of graft viability in uncontrolled DCD donors, particularly donors with a high creatinine level [53]. However, research is required to identify a strong and reliable measure for predicting kidney viability from machine perfusion [36]. Perfusion parameters (renal flow and renal vascular resistance) have low predictive values and should not be used as the sole criterion to assess viability of kidney grafts [54].

• The effect of oxygenated HMP was investigated in an RCT initiated by the Consortium on Organ Preservation in Europe on type III DCD kidneys and ECD kidneys [44]. Graft loss was significantly lower after oxygenated HMP compared to HMP [55]. No significant differences between the two groups were shown for DGF, PNF and patient death. No difference in eGFR at one year was observed between HMPO vs. HMP; however, sensitivity analysis, accounting for all-cause graft failure, showed a higher eGFR in oxygenated HMP [55].

• A short period of normothermic machine perfusion (NMP) immediately prior to implantation has been shown to improve kidney graft function, replenish ATP and reduce injury in experimental models [56, 57].

• A retrospective study of normothermic regional perfusion (NRP) in uncontrolled DCD donors concluded that NRP appears to decrease graft failure when used as a preconditioning technique with subsequent HMP preservation in these donors [58].

• Active research is being developed on preservation of prolonged warm-ischaemically damaged human kidneys (types I and II DCD) by in situ normothermic extracorporal hemoperfusion with oxygenation and leukocyte depletion before procurement [59]. Oxygen carriage is achieved by using blood depleted of leukocytes. Potential advantages of this preservation technique are reduction in ischaemia-reperfusion injury as well as the possibility of assessing organ viability.

• Currently there is one registered ongoing RCT on pre-implantation NMP using an oxygenated, sanguineous normothermic perfusion solution (http://www.isrctn.com/ISRCTN15821205). However, kidney function can be evaluated during NMP by assessing macroscopic appearance of blood perfusion, renal blood flow and urine output [60].

• Continuous subnormothermic machine perfusion and controlled oxygenated rewarming has demonstrated improved creatinine clearance and preservation of structural integrity compared with continuous oxygenated HMP in a research setting [61].

3.1.3 Donor Kidney biopsies

Donor kidney biopsies can serve different purposes including:

- histological assessment of organ quality prior to transplantation (often referred to as procurement or harvest biopsies);
- histological analysis of focal lesions, especially if there is a suspicion of neoplasia;
- detection of donor derived lesions as reference for subsequent post-transplant biopsies (often referred to as baseline, zero-time or implantation biopsies).

3.1.3.1 Procurement Biopsies

3.1.3.1.1 Background and prognostic value

Procurement biopsies are used for the detection of tissue injury to aid the decision of whether or not a deceased donor kidney is suitable for transplantation. These biopsies are most commonly performed in donors with clinical suspicion of chronic kidney injury (ECDs) [62].

Kidney discard in Europe is rarely based on histology findings, as procurement biopsies are not regularly performed for graft allocation in the Eurotransplant region [62]. However, since biopsy findings are the most frequent cause for discarding donor organs in the United States [63-65], their prognostic value has been analysed in numerous studies. A recently published systematic review of studies on donor kidney biopsies revealed a lack of prospective studies and marked heterogeneity regarding the type of lesions being assessed, their scoring, the definitions of post-transplant outcomes and the statistical methods employed [66]. Therefore, the published evidence suggests that the use of procurement biopsies for deciding on suitability for transplantation of donor kidneys may have some important limitations including the following [62, 66, 67]:

- There is no consistent association between histological lesions observed in donor kidney biopsies and post-transplant outcomes.

The concept of procurement biopsies in elderly donors was introduced by a study from Gaber et al., in 1995. This study observed significantly worse outcomes in recipients of kidneys with > 20% globally sclerotic glomeruli [68]. However, subsequent studies yielded highly variable results and it cannot be concluded that glomerulosclerosis is independently associated with graft outcomes [66]. A similar variability was also observed for other potentially relevant lesions like arterial injury, interstitial fibrosis and tubular atrophy with each showing predictive value in some studies, but not in others [66].

- There is no agreement on prognostically relevant lesions and how they should be scored.

Specific grading systems for donor kidney biopsies have not yet been developed. Lesion scoring in pre-transplant biopsies is mostly based on the Banff consensus for post-transplant renal allograft pathology, which is supported by the 2007 Banff Conference report [69].

Many attempts have been made to use composite semi-quantitative scoring systems to express the global extent of tissue injury in donor kidney biopsies. These scoring systems are mostly based on simple addition of the Banff scores for individual lesions, most commonly glomerulosclerosis, arteriolar hyalinosis, arterial intimal fibrosis, interstitial fibrosis and tubular atrophy and rarely include clinical parameters like donor age [70], serum creatinine values and donor hypertension [71].

A limited number of histological scoring systems are based on modelling analysis [70-74]. Only the Maryland Aggregate Pathology Index (MAPI) [74] scoring system and the Leuven donor risk score [70], use graft failure as their endpoint and have been independently validated in a second cohort. Other studies used surrogate clinical endpoints like DGF [72] and estimated glomerular filtration rate (eGFR) at three months [73] to calculate histological models. In addition, these models were not validated in independent cohorts. The variation in how the components are weighted to achieve the composite score and the different endpoints used may explain the conflicting conclusions in the literature [62, 66, 67].

- Due to the time constraints of organ allocation procurement biopsies are mostly read on frozen sections by on-call pathologists, which might affect the diagnostic reliability of reported findings.

This may have substantial impact on the diagnostic reliability of the procedure since frozen sections are prone to morphological artefacts that can impair the detection and scoring of potentially important lesions such as arteriolar hyalinosis and interstitial fibrosis [75, 76]. There is strong evidence that dedicated renal pathologists should examine formalin-fixed paraffin-embedded core-needle biopsies. Paraffin histology employing special stains is technically superior to frozen sections since morphological details are better preserved on paraffin sections than on frozen sections and potentially confounding artefacts can be avoided. Rapid processing of tissue for paraffin histology is technically feasible, but the respective protocols are not universally implemented and are not available on a 24/7 basis in most departments. Another source of variability is the professional experience of the pathologist in charge. Procurement biopsies are commonly read by the on-call general
pathologist who frequently has no specific training in renal pathology. A recent study specifically addressing this issue found that the on-call pathologists tended to overestimate chronic injury in biopsies [77].

3.1.3.2 Type and size of biopsy
Many transplant centres obtain wedge biopsies of donor kidneys rather than needle biopsies due to the presumed higher risk of bleeding complications with the latter. Wedge biopsies sample the cortex superficially whereas needle biopsies reach deeper aspects of the cortex. Needle biopsies also allow sampling from different areas of the kidney. Submit 14 or 16 G needle biopsies as obtaining adequate biopsies with 18 G needles requires multiple cores [78]. Several studies comparing wedge with needle biopsies concluded that needle biopsies perform much better in the evaluation of vascular lesions because interlobular arteries are rarely sampled in wedge biopsies. Both methods were comparable for glomerular and tubulointerstitial lesions [79-82]. It was also demonstrated that glomerulosclerosis is significantly more pronounced in the subcapsular zone compared with deeper areas of the cortex [83]. The problem of insufficient sampling of arteries and over representation of (subcapsular) glomerular scars in wedge biopsies, can only be avoided if particular attention is paid to the correct performance of the biopsy, with a minimal depth of 5 mm [84]. The predictive value of glomerulosclerosis increases significantly with higher numbers of glomeruli in the wedge biopsy, with ideally at least 25 glomeruli required for evaluation [81]. There is limited evidence regarding complication rates in pre-implantation biopsies.

Use of a skin punch biopsy device might be an attractive alternative. Skin punch biopsies measure 3 mm in diameter. They have a shorter length than needle biopsies therefore avoiding injury to large calibre arteries at the corticomedullary junction whilst still sampling tissue from deeper areas of the cortex [85].

3.1.3.4 Implantation biopsies
Implantation biopsies are used to provide baseline information on donor kidney injury for comparison with subsequent post-transplant kidney biopsies. Baseline biopsies can be essential for clear distinction between pre-existing damage and acquired lesions. They are particularly valuable in cases of thrombotic microangiopathy, arteriolar hyalinosis or acute tubular injury. In contrast to procurement biopsies that are obtained at the time of organ harvesting, implantation biopsies are usually taken before implantation in order to cover potential effects of CIT. Their diagnostic contribution has not been formally quantified in the literature which might be due to the difficulties of measuring the value of implantation biopsies for improving diagnoses. Despite the lack of formal studies investigating their value it seems very reasonable to perform implantation biopsies in deceased donor kidneys.
3.1.4 Living and deceased donor implantation surgery

3.1.4.1 Anaesthetic and peri-operative aspects

Good communication between nephrologists, anaesthetists and surgeons is required for optimal anaesthetic and peri-operative care of the renal transplant patient. Anaesthetic care of the living kidney donor [86] and renal transplant recipient [87] have been reviewed and recent guidelines from the European Renal Association-European Dialysis and Transplantation Association (ERA-EDTA) [88] are cross referenced.

3.1.4.2 Immediate pre-op haemodialysis

Routine use of haemodialysis immediately prior to renal transplantation is not indicated [88]. Hyperkalaemia is the most common indication for haemodialysis pre-operatively. The risks of haemodialysis compared with medical therapy must be considered along with the risks of intra-operative fluid overload, electrolyte and acid-base disturbances, particularly where a deceased donor kidney is transplanted with a significant risk of DGF. Pre-operative haemodialysis may initiate a pro-inflammatory state, delay surgery, increase the CIT and increase the risk of DGF [89].

3.1.4.3 Operating on patients taking anti-platelet and anti-coagulation agents

Many patients active on the transplant waiting list have vascular disease and/or a pro-thrombotic condition that should be risk-assessed prior to transplantation. Dual anti-platelet therapy is commonly given to patients with coronary artery stents for six to twelve months; peri-operative management plans for these patients should be discussed with a cardiologist so that the risks of withdrawal of the anti-platelet agent can be fully considered. Options for reversal of anti-coagulation and post-operative anti-coagulation should be discussed with a haematologist prior to patient listing.

Some patients will be active on a transplant waiting list whilst continuing to take anti-platelet and/or anti-coagulation agents. The indication for anti-platelet or anti-coagulation agents should be clearly documented for each individual. Potential increased risk of peri-operative bleeding needs to be weighed against potential harm from arterial or venous thrombosis. In accordance with the American College of Chest Physicians and the European Society of Cardiology guidelines [90, 91], the literature suggests that continuing anti-platelet therapy with aspirin, ticlopidine or clopidogrel does not confer a significantly greater risk of peri/post-operative complications [92], however, the number of patients studied was low. If needed, the effect of anti-platelet agents can be reduced with intra-operative platelet infusions.

3.1.4.4 What measures should be taken to prevent venous thrombosis including deep vein thrombosis during and after renal transplant?

Peri-operative administration of short-acting anti-coagulation agents reduces peri-operative risk of venous thrombosis (including in ilio-femoral and renal veins); however, due to associated increased blood loss administration requires knowledge of individual patient risk factors. None of the current major thrombosis prevention guidelines directly address thromboprophyliaxis in the renal transplant peri-operative period. A small
RCT [93] showed no difference in early post-operative graft loss or thromboembolic complications with or without prophylactic anti-coagulation. Those administered prophylactic anti-coagulation had significantly lower haemoglobin whilst those administered prophylactic unfractionated heparin had prolonged lymph drainage. Based on this study, routine pharmacological prophylaxis is not recommended in low-risk living donor recipients. Mechanical measures to decrease ileo-femoral deep vein thrombosis (DVT) can be used where there is no contraindication due to peripheral vascular disease particularly where there are concerns about bleeding risks with pharmacological prophylaxis.

**3.1.4.5 Is there a role for peri-operative antibiotics in renal transplantation?**

Prophylactic peri-operative antibiotics are generally used in renal transplant surgery but the optimal antibiotic regimen is not known and increasing antibiotic resistance may hamper their effectiveness in this setting. A multicentre, prospective RCT showed no difference at one month in surgical site, bacterial, fungal or viral infection between those receiving a single dose broad spectrum antibiotic at induction of anaesthesia compared to those receiving antibiotic 12 hourly for 3-5 days [94]. A retrospective comparison of peri-operative intravenous cefazolin prophylaxis compared to no antibiotic showed no difference in infectious complications (surgical site, urinary tract, bacteraemia or central catheter-related infection) in the first month after renal transplantation [95].

**3.1.4.6 Is there a role for specific fluid regimes during renal transplantation and central venous pressure measurement in kidney transplant recipients?**

Careful peri- and post-operative fluid balance is essential for optimal renal graft function. There is no evidence determining if crystalloids or colloids are better for intravenous fluid management during renal transplant surgery, however colloids may be immunogenic. If normal saline (0.9%) is used, monitoring for metabolic acidosis is recommended in the peri-operative period. A prospective double-blind RCT compared normal saline to lactated Ringer’s solution as intra-operative intravenous fluid therapy. Serum creatinine at day three post-surgery did not differ between the two groups. However, Ringer’s lactate caused less hyperkalaemia and metabolic acidosis than normal saline. Balanced solutions may be the optimal and safer option for intra-operative intravenous fluid therapy [96].

Central venous pressure (CVP) measurement helps anaesthetists guide fluid management. A small prospective non-blinded RCT compared two normal (0.9%) saline regimens: constant infusion (10-12 mL/kg⁻¹/h⁻¹ from start of surgery until reperfusion) and CVP-based infusion (target CVP appropriate to stage of operation) [97]. Central venous pressure directed infusion produced a more stable haemodynamic profile, better diuresis and early graft function. Directed hydration may decrease DGF rates and CVP measurement may help optimise early graft function.

3.1.4.7 Is there a role for dopaminergic drugs, furosemide or mannitol in renal transplantation?

Low-dose dopamine (LDD) has been used in renal transplantation due to a perceived improvement in urine output and early graft function. Use of LDD in kidney donors is outside of the scope of this section. Conflicting results prevent a consensus statement on routine use of LDD in transplant recipients. A small (n=20) prospective randomised cross-over study in deceased donor renal transplantation suggested significant improvements in urine output and creatinine clearance in the first nine hours post-surgery without adverse events [98]. By contrast, a retrospective comparison of LDD in the first twelve hours post-deceased donor renal transplantation showed no difference in diuresis or kidney function, but those administered LDD (n=57) had increased heart rates, longer intensive therapy unit stay and higher six-month mortality than those not treated with LDD (n=48) [99].

Considerable variation exists in the use of diuretics during renal transplant recipient surgery and there is little evidence to suggest any benefit from their use [100]. No evidence on the use of mannitol during renal transplant recipient surgery was found during the panel’s literature search. Use of mannitol in kidney donors is outside the scope of this section.

3.1.5 Surgical approaches for first, second, third and further transplants

Transplant (bench/back-table) preparation is a crucial step in the transplantation process. The kidney must be inspected whilst on a sterile ice slush, removing peri-nephric fat when possible to permit inspection of the quality of the organ and to exclude exophytic renal tumours. Biopsy of the kidney on the back-table may be performed to help in the multifactorial decision-making process regarding the quality and usage of the kidney for both single and/or dual transplantation. Suspicious parenchymal lesions also require biopsy. Techniques for intra-operative kidney biopsy are discussed in section 3.1.3.

The number, quality and integrity of renal vessels and ureter(s) should be established and lymphatics at the renal hilum ligated. The quality of the intima of the donor renal artery should be evaluated. Branches of the renal artery not going to the kidney or ureter(s) should be tied.

In deceased donor kidney transplantation the quality of the aortic patch should be determined. If severe atheroma of the patch, ostium or distal renal artery is seen then the aortic patch and/or distal renal artery can be removed to provide a better quality donor renal artery for implantation. Back table reconstruction of multiple donor arteries is discussed in section 3.1.5.1. The length of the renal vein should be evaluated. Renal vein branches should be secured/tied.

For a deceased donor right kidney, lengthening the renal vein on the back table may be performed if needed with donor inferior vena cava (IVC) [101]. Techniques for lengthening a short living donor right renal vein from donor gonadal vein or recipient saphenous vein require pre-operative planning and specific consent (discussed in section 3.1.5.1).
The length, quality and number of the ureter(s) should be established. The peri-pelvic and proximal peri-ureteral tissue in the ‘golden triangle’ should be preserved.

### 3.1.5.1 Single kidney transplant - living and deceased donors

The standard surgical approach for first or second single kidney transplant (SKT) operations remains open kidney transplant (OKT). Emerging surgical technologies using minimal access surgical approaches have been developed and the different surgical approaches (minimally invasive open, laparoscopic and robot-assisted) were compared in a systematic review [102].

An extra-peritoneal approach to either iliac fossa should be used as the operative approach in most first or second SKT operations. There is no evidence to prefer placement of a left or right kidney into either iliac fossa [103]. Peri-iliac vessel lymphatics should be ligated to try and prevent post-operative lymphocele. Appropriate segments of iliac artery and vein should be mobilised to facilitate appropriate tension-free vascular anastomoses and the final positioning of the transplanted kidney. There is evidence supporting the benefits of cooling the kidney surface during implantation [104].

A variety of techniques have been described to help with the anastomosis of a short renal vein. This is most commonly encountered with a right kidney, especially from a living donor. To achieve equivalent outcomes with right kidneys appropriate surgical technical manoeuvres may be needed to optimise right kidney implantation.

A number of studies suggest marginally worse outcomes with use of the right compared to left kidney. Two large registry studies demonstrate a slightly higher risk of early graft failure using right compared to left kidneys from living donors [105-107]. A registry study of 2,450 paired kidneys, donated after cardiac death, observed with right kidneys: more early surgical complications; an increased risk in DGF (Odds Ratio [OR] 1.46); and inferior one year graft survival (OR 1.62), but not at subsequent time points [105]. However, surgical techniques used to compensate for a right kidney, anastomosis time and surgeon experience were not recorded. A recent registry study of 87,112 deceased-donor kidney recipient pairs reported a modest increase in DGF (adjusted OR 1.15) and all-cause graft failure (adjusted hazard ratio 1.07), within the first six months, associated with use of the right kidney, but there was no association with recipient mortality [108]. Furthermore, data from cohort studies [101, 103] and one registry study [104] suggest equivalent outcomes with either left or right deceased donor kidneys. Meta-analysis of data from one RCT and fourteen cohort studies suggested equivalent graft outcomes [109]. Overall, these findings do not support declining an organ for kidney transplantation based on laterality of kidney offered.

Techniques to manage a short renal vein can be addressed in the donor and/or recipient. Ligation of internal iliac vein(s) may be necessary to elevate the iliac vein and avoid tension on the renal vein anastomosis [103]. Transposition of the iliac artery and vein may enhance the position for the venous anastomosis [110]. The right renal vein may be lengthened. With deceased donor kidneys this is usually done with donor IVC [111]. In living donors, lengthening of the renal vein may be achieved with donor gonadal vein retrieved at donor nephrectomy [112] or with recipient saphenous vein [113], although both require specific consent and in general the other aforementioned techniques are preferred.

Recommendation | Strength rating
--- | ---
Assess the length of the donor renal vein and if it is short consider one of a variety of surgical techniques to optimise the venous anastomosis. | Weak

A history suggesting previous iliac or femoral vein thrombosis should initiate pre-operative imaging to establish patency of one iliac vein and the IVC. An intra-operative finding of an unexpected iliac vein and/or vena cava thrombosis may lead to abandonment of implantation. With pre-operative planning, native renal (orthotopic) or superior mesenteric vein or gonadal vein collaterals can be used.

The external or common iliac arteries are equally good for arterial anastomosis. The internal iliac artery is more frequently affected by atherosclerosis than the external or common iliac arteries. End-to-side anastomosis of donor renal artery to recipient external and/or common iliac artery is recommended in general over an end-to-end anastomosis to the internal iliac artery. The only RCT comparing these techniques suggests no difference [114]; however, the study was limited by small numbers and a high (8%) overall renal artery thrombosis rate.

The sites of the vascular anastomosis should be chosen carefully according to the length of the renal artery and vein to avoid kinking of the vessels when the kidney is placed into its final location, usually in the iliac fossa. The site of the arterial anastomosis should avoid atheromatous plaques in the iliac artery to decrease the risk of iliac artery dissection. The intima of the donor and recipient arteries should be checked prior to commencing the arterial anastomosis to ensure that there is no intimal rupture/flap. If this is found it must be repaired prior to, or as part of, the arterial anastomosis.

A Carrel patch is usually maintained on a deceased donor renal artery although it can be removed if there is either severe ostial atheroma/stenosis (with good quality proximal renal artery) or if the length of the renal artery is too long for the appropriate implantation site on the iliac artery (which is more common with the right renal artery).

Multiple renal arteries supplying a deceased donor kidney can be maintained on a Carrel patch (of appropriate length) and implanted as a single anastomosis. In living donor transplantation, multiple renal arteries require a variety of strategies to achieve optimum re-perfusion [100]. Two arteries can be implanted separately or to achieve a single anastomosis: a very small second artery (especially if supplying the upper pole) may be sacrificed; the two arteries may be joined together (as a trsour graft); or the smaller artery can be anastomosed onto the side of the main artery (end-to-side anastomoses). A lower polar artery may be re-vascularised via anastomosis to the inferior epigastric artery [115]. In living donor transplantation where three or more donor arteries exist, consideration should be given to alternate kidney donors. In circumstances using a living donor kidney with three or more donor arteries, strategies include a combination of the above techniques or, after appropriate consent, use an explanted (recipient’s own) internal iliac artery graft [116] or saphenous vein graft [117].

In cases where an iliac artery prosthetic replacement has previously been carried out because of severe symptomatic iliac atheroma, the renal artery should be implanted into the prosthesis. Administration of systemic heparin should be considered prior to clamping of a vascular prosthesis [118].

A variety of sutures and suturing techniques for the vascular anastomosis are described, but in general practice, a 5/0 and 6/0 non-absorbable mono-filament polypropylene suture(s) are used for the renal vein and renal artery anastomosis. Despite this, there is no evidence to recommend one suturing technique over another to prevent, for example, transplant artery stenosis. Use of an expanded polytetrafluoroethylene suture compared to standard polypropylene suture may reduce blood loss due to a better needle/thread ratio [119].

In third or further transplants the surgical approach must be planned pre-operatively so that appropriate arterial inflow and venous outflow exists with adequate space to implant the new kidney [120, 121]. Nephrectomy of an old transplant kidney may be required prior to transplantation or at the time of transplantation [120]. Mobilisation of the common or internal iliac artery, internal iliac vein or IVC may be required. An intra-peritoneal approach (via the iliac fossa or midline) may be required [122]. Rarely orthotopic transplantation is needed [120, 123].

Evidence suggests that minimising the anastomosis time and/or rewarming time results in reduced DGF [124]. The effect on long term graft function is uncertain, but may also be impacted by short Anastomosis time [125].

3.1.5.2 Robot-assisted kidney transplant surgery

Robot-assisted kidney transplant (RAKT) surgery using living donor kidneys has been evaluated in multi-centre prospective non-randomised studies (using IDEAL consortium principles) [126]. Single-centre prospective non-randomised studies are on-going addressing RAKT with use of deceased donor kidneys. Both trans- and extra-peritoneal approaches for RAKT are described. Potential advantages of RAKT may exist (decreased post-operative pain, incision length and lymphocele rate). Potential issues with RAKT are the exclusion of recipients with severe atherosclerosis or third (or further) kidney transplants, a higher than expected rate of DGF and a small number of reported early arterial thromboses despite carefully selected cases [127]. The learning curve for RAKT has been reported to be 35 cases for experienced surgeons in a retrospective multicentre series of 187 patients undergoing RAKT [128]. Complication and DGF rates decreased significantly and plateaued after the first 20 cases. The rate of Clavien-Dindo grade III/IV complications was 14% during the first ten RAKTs, but only 3% after this [128]. The rate of arterial graft thrombosis (1.6%) was comparable with that for open kidney transplant (0.5 - 3.5%) [128]. A ten year single-centre retrospective analysis of 239 obese RAKT patients concluded that RAKT can be safely performed in obese patients with minimal risk of developing a surgical site infection [129]. A graft failure rate of 7.1% was reported during follow-up mostly due to acute rejection. Patient and graft survival was 95% and 93% at three years, respectively [129]. Evidence is too premature to recommend RAKT outside of appropriately mentored prospective studies.

3.1.5.3 Dual kidney transplants

Dual kidney transplant (DKT) is performed when the quality of a single deceased donor kidney is thought to be insufficient for appropriate long-term graft function and that the outcome with both kidneys would be better. A variety of surgical techniques have been described to implant the pair of donor kidneys [130]. These include unilateral extra-peritoneal (UEP) or intra-peritoneal (UIP) and bilateral extra-peritoneal (BEP) or intra-peritoneal (BIP) that can be via a midline [131] or two lateral incisions.

The aim of a unilateral approach is to leave the contralateral iliac fossa intact for future transplantation in the event of graft loss and to reduce CIT for the second kidney transplant [132]. The unilateral approach may require mobilisation and division of the internal iliac vein to facilitate the two renal veins to iliac vein anastomoses. Modifications of the unilateral technique include single renal artery and vein anastomoses (with bench reconstruction) to further reduce CIT for the second kidney [133-135]. Dual kidney transplant takes longer and has higher blood loss than SKT regardless of the technique used. Data suggest shorter operative time and hospital stay with UEP compared to BEP [136], but other data suggest similar outcomes from all DKT techniques. No RCT exists to recommend one technique for all patients or situations.

En-bloc retrieval is performed when kidneys are retrieved from children weighing < 15 kg. Depending on the size of the donor kidney and size and weight of the adult recipient(s), en-bloc transplantation of the two kidneys may be performed or, if appropriate, the aorta and IVC patch may be divided for SKT [137].

3.1.5.4 Ureteric implantation in normal urinary tract

Ureteric anastomotic techniques described for renal transplant recipients with no underlying urological abnormality include: extra (Lich-Gregor) or intra (Leadbetter-Politano) vesical uretero-neo-cystotomy and uretero-ureterostomy using native ureter. A meta-analysis [138] of two RCTs and 24 observational studies
favoured the extra-vesical Lich-Gregoir technique to an intravesical approach leading to reduced overall complications (specifically urine leak, stricture and post-operative haematuria). Fewer urinary tract infections (UTIs) were observed with the extravesical approach when compared with the intra-vesical technique in one RCT [139]. Pyelo- or uretero-ureterostomy to the ipsilateral native ureter has been described as a primary technique in recipients with non-refluxing native ureters [140]. A meta-analysis suggested ureteric stricture, obstruction, and stone formation were more common after uretero-ureterostomy whereas vesicoureteral reflux and UTIs were more common after uretero-neo-cystostomy [141].

The donor ureter should be kept as short as possible with peri-ureteric fat preserved to ensure adequate ureteric blood supply. The location on the bladder to position an extra-vesical anastomosis was shown in one small RCT to be advantageous at the posterior bladder rather than anterior position to facilitate future endoscopic manipulation if needed, and reported less hydronephrosis post stent removal [142]. In cases where donor ureter has been damaged at retrieval then pyelo-native-ureterostomy or pyelo-neo-cystotomy can be performed. Mono-filament absorbable sutures should be used for the urinary anastomosis to prevent stone formation around the suture material [143].

Transplant ureteric anastomosis can be performed with or without a ureteric stent. If a stent is placed a second procedure is generally required for removal. A Cochrane review [144] concluded that stents are recommended to reduce major urological complications, especially urinary leak. The optimal timing for stent removal has yet to be defined [145]. A meta-analysis of five RCTS including 568 kidney transplantation patients showed a significant reduction in UTIs for early (≤ 7 days) vs. late removal (≥ 14 days) [146]. No significant differences where observed between the two groups in relation to post-operative complications such as ureteral stricture, ureteral obstruction, and ureteral leakage [146]. A second meta-analysis including 3,612 patients also reported a significant reduction in UTIs with early stent removal (< 3 weeks) vs. late removal (> 3 weeks) [147]. No significant differences where observed between the two groups regarding the incidents of ureteral stenosis and ureteral leakage [147].

Most commonly, stents are removed with local anaesthetic flexible cystoscopy unless there is a need to combine with another procedure warranting general anaesthetic. Various techniques to reduce the morbidity of a second procedure involve tying the stent to the catheter or use of percutaneous stents [148].

Duplex ureters are not infrequently identified at organ retrieval/kidney benching or during work-up for LDN [149, 150]. Duplex ureters can be anastomosed together and then joined to the bladder as one unit (double pant) or kept as two separate anastomoses. This also applies to the two single ureters in DKT in adults or with en-bloc transplantation from paediatric donors. The arguments for two separate ureteric anastomoses to the bladder are that an already tenuous blood supply may be further compromised with added suturing and handling, and if there is an issue with one ureter the other should remain unaffected. The advantages to forming one single (two ureter) anastomosis to the bladder are that only one cystotomy is needed; it may be faster and complications may be reduced. There is a lack of high-quality evidence relating to duplex ureters.

3.1.5.5 Transplantation/ureteric implantation in abnormal urogenital tract

The following points should be considered when performing kidney transplantation in the abnormal urogenital tract:

- In patients with an ileal conduit, a kidney transplant may be placed upside down to align the ureter to the conduit and avoid a redundant ureter [151].
- The technique used to implant transplant ureter(s) into an ileal conduit is the same as the method used with native ureter(s) (Bricker; Wallace).
- In bladder augmentation or continent pouches, ureters should be implanted with a tunnel technique or extra-vesically (Lich-Gregoir). The latter is favoured in most patients.
- In patients with a Mitrofanoff catheterisable stoma or continent ileo-caecal pouch with catheterisable stoma, consideration should be given to the positioning of the catheterisable stoma (umbilical or iliac fossa - usually right-side) with clear communication with the transplant surgeons so that the position of any future transplant kidney is not compromised. If an intra-peritoneal placement of a future kidney transplant is likely, then placement of a Mitrofanoff exiting in the iliac fossa is preferable at the umbilicus. If a future kidney transplant is likely in the right iliac fossa then placement of a Mitrofanoff exiting at the umbilicus or left iliac fossa may be preferable.

3.1.6 Donor complications

Living-donor nephrectomy, like any other intervention, is potentially associated with complications and mortality. However, the fact that the operation is performed on a healthy individual amplifies the relevance of any complications. Potential complications should be included in the process of informed consent.

Reported surgical mortality is 0.01% to 0.03% with no apparent alteration due to changes in surgical techniques or donor selection in recent years [152, 153]. According to a recent systematic review (190 studies) and meta-analysis (41 studies) on complications in minimally invasive LDN, reporting on a total of 32,308 LDNs, intra-operative complications occur in 2.2% (the most common being bleeding in 1.5% and injury to other organs in 0.8%) and post-operative complications occur in 7% (infectious complications in 2.6% and bleeding in 1%) [152]. Conversion to open surgery was reported in 1.1%, half due to bleeding and half due to injury to other organs. Surgical re-interventions occurred in 0.6%; the majority due to bleeding or to evacuate a haematoma [152]. A low trigger for conversion or re-operation should be observed in order to minimise the risk of serious complications.

A recent review looked for complications in 14,964 LDNs performed in the U.S. from 2008-2012 and found an overall peri-operative complication rate of 16.8%, gastrointestinal (4.4%), bleeding (3.0%), respiratory (2.5%), surgical/anaesthesia-related injuries (2.4%), and “other” complications (6.6%). Among the sample, 2.4% required intensive care and in-hospital mortality was 0.007% [16].

Major Clavien Classification of Surgical Complications grade IV or higher affected 2.5% of donors. Risk factors for Clavien grade IV or higher events included obesity (adjusted odds ratio [aOR] 1.55, \( p = 0.0005 \)), pre-donation haematologic (aOR 2.78, \( p = 0.0002 \)), psychiatric conditions (aOR 1.45, \( p = 0.04 \)) and robotic nephrectomy (aOR 2.07, \( p = 0.002 \)). An annual centre volume > 50 (aOR 0.55, \( p < 0.0001 \)) was associated with lower risk [16].

3.1.6.1 Long-term complications

Long-term complications are mostly related to the single-kidney condition. Renal function in living donors decreases after donation before improving for many years; however, in the long run it shows signs of slight deterioration [154-156]. There is a steady increase in the incidence of proteinuria; hypertension post-transplant having been shown as the main cause of increased albumin excretion [157].

The overall incidence of end-stage renal disease (ESRD) (0.4-1.1%) does not differ from the general population [154, 155, 158, 159]. According to a recent large retrospective study, the majority of ESRD developing after living kidney donation is due to new-onset disease that would have affected both kidneys [160]. However, there are some identified risk factors for deterioration of renal function after donation. According to a recent study that evaluated 119,769 live kidney donors in the United States, obese (BMI > 30) living kidney donors have a 1.9-fold higher risk for ESRD compared to their non-obese counterparts [161]. Long-term risk of death is no higher than for an age- and co-morbidity-matched population [153, 158].

Health related quality of life (HRQoL), including mental condition, remains on average better than the general population after donation [158, 159, 162]. However, some donors experience significant deterioration in their perceived QoL [162]. While global HRQoL is comparable or superior to population normative data, some factors identifiable around time of donation including longer recovery, financial stressors, younger age, higher BMI, lower education, smoking and higher expectations prior to donation, may identify donors more likely to develop poor HRQoL, providing an opportunity for intervention [158, 159, 162]. It is paramount that a careful
risk–benefit assessment is done and that proper information is given to the prospective donor, this should also include recommendations on health-promoting behaviour post-donation [163].

3.1.7 **Recipient complications**

3.1.7.1 **General complications**

Surgical complications during and after kidney transplantation may expose the recipient to an increased risk of morbidity and mortality. The incidence and management of such complications is therefore of primary importance [138, 145, 164-176]. We herein describe in detail the most common surgical complications in renal transplantation.

3.1.7.2 **Haemorrhage**

Haematomas are usually a minor complication in renal transplantation. Their incidence is reported to be between 0.2-25% [177, 178]. Small and asymptomatic haematomas do not usually require any intervention. In case of larger haematomas, clinical signs and symptoms due to external pressure with graft dysfunction and/or thrombotic graft vessel complications can be present. These cases may be treated by percutaneous drainage under computed tomography (CT) or ultrasound (US) guidance or may require surgical treatment [177].

3.1.7.3 **Arterial thrombosis**

Transplant renal artery thrombosis is a rare complication with a prevalence ranging from 0.5-3.5% [179]. Usually, it is a consequence of a technical error during the anastomosis although other causes may be related to both the donor and recipient's artery condition (i.e. atherosclerosis), intimal rupture during kidney harvesting, acute rejection episodes, external compression by haematoma or lymphocele, hypercoagulative state, severe hypotension, and toxicity of immunosuppressive agents (cyclosporine or sirolimus) [180]. The clinical manifestations are acute reduction of urine output and the elevation of renal function tests, often resulting in graft loss [177]. The diagnosis is obtained with eco-colour-Doppler [177]. Surgical exploration is usually recommended to evaluate the status of the graft. In the rare event the graft appears salvageable, a thrombectomy must be performed. In this situation, the iliac artery is clamped and an arteriotomy vs. a dissection of the vascular anastomosis must be performed in order to remove the clot. The graft can be flushed in-situ and re-vascularised [177]. Unfortunately, in the majority of the situations, the graft is not perfused and therefore an allograft nephrectomy must be performed [177, 181]. Alternatively, thrombolytic agent administration through a catheter directly into the transplant renal artery can be an efficient treatment, after the first ten to fourteen post-transplantation days [177].

3.1.7.4 Venous thrombosis

Transplant renal vein thrombosis is an early complication (prevalence 0.5-4%) and one of the most important causes of graft loss during the first post-operative month [182]. The aetiology includes technical errors and/or difficulties during surgery [177] and the hypercoagulative state of the recipient [183, 184]. Colour-Doppler-flow-ultrasonography shows absence of venous flow with an abnormal arterial signal (usually a plateau-like reversed diastolic flow). Furthermore, it is common to see an enlargement of the graft due to venous congestion [185]. Surgical exploration is usually recommended despite the fact that the majority of the cases will result in graft loss. In those cases where the venous thrombosis has not resulted in kidney loss at surgical exploration, a venotomy with surgical thrombectomy after clamping the iliac vein can be performed. Alternatively, an explantation and subsequent re-implantation can be considered [177]. Thrombolytic agents can also be used; however, their results have not been satisfactory [177, 186, 187].

Summary of evidence LE

| The diagnosis of renal vein thrombosis depends on colour-Doppler-flow-ultrasonography followed by surgical exploration to assess the status of the graft. | 2b |
| Thrombectomy in the case of a viable graft and allograft nephrectomy in the case a non-viable graft are the treatment options for renal vein thrombosis. | 2b |

Recommendations

| Perform ultrasound-colour-Doppler in case of suspected graft thrombosis. | Strong |
| Perform surgical exploration in case of ultrasound finding of poor graft perfusion. | Weak |
| If venous thrombosis is confirmed intra-operatively, perform a surgical thrombectomy in case of a salvageable graft or an allograft nephrectomy in case of a non-viable graft. | Weak |
| Do not routinely use pharmacologic prophylaxis to prevent transplant renal vein thrombosis. | Strong |

3.1.7.5 Transplant renal artery stenosis.

The incidence of transplant renal artery stenosis is 1-25% [188, 189]. Risk factors include small calibre and atherosclerosis of the donor artery, trauma to donor artery at procurement, absence of arterial patch, suturing technique (interrupted vs. continuous), and damage to the iliac artery during transplantation [190, 191]. It is more common at the site of the anastomosis [190, 191]. It can be suspected in case of arterial hypertension refractory to medical treatment and/or an increase in serum creatinine without hydronephrosis or urinary infection. The diagnosis is performed by US-colour-Doppler, showing a peak systolic velocity (PSV) of > 200 cm/s in the graft renal artery [190]. In cases of doubt a magnetic resonance angiogram or a CT angiogram can be performed [192]. It is important to determine whether the stenosis is haemodynamically significant or not. Usually, a stenosis of over 50% is considered a risk for kidney impairment [193]. In case of mild stenosis (<50%) and absence of symptoms with no deterioration of the allograft, management is normally conservative; although, a strict follow-up with US-colour-Doppler and clinical parameters has to be adopted due to the possible risk of graft failure [190]. In cases of clinically significant stenosis and/or > 50% on US-colour-Doppler, a confirmatory angiogram should be performed. If confirmed and a decision to treat is taken, treatments include percutaneous transluminal angioplasty/stent or surgical intervention. Interventional radiology is typically the first choice although patients considered unsuitable for radiological angioplasty due to recent transplant, multiple, long and narrow stenosis, or after failure of angioplasty may benefit from surgical treatment [190, 191].

Summary of evidence LE

| Suspect transplant renal artery stenosis in case of refractory arterial hypertension and/or increasing serum creatinine without hydronephrosis/infection. | 3 |
| The diagnosis for transplant renal artery stenosis is by US-colour-Doppler, showing a peak systolic velocity of > 200 cm/s in the graft renal artery. | 2a |
| Interventional radiology is the first-line treatment option for transplant renal artery stenosis; however, in patients considered unsuitable for radiological angioplasty surgical treatment may be considered. | 3 |

Recommendations

| Perform ultrasound-colour-Doppler to diagnose an arterial stenosis, in case of undetermined results on ultrasound consider a magnetic resonance or computed tomography angiogram. | Strong |
Perform percutaneous transluminal angioplasty/stent, if feasible, as first-line treatment for an arterial stenosis. | Strong
---|---
Offer surgical treatment in case of recent transplant, multiple, long and narrow stenosis, or after failure of angioplasty. | Strong

### 3.1.7.6 Arteriovenous fistulae and pseudo-aneurysms after renal biopsy

Percutaneous biopsy may result in arteriovenous (AV) fistulae and/or intra-renal pseudo-aneurysms in 1-18% of cases [194]. The aetiology of the AV fistula is related to the simultaneous injury of adjacent arterial and venous branches. A pseudo-aneurysm occurs when only the arterial branch is damaged. Both conditions are diagnosed with US-colour-Doppler [177]. The majority of AV fistulae are asymptomatic, resolving in one to two years spontaneously, whilst approximately 30% of them persist and become symptomatic. Typically, the symptoms are hypertension, haematuria, and graft dysfunction due to shunting between arterial and venous vessels. There is an increased risk of spontaneous rupture in case of enlarging pseudo-aneurysms. For both AV fistulae and pseudo-aneurysm, angiographic selective or super selective embolisation represents the treatment of choice [195]. Partial or radical allograft nephrectomy is currently considered the last option [177].

### 3.1.7.7 Lymphocele

Lymphocele is a relatively common (1-26%) complication [196]. There is a significant aetiological association with diabetes, mammalian target of rapamycin (mTOR) inhibitors (i.e. sirolimus) therapy, and acute rejection [197]. For large and symptomatic lymphocele, laparoscopic fenestration is associated with the lowest overall recurrence (8%) and complication (14%) rate compared to open surgery and aspiration therapy [198]. Placement of a percutaneous drain (i.e. Pig-Tail) is an option with a success rate as high as 50% [163]. Percutaneous aspiration can be performed although the recurrence rate can be as high as 95% [198], with an increased risk of local infection (6-17%) [198]. Furthermore, sclerosant agents such as ethanol, fibrin sealant, gentamicin, or octreotide reduce the recurrence rate compared to simple aspiration [198, 199].

### 3.1.7.8 Urinary leak

Urinary leakage occurs in 0-9.3% of cases [200]. Anastomotic urine leaks can be ureteral or vesical [201]. Ureteral necrosis and/or suture failure are the most important causes [202, 203]. Non-technical risk factors include recipient age, number of renal arteries, site of arterial anastomosis, occurrence of acute rejection episodes, bladder problems, and immunosuppressive regimen [204]. Urinary leak can be suspected by the urine output and the creatinine level in the drain fluid [202]. In order to decrease the risk of ureteral necrosis, it is important to preserve vascularisation of the distal ureter [202]. Furthermore, the routine use of a JJ-stent is recommended [203, 205]. The management of urinary leak depends on the location (renal pelvis, proximal or distal ureter, and bladder), the time of appearance and the volume of the leak. For early and low volume urine leaks the treatment may be conservative (i.e. urethral catheter, percutaneous nephrostomy and JJ-stent) [206]. In case of failure of the conservative management, or massive leak, surgical repair must be undertaken. Ureteral re-implantation directly to the bladder or to the native ureter provide similar results [141, 206].

3.1.7.9 Ureteral stenosis

Ureteral stenosis is a common complication in recipients, with an incidence of 0.6-10.5% [207]. Early stenosis (within three months of surgery) is usually caused by surgical technique or compromised ureteral blood supply during surgery. Late stenosis (after > six months) is provoked by infection, fibrosis, progressive vascular disease and/or rejection [202, 208]. Clinically significant ureteral stricture should be considered when persistent hydronephrosis on US occurs in association with impaired renal function. The first approach in the management of stricture is the placement of a percutaneous nephrostomy tube with an antegrade pyelogram [207]. The following treatment options depend mainly on the timing, recoverable kidney function, anatomy of the stricture, patient body habitus/comorbidities, and surgeon preference. Strictures < 3 cm in length may be treated endoscopically either with percutaneous balloon dilation or antegrade flexible ureteroscopy and holmium laser incision. In this scenario the success rate approaches 50%; although, maximum success is obtained for strictures < 1 cm [209-211]. In case of a recurrence after a primary endourological approach and/or stricture > 3 cm in length, surgical reconstruction should be performed [208] including direct ureteral re-implantation, pyelo-vesical re-implantation (with or without psoas hitch and/or Boari Flap) or in cases with a normal native ureter, uretero-ureterostomy [212, 213]. Long-term graft and patient survival are not significantly affected [214].

--- | ---
In case of ureteral stricture, place a nephrostomy tube for both kidney decompression and stricture diagnosis via an antegrade pyelogram. | Strong
Manage strictures < 3 cm in length either with surgical reconstruction or endoscopically (percutaneous balloon dilation or antegrade flexible ureteroscopy and holmium laser incision). | Strong
Treat late stricture recurrence and/or stricture > 3 cm in length with surgical reconstruction in appropriate recipients. | Strong

3.1.7.10 Haematuria

The incidence of haematuria ranges from 1-34% [200]. According to the literature, the Lich-Gregoire technique provides the lowest incidence of haematuria. Furthermore, meticulous haemostasis during re-implantation results in minimal bleeding [138, 200, 201]. Bladder irrigation is the first-line treatment. Some cases require cystoscopy with evacuation of clots and/or fulguration of bleeding sites [200].

3.1.7.11 Reflux and acute pyelonephritis

The frequency of vesicoureteral reflux is between 1-86% [200, 215]. Acute graft pyelonephritis occurs in 13% of graft recipients. Patients with lower tract urinary infections and cytomegalovirus (CMV) infection present a higher risk of acute graft pyelonephritis [216]. Endoscopic injection of dextranomer/hyaluronic acid copolymer may be the first approach for treatment of vesicoureteral reflux associated with acute pyelonephritis, with a success rate ranging from 57.9% after the first injection to 78.9% after the second injection [217]. Ureteral re-implantation or pyelo-ureterostomy with the native ureter is a viable second treatment option [212].

Recommendation | Strength rating
--- | ---
Use an endoscopic approach as first-line treatment for symptomatic reflux. | Weak
3.1.7.12 Kidney stones

Urolithiasis occurs in 0.2-1.7% of recipients [218, 219]. The most frequent causes are hyper filtration, renal tubular acidosis, recurrent UTIs, hypocitraturia, hyperuricaemia, hyperuricemia, excessive alkaline urine, persistent tertiary hyperparathyroidism and ureteral strictures [220, 221]. Another risk factor can be urinary anastomosis, with the lowest stone rate using Lich-Gregoir technique [219]. The most frequent clinical signs are fever, increased serum creatinine level, decreased urine output, and haematuria. Pain is usually not referred to due to impaired innervation. A US examination usually provides the diagnosis although a CT of the kidneys, ureters and bladder may be needed to confirm the location and size of the stone [220]. The management depends on the location and size of the stone, and the presence of obstruction. In case of obstructive stones first-line treatment includes placement of a nephrostomy tube, or in some occasions a JJ-stent [222]. Extracorporeal shock wave lithotripsy (ESWL) is usually considered the first approach for stones < 15 mm with stone-free rates varying between 40 and 80% depending on the location of the stone [222]. Ureteroscopy, including antegrade and retrograde approaches, can be considered for stones < 20 mm, with a success rate of up to 67% [140, 219, 223]. For larger stones (> 20 mm), percutaneous nephrolithotomy (PNL) can be offered with high overall effective stone-free rates. In cases of large impacted stones, uretero-ureteral anastomosis, pyelo-ureteral anastomosis, or uretero-vesical re-implantation may provide excellent results for both stone and ureteral obstruction [219].

3.1.7.13 Wound infection

Wound infections occur in about 4% of cases. Risk factors include recipients > 60 years, high BMI, anaemia, hypo-albuminemia, long surgical times (> 200 min) [224]. Bacteria commonly involved are Enterobacteriaceae, Staphylococcus aureus and Pseudomonas [212]. Subcutaneous sutures, pre-dialysis transplantation, sealing or ligation of lymphatic trunks, prophylactic fenestration, reducing corticosteroid load, and avoiding sirolimus/everolimus therapy can decrease wound complication rates [224].

3.1.7.14 Incisional hernia

Incisional hernia occurs in approximately 4% of open kidney transplantations. Risk factors include age, obesity, diabetes, haematoma, rejection, re-operation through the same transplant incision and use of m-TOR inhibitors. Mesh infection is a risk factor for incisional hernia recurrence [225]. Open and laparoscopic repair approaches are safe and effective [225].

3.1.8 Urological malignancy and renal transplantation

The following section is limited to a synopsis of three systematic reviews conducted by the EAU Renal Transplantation Panel.

3.1.8.1 Malignancy prior to renal transplantation

3.1.8.1.1 In the recipient

Standard procedure for transplant candidates includes systematic screening for the presence of any active/latent cancer or a past history of cancer. In candidates with a previous history of urological cancer, it can be challenging to decide if patients are suitable for transplantation and, if so, how long the waiting period prior to transplantation should be. To date, the waiting period has been primarily based on the Cincinnati Registry, which takes into account the type of tumour and the time between its treatment and kidney transplantation. However, the Cincinnati Registry has potential drawbacks as it does not consider the epidemiology of tumours.
or that diagnostic and therapeutic procedures/tests have changed over time and that prognostic tools have improved. Additionally, treatment and the staging of the disease are not defined.

According to a recent systematic review the risk of tumour recurrence was similar between transplantation (n=786) and dialysis (n=1,733) populations for renal cell carcinoma (RCC) and prostate cancer (PCa). This was especially true for low grade/stage PCa, for which the risk of recurrence was low and consistent with nomograms [226]. For low stage/grade RCC the recurrence rate was significant for both dialysis and renal transplantation; however, recurrences were actually contralateral RCC with no impact on patient or graft survival [226].

Testicular cancer had a low risk of recurrence but case reports highlighted the possibility of late recurrence even for stage I tumours [226].

For urothelial carcinoma, studies were mainly related to upper urinary tract carcinomas in the context of aristolochic acid nephropathy for which the rate of synchronous bilateral tumour was 10-16% and the rate of contralateral recurrence was 31-39% [226].

These findings imply that a kidney transplant candidate with a history of appropriately treated low stage/grade PCa (PSA ≤ 10, Gleason score ≤ 6 and T1/T2a) or low grade T1 RCC could be listed for renal transplantation without any additional delay compared to a cancer-free patient. However, as the level of evidence was low, more studies are needed to standardise waiting periods before renal transplantation.

### 3.1.8.1.2 In the potential donor kidney

In the general population, RCC constitutes 3% of all malignancies, with the incidence being highest in patients aged > 60 years. The current increasing age of donors may lead to a higher number of incidental RCCs found in donor kidneys and could theoretically decrease the number of kidneys suitable for transplantation. The main surgical approach to these kidneys is ex vivo tumour excision on the back-table with an oncological margin, frozen section biopsy, bench surgery renorraphy, and finally transplantation in the conventional fashion [227].

A recent systematic review assessed the effectiveness and harms of using kidneys with small renal tumours, from deceased or living donors, as a source for renal transplantation and it reported that five year overall and graft survival rates were 92% and 95.6%, respectively [227]. Tumour excision was performed ex vivo in all cases except for two (107/109 patients), and the vast majority of excised tumours were RCCs (88/109 patients), with clear-cell subtype the most common [227]. This systematic review, although with low-level evidence, suggested that kidneys with small renal masses are an acceptable source for renal transplantation and do not compromise oncological outcomes with similar functional outcomes to other donor kidneys.

3.1.8.2 Malignancy after renal transplantation

Cancer development after kidney transplant has become a major problem as it is one of the main causes of death in this population. Urological cancers, have an increased incidence after kidney transplantation partly due to the increasing age of recipients and their prolonged survival after transplantation.

Treatment of localised PCa following kidney transplantation is challenging due the presence of the kidney graft in the pelvic cavity close to the prostate. Two systematic reviews reported that oncological outcomes following PCa treatment in kidney transplant recipients are comparable to the non-transplanted population [228, 229] and surgery (radical prostatectomy), carried out in tertiary high-volume referral centres was the treatment choice in 75 to 85% of patients [228, 229]. Marra et al. reported cancer-specific survival rates of 96.8% for surgery, 88.2% for radiotherapy with androgen deprivation therapy and 100% for brachytherapy at mean follow-up of 24 months [229]. Hevia et al. reported five year cancer-specific survival of 97.5% for surgery, 87.5% for external beam radiation and 94.4% for brachytherapy [228].

3.1.9 Matching of donors and recipients

Histocompatibility antigens show remarkable polymorphism and human leukocyte antigen (HLA) matching is still very important in kidney transplantation as transplant outcome correlates with the number of HLA mismatches [230-233]. Human leukocyte antigen incompatibility can result in proliferation and activation of the recipient's CD4+ and CD8+ T-cells with concomitant activation of B-cell allo-antibody production. This may lead to cellular and humoral graft rejection. Matching should concentrate on HLA antigens, which impact outcome. Human leukocyte antigens A, B, C as well as DR must be determined in all potential recipients and donors according to current guidelines and national allocation rules [230-235]. Additionally, it is recommended to determine HLA-DQ antigens of donor and recipient. Furthermore, HLA-DP antigen characterisation may be performed, especially for sensitised recipients [230-235].

All patients registered for renal transplantation must have their serum screened for anti-HLA antibodies, which are particularly common after pregnancy, previous transplant, transplant rejection, and blood transfusions [230-235]. Thorough pre-transplant testing for HLA antibodies must be performed according to current recommendations [230-235]. Sera from potential organ recipients should be screened for HLA-specific antibodies every three months or as stipulated by the national and/or international organ exchange organisations [230-235]. In addition, screening for HLA-specific antibodies should be carried out at two and four weeks after every immunising event, e.g. blood transfusion, transplantation, pregnancy, and graft explantation [230-235]. Highly sensitised patients should have prioritised access to special allocation programmes [232, 233, 235], such as the acceptable mismatch (AM) programme of Eurotransplant [236]. A careful analysis of HLA antibody specificities must be carried out to avoid unacceptable HLA antigens and to determine acceptable HLA antigens in potential donors, who are expected to give a negative cross-match result. The definition of unacceptable HLA antigens should be implemented according to local allocation rules and international recommendations [230-234, 237]. The information on unacceptable HLA antigens should be highlighted with the patient's details in the database of the national kidney-sharing programme, preventing the unnecessary transport of kidneys to recipients with high antibody sensitivity.

To avoid hyper-acute rejection (HAR), adequate (e.g. CDC, virtual) cross-match tests must be performed before each kidney and combined kidney/pancreas transplantation in accordance with national and international recommendations [230-233, 235].
Laboratories which provide HLA-testing, HLA antibody testing and cross-matching for transplant centres must have valid accreditation to ensure accuracy and reliability [224, 225, 230-232]. They must follow the standards of national and international organisations, such as the European Federation for Immunogenetics [235].

Previously, compatibility for ABO blood group antigens and HLA antigens was of critical importance in kidney transplantation. This may change in the future, e.g. in the new U.S. allocation system A2 and A2B donors are transplanted into B recipients [233]. To avoid an increasing imbalance between demand and supply in deceased donor kidney transplantation in O recipients, ABO identity is demanded by several organ allocation organisations with a few exceptions, e.g. as in zero HLA-A+B+DR-mismatch kidneys [233, 234]. With the introduction of antibody elimination methods, potent immunosuppression and novel agents (e.g. anti B-cell drugs), successful ABO-incompatible living donor transplantations, with good long-term outcomes are possible [238, 239]. However, higher costs and infection rates have been described.

Even the barrier of a positive cross-match due to preformed HLA antibodies is under discussion with newer “desensitisation” techniques available in cases with available living donors [240, 241]. Success rates are lower, antibody-mediated rejections are frequent, but survival may be better compared to waiting list survival on dialysis. While this is a rapidly evolving field, further research is needed to define standard protocols. Until then such “desensitisation” protocols are experimental and patients undergoing “desensitisation” should be treated in specialised centres, where outcomes are documented. Patients should be informed adequately of the risks and limitations and alternative strategies (e.g. acceptable mismatch programmes, cross-over transplantation and donor chains) should be discussed.

### 3.1.10  **Immunosuppression after kidney transplantation**

The principle underlying successful immunosuppression is ‘the balance of survival’. Practitioners must prescribe a dosage of drug high enough to suppress rejection without endangering the recipient’s health. Increased understanding of immune rejection has led to the development of safe modern immune suppression agents [242, 243], which suppress sensitised lymphocyte activity against a transplant. Immunosuppression is particularly important during the initial post-transplant period when there is a high incidence of early post-transplant rejection.

In later post-operative stages, ‘graft adaptation’ occurs, resulting in the very low rejection rates seen in maintenance patients. Rejection prophylaxis should therefore be reduced over time by steroid tapering and gradual lowering of calcineurin inhibitor (CNI) [242-244].

Non-specific side effects of immunosuppression include a higher risk of malignancy and infection, particularly opportunistic infections [242-244]. All immunosuppressants also have dose-dependent specific side effects. Current immunosuppressive protocols aim to reduce drug-specific side effects using a synergistic regimen. A truly synergistic regimen allows profound dose reductions of immunosuppressive drugs; therefore, reducing side effects whilst still maintaining efficacy due to the synergistic effects of the immunosuppressants.

The currently recommended standard initial immunosuppression regime provides excellent efficacy with good tolerability [242-245]. It is given to most patients and consists of:
• calcineurin inhibitors (preferably tacrolimus, alternatively cyclosporine);
• mycophenolate (MMF or enteric-coated mycophenolate sodium [EC-MPS]);
• steroids (prednisolone or methylprednisolone);
• induction therapy (preferably basiliximab in low and standard risk patients and anti-thymocyte globulin [ATG] in high-risk patients).

This multidrug regimen reflects the current standard of care for the majority of transplant recipients worldwide [242-244] and may be modified according to local needs and immunological risk. This standard regimen is likely to change as new immunosuppressive drugs and new treatment regimens are developed [242-244]. In addition, any initial drug regimen will need to be tailored to the individual needs of a patient as suggested by the appearance of side effects, lack of efficacy or protocol-driven requirements.

<td>Strong</td>
</tr>
</tbody>
</table>

3.1.10.1 Calcineurin inhibitors

Both cyclosporine and tacrolimus have significant side effects that are hazardous to the graft and patient [242-249]. Most importantly, both are nephrotoxic [250, 251], and long-term use is an important cause of chronic allograft dysfunction [252], eventually leading to graft loss or severe chronic kidney disease in recipients of non-renal organs. Both CNIs are considered to be ‘critical-dose’ drugs, so that any deviations from exposure can lead to severe toxicity or failure of efficacy. Due to their narrow therapeutic window and the potential for drug-to-drug interaction, CNIs should be monitored using trough levels, which provide a reasonable estimate for exposure [249].

Meta-analysis of tacrolimus and cyclosporine has demonstrated similar outcomes with respect to overall patient and graft survival [242-248, 253, 254]. Tacrolimus provided better rejection prophylaxis and was associated with better graft survival, when censored for death in some analyses. Renal function was favourable for tacrolimus treated patients, in a number of trials [254-259]. Therefore, both CNIs can be used for the effective prevention of acute rejection, but due to higher efficacy tacrolimus is recommended by current guidelines as first-line CNI [243].

For both CNIs several different formulations are available [249, 260-268]. Tacrolimus once-daily dosing seems to be preferred by patients and is associated with better adherence and lower pharmacokinetic variability [249, 269, 270]. Precautions (e.g. close surveillance and determination of drug levels) should be instituted after conversion from one formulation to another [268, 271-275]. In case of specific side effects of a CNI (e.g. hirsutism, alopecia, gingival hyperplasia, diabetes, polyoma nephropathy) conversion to another CNI can be a successful strategy to reduce side effects [242-244, 276]. Due to differences in the efficacy and safety profile, the choice of CNI should include the individual risks and benefits for each patient.

Despite their side effects, CNIs have been a cornerstone of modern immunosuppressive regimens for more than thirty years as they have resulted in an exemplary improvement in kidney graft survival [242, 243]. Future protocols aim to minimise or even eliminate CNIs [244, 247, 249, 277-280]. However, until such strategies provide superior outcomes, CNIs remain the standard of care [242, 243, 281]. For severe CNI-related side effects, CNI withdrawal, replacement, or profound reduction may be needed [242, 244, 247, 277, 278]. Special attention should be paid to maintenance patients, who may need less CNIs than previously thought [242, 244, 249, 278, 279, 282].

3.1.10.2 Mycophenolates (MPA)
The mycophenolates, MMF and EC-MPS, are based on mycophenolic acid, which inhibits inosine monophosphate dehydrogenase (IMPDH) [283-287]. This is the rate-limiting step for the synthesis of guanosine monophosphate in the de novo purine pathway. As the function and proliferation of lymphocytes is more dependent on de novo purine nucleotide synthesis compared to other cell types, IMPDH inhibitors may provide more specific lymphocyte-targeted immunosuppression. The co-administration of MPA with prednisolone and CNI has resulted in a profound reduction of biopsy-proven rejections [242, 245, 283-287]. Mycophenolic acid is not nephrotoxic; however, it inhibits bone marrow function and may cause CMV infections and gastrointestinal side effects, particularly diarrhoea [242, 245, 283-287]. There is also a higher incidence of polyoma nephropathy, especially when mycophenolate is combined with tacrolimus [288].

Both MPA formulations are equally effective with an almost identical safety profile [240, 278, 281, 283-286], though some prospective studies suggest a better gastrointestinal side-effect profile for EC-MPS in patients who have suffered from MMF-related gastrointestinal complaints, although firm evidence from prospective randomised studies is lacking [283-287, 289].

Mycophenolic acid is recommended by guidelines [243]. Standard doses in combination with cyclosporine are MMF 1 g or EC-MPS 720 mg twice daily, although higher initial doses have been suggested [242, 243, 283-287]. Despite its frequent use with tacrolimus, there is insufficient evidence to support the optimal dosage for this combination [242, 283, 285, 286, 290]. Tacrolimus has no influence on MPA exposure and leads to approximately 30% higher MPA exposure compared to cyclosporine. Most transplant centres use the same starting dose as in cyclosporine-treated patients, however dose reductions are frequent, especially because of gastrointestinal side effects. Weak evidence suggests that MPA dose reductions are associated with inferior outcomes, especially in cyclosporine treated patients [284-286, 291, 292]. Due to the high incidence of side effects, some centres perform a protocol-driven MPA dose reduction in tacrolimus treated patients [283, 285]. Regular monitoring for polyoma (BK virus) is recommended in patients given MPA combined with tacrolimus [242, 288].

Due to a higher incidence of CMV disease with MPA [287], either CMV prophylaxis or a pre-emptive strategy with regular screening for CMV viraemia should be instituted [242, 293]. Cytomegalovirus prophylaxis with antiviral medications (e.g. valganciclovir) should be used routinely in CMV positive recipients and in CMV negative recipients of CMV positive organ transplants, because prophylaxis has recently been shown to reduce CMV disease, CMV-associated mortality in solid organ transplant recipients, and leads to better long-term graft survival in kidney allograft recipients.

The benefit for MPA drug monitoring is uncertain and currently not recommended for the majority of patients [283, 285, 286, 294].

In maintenance patients, the potency of MPA can be used for successful steroid withdrawal in most patients [295] or for substantial dose reductions of nephrotoxic CNIs, which may lead to better renal function [242-245, 247, 278, 296]. Although there have been several studies of the potential for CNI-free protocols with MPA and steroids, complete CNI avoidance or withdrawal over the first three years has been associated with a substantially increased rejection risk and even worse outcomes in prospective randomised studies [242, 244, 278]. In contrast, CNI withdrawal under MPA and steroids appeared to be safe in long-term maintenance patients beyond five years post-transplant and resulted in improved renal function [242, 244, 247, 278, 296, 297].

Recommendation Strength rating
Administer mycophenolate as part of the initial immunosuppressive regimen. Strong

3.1.10.3 Azathioprine
Mycophenolate is now routinely used as a primary therapy in place of azathioprine in most units worldwide. In comparison to azathioprine, MPA reduced rejection rates significantly in prospective randomised trials [242, 243, 245, 283-287]. Although a large, prospective study found that azathioprine may give acceptable results in a low-risk population [298], azathioprine is usually reserved for patients who cannot tolerate MPA [242, 243, 283, 284, 286]. When added to dual therapy with cyclosporine and steroids, a meta-analysis found no significant benefit for azathioprine with respect to major outcome parameters [299].

Recommendation Strength rating
Azathioprine may be used in a low-risk population as an immunosuppressive drug, especially for those intolerant to mycophenolate formulations. Weak

3.1.10.4 Steroids
Steroids have a large number of side effects [242-244, 295], especially with long-term use. Most practitioners still consider steroids (either prednisolone or methylprednisolone) to be a fundamental adjunct to primary immunosuppression, even though successful steroid withdrawal has been achieved in the vast majority of patients in many prospective, randomised trials [242, 244, 245, 295, 300, 301]. The risk of steroid withdrawal depends on the use of concomitant immunosuppressive medication, immunological risk, ethnicity, and time after transplantation. Although the risk of rejection diminishes over time, potential benefits may be less prominent after a prolonged steroid treatment period [242-245, 295]. Recent studies suggest similar efficacy but less diabetes after early steroid withdrawal or steroid minimisation in low-risk patients treated with tacrolimus, MPA and induction (either basiliximab or ATG) [302, 303].

Recommendations Strength rating
Initial steroid therapy should be part of immunosuppression in the peri-operative and early post-transplant period. Strong

Consider steroid withdrawal in standard immunological risk patients on combination therapy with calcineurin inhibitors and mycophenolic acid after the early post-transplant period. Weak

3.1.10.5 Inhibitors of the mammalian target of rapamycin (m-TOR)
The immunosuppressants, sirolimus and everolimus, inhibit the mammalian target of rapamycin and suppress lymphocyte proliferation and differentiation [242, 277, 304-306]. They inhibit multiple intracellular pathways and block cytokine signals for T-cell proliferation. Similar effects are seen on B-cells, endothelial cells, fibroblasts, and tumour cells. Inhibitors of m-TOR are as effective as MPA when combined with CNIs in preventing rejection [242, 245, 277, 304-307]. However, m-TOR inhibitors exhibit dose-dependent bone marrow toxicity [242, 277, 304-306]. Other potential side effects include hyperlipidaemia, oedema, development of lymphoceles, wound healing problems, pneumonitis, proteinuria, and impaired fertility. The extensive side effect profile is responsible for inferior tolerability compared to MPA and potential differences in outcome in early years, when higher doses were used [308-313].

To date, no prospective comparative studies have been carried out on the m-TOR inhibitors sirolimus and everolimus [314]. Both m-TOR inhibitors have an almost identical side effect profile and mainly differ in their pharmacokinetic properties [242, 277, 304-306, 315]. Sirolimus has a half-life of about 60 hours, is given once a day and is licensed for prophylaxis in kidney recipients only. Everolimus has a half-life of about 24 hours, is licensed for kidney, liver and heart recipients and is given twice a day. Everolimus is licensed for use with cyclosporine and can be given simultaneously with cyclosporine, while sirolimus should be given four hours after cyclosporine. The pharmacological drug-drug interaction with cyclosporine is far less relevant for tacrolimus, resulting in the need for a higher starting dose of m-TOR inhibitors in combination with tacrolimus [258, 316, 317]. Sirolimus is also licensed in combination therapy with steroids for cyclosporine withdrawal from combination therapy with cyclosporine.

Therapeutic monitoring of trough levels is recommended because of the narrow therapeutic window and the risk of drug-to-drug interactions [242, 277, 304-306, 315].
When combined with CNIs, antimicrobial prophylaxis for *Pneumocystis jirovecii* pneumonia should be administered for one year following transplantation, e.g. low-dose cotrimoxazole [242, 304-306]. Most importantly, combination therapy with CNIs aggravates CNI-induced nephrotoxicity, although m-TOR inhibitors themselves are non-nephrotoxic [242]. Several studies suggest less favourable outcomes and increased drug discontinuations due to adverse events for this combination, especially if CNIs are maintained at standard dosages [242, 245, 247, 258, 307, 309, 310, 318-323]. Calcineurin inhibitor dosage should therefore be substantially reduced in combination therapy with m-TOR inhibitors, which seems to have no impact on efficacy, due to the highly synergistic potential of this combination therapy [277, 304-306, 312, 315].

Several studies suggest m-TOR inhibitors cannot replace CNIs in the initial phase after transplantation due to lower efficacy and a less favourable side effect profile, particularly wound healing problems and lymphoedemas [240, 242, 243, 274, 298, 299, 304, 306, 314]. Other trials suggest that m-TOR inhibitors may replace CNI at later stages, e.g. three months after transplantation, with improvements in renal function, predominantly in cyclosporine treated patients [242, 244, 245, 247, 256, 277, 304-306, 309, 310, 312, 324-326]. It is unclear if there is a real benefit in comparison to patients on tacrolimus and MPA [256, 325]. However, there is an increased risk of rejection and development of HLA antibodies [242, 244, 256, 277, 327], which may be offset by the benefit of the non-nephrotoxic immunosuppression. Patients treated with m-TOR inhibitors develop less leucopenia and opportunistic viral infections, especially less CMV infections compared to MPA [258, 309, 312, 322-324, 328].

Proteinuria and poor renal function at conversion are associated with inferior outcomes [242, 244, 277, 304-306]. Conversion from CNIs is not advisable in patients with proteinuria > 800 mg/day, and a cautious and individual approach should be followed in patients with GFR < 30 mL/min.

Due to an anti-proliferative effect and a lower incidence of malignancy in m-TOR inhibitor treated patients, conversion from CNIs to m-TOR inhibitors may be beneficial for patients, who develop malignancy after transplantation, or who are at a high risk for the development of post-transplant malignancy or skin cancer [242, 244, 277, 304-306, 311-313, 329-332]. Several studies and case reports have suggested that patients with Kaposi sarcoma under CNI therapy benefit from conversion to an m-TOR inhibitor [330].

In summary, m-TOR inhibitors are not recommended as initial immunosuppressive therapy due to their side effect profile and higher discontinuation rates [243]. However, m-TOR inhibitors are a well-studied alternative treatment option.

#### 3.1.10.6 Induction with Interleukin-2 receptor antibodies

Basiliximab, a high-affinity anti-interleukin-2 (IL-2) receptor monoclonal antibody is approved for rejection prophylaxis following organ transplantation [242, 243, 245, 333-337]. Basiliximab is given before
transplantation and on day four post-transplant. The drug is safe, and IL-2 receptor antibodies have been shown in RCTs to reduce the prevalence of acute cellular rejection by approximately 40% [242, 243, 245, 333-335]. Meta-analyses [245, 333-335] have confirmed the efficacy, although no positive effect on patient or graft survival could be demonstrated, large retrospective cohort studies and recent large prospective studies suggest such a benefit [242, 243, 338, 339]. Several large controlled trials support the efficacy and safety of quadruple therapy with tacrolimus, mycophenolate and steroids. Interleukin-2 receptor antibodies may allow early steroid withdrawal [295], although higher rejection rates were described in some studies. Most importantly, IL-2 receptor antibodies allow a substantial reduction in CNIs or steroids, while maintaining excellent efficacy and renal function [242-245, 302, 333-335]. Therefore, this regimen is proposed as first-line immunosuppression in patients with low to normal immunological risk [243, 339].

### 3.1.10.7 T-cell depleting induction therapy

Prophylactic immunosuppression regimens in many countries, particularly the U.S., use potent T-cell depleting ‘induction’ treatments [242, 243, 245, 333, 338, 340-343]. Most frequently, ATG is used for prevention of rejection in immunological high-risk patients, as supported by meta-analysis [339], and recommended by guidelines [243, 344]. In addition, these potent biological agents are used for the treatment of severe, steroid resistant rejection episodes [340, 343].

Use of T-cell depleting antibodies in immunological low-risk patients has not been associated with improved long-term outcomes but with an increased risk of severe opportunistic infections and malignancy, particularly post-transplant lymphoproliferative disease [242, 243, 245, 333, 339-341]. Some centres use these agents to provide effective rejection prophylaxis in order to facilitate steroid withdrawal [302, 338, 342].

### 3.1.10.8 Belatacept

Belatacept is a fusion protein, which effectively blocks the CD28 co-stimulatory pathway and thereby prevents T-cell activation [277, 345, 346]. Belatacept is intravenously administered and indicated for use as part of a CNI-free regimen together with basiliximab induction, MPA, and corticosteroids. Long-term data from three randomised studies of de novo kidney transplant recipients demonstrated better renal function vs. cyclosporine-based immunosuppression, although rates and grades of acute rejection were higher for belatacept in the first year post-transplant [242, 245, 257, 277, 345-351]. In patients receiving a standard deceased or living donor kidney, better graft survival was observed, while similar graft survival rates were found with ECDs. Interestingly, belatacept-treated patients had better preserved histology and developed less donor specific antibodies (DSA) compared to cyclosporine [352]. The long-term safety profile of belatacept treated patients was similar to cyclosporine controls, less belatacept treated patients developed metabolic complications or discontinued treatment due to adverse events [350, 351, 353, 354]. In addition, the option of converting patients (either stable patients or due to CNI or m-TOR associated toxicity) was explored with promising initial results [348, 355-357]. Specific safety signals include a higher rate of post-transplant lymphoproliferative disorder (especially in Epstein-Barr virus (EBV) negative patients), more herpes infections, and tuberculosis in patients from endemic areas [277, 345, 346]. Belatacept was approved in the U.S. and in Europe for EBV positive patients, but is not yet available in many countries. Additional studies are ongoing to fully explore the value of this compound.

### 3.1.11 Immunological complications

Immunological rejection is a common cause of early and late transplant dysfunction [243, 358-362]. There is great variation in the timing and severity of rejection episodes and how they respond to treatment. Today two
main types of immunological reactions are distinguished, T-cell mediated rejections (TCMR) and antibody-mediated rejections (ABMR) [243, 358-360]. Antibody-mediated rejection and TCMR may be diagnosed together, called mixed acute rejection. Antibody-mediated rejection may occur as hyperacute rejection (HAR), active rejection or chronic rejection. Chronic ABMR is considered as one of the leading causes of late graft loss.

The ultimate standard for the diagnosis of rejection is transplant biopsy [243], because it is impossible to differentiate acute rejection solely on clinical indicators from other causes of renal dysfunction (e.g. acute tubular necrosis, infection, disease recurrence or CNI nephrotoxicity). Therefore, all rejections should be verified by renal biopsy and biopsies should be classified according to the most recent Banff criteria [363], which are the basis for prognosis and treatment [241, 358, 361]. Renal transplant biopsy should be conducted preferably under US control, using an automated needle biopsy system (e.g. Tru-Cut biopsy gun) [243, 358] with a 16 G needle to assure specimen adequacy. The biopsy procedure is considered safe but complications such as bleeding and AV fistulas may occur [243, 364, 365]. The reported risk of major complications (including substantial bleeding, macroscopic haematuria with ureteric obstruction, peritonitis or graft loss) is approximately 1%. Most important contraindications are anti-coagulant therapy including anti-platelet agents and uncontrolled hypertension.

### 3.1.11.1 Hyper-acute rejection

Hyper-acute rejection is the most dramatic and destructive immunological attack on the graft [230, 243, 358, 359]. It results from circulating, complement-fixing IgG antibodies, specifically reactive against incompatible donor antigen, which engages with and destroys the vascular endothelium within minutes or hours after vascularisation. It occurs in ABO-incompatible grafts due to the presence of high titres of pre-existing iso-antibodies against blood group antigens. In ABO-matched grafts, HAR is mediated by anti-donor HLA IgG antibodies. With the development of the cross-match test before transplantation, HAR has become an extremely uncommon complication [230]. Imaging and histology reveals generalised infarction of the graft, which has to be treated by graft nephrectomy. Therefore, prevention is crucial, either by avoidance of high iso-antibodies against incompatible blood group antigens in case of an ABO-incompatible renal transplant and/or by performing a regular cross-match before transplantation (see section 3.1.9).

<td>Prevent hyper-acute rejection by adequate ABO blood group and HLA matching of donor and recipients.</td>
</tr>
</tbody>
</table>
3.1.11.2 Treatment of T-cell mediated acute rejection

As only a few randomised trials have investigated different treatment options for this clinical problem, therapy is mainly based on empirical experience rather than on clinical evidence [243, 343, 358, 366]. Parenteral methylprednisolone (500 mg to 1 g) should be given intravenously as one pulse per day for three days. Anuria or a steep rise in the serum creatinine may indicate steroid-refractory rejection and the need for another three day course of pulsed methylprednisolone therapy [243, 358]. In addition, baseline immunosuppression should be optimised to ensure adequate drug exposure [243, 358, 366]. In severe rejection, a conversion from cyclosporine to tacrolimus and/or from azathioprine to MPA is recommended [243, 358].

T-cell depleting biological agents, such as ATG may be given in severe steroid-refractory cases [243, 340, 343, 358, 366]. If biological agents are used, other immunosuppressive therapy should be adapted and daily T-cell monitoring should be considered to minimise the dose of the biological agent [340]. Before immunosuppression is intensified, especially before the use of T-cell depleting agents, the prognosis of the graft should be critically assessed against the risks of the aggravation of immunosuppression. The patient should be counselled adequately.

3.1.11.3 Treatment of antibody mediated rejection (ABMR)

Treatment of ABMR relies mainly on retrospective studies and empirical treatment guidelines [367]. Consensus is that it is important to classify the clinical and histological phenotype of the rejection in order to make adequate treatment decisions [367]. Important clinical factors are time of rejection (early acute < 30 days post-transplant vs. late), presence of vs. de novo donor-specific antibodies (DSA), and histology (active vs. chronic rejection).

For active ABMR due to pre-existing DSA treatment with a steroid bolus (at least three days of 500 mg/day) in combination with intravenous immunoglobulin (IVIG) and plasmapheresis or immune-adsorption is recommended. Intravenous immunoglobulin (IVIG) [243, 358, 368-373] may modulate and/or suppress antibody production. Intravenous immunoglobulin alone seems insufficient for effective treatment and IVIG is used today in a multimodal regimen. Dosages vary widely from 0.2-2.0 g/kg bodyweight, and no comparative studies (e.g. on the dose or optimal concomitant immunosuppression) have been published. Retrospective and prospective case series clearly suggest efficacy of antibody removal using plasmapheresis or immune-adsorption columns [243, 358, 368-373], although details of the procedures vary widely. Adjunctive therapies such as complement inhibitors, rituximab or splenectomy might be considered in severe early acute cases. Despite controversial data on the utility of anti-CD20 antibody [243, 343, 358, 368-373], rituximab may also be considered as adjunctive therapy in late active ABMR according to expert consensus. Although T-cell depleting agents such as ATG appear to have limited value they are frequently used during mixed acute rejection [241]. However, retrospective series suggests aggravated toxicity, when rituximab is combined with ATG [374], or steroids [343]. Furthermore, many centres will optimise maintenance therapy with MPA and steroids and sufficient tacrolimus trough levels should be achieved [243, 358, 368-370, 373].

Chronic acute mixed rejection due to pre-existent DSA has no specific treatment recommendations except for optimisation of maintenance therapy and eventually IVIG as an adjunctive treatment with a low level of evidence. In patients presenting with de novo DSA optimisation of maintenance, immunosuppression is recommended and non-adherence should be addressed and managed accordingly. If histology shows active ABMR plasmapheresis, rituximab and IVIG can be considered as potential adjunctive agents without good evidence from clinical trials. If biopsy demonstrates pure chronic ABMR no special treatment is recommended due to lack of convincing data, except for IVIG as potential treatment option without firm evidence. Treatment for chronic ABMR appears to be less successful [358, 368, 370].

In summary, several regimens have proven some efficacy in ABMR. However, except for a beneficial effect of early antibody removal, the lack of firm evidence does not permit evidence-based recommendations for treatment. As a consequence, prevention of ABMR by adequate pre-transplant screening, regular DSA monitoring, avoidance of suboptimal immunosuppression and reinforcement of adherence are crucial [230, 358, 372, 375].
3.1.12 Follow-up after transplantation
Long-term graft function is of critical importance for the success of a transplant [243, 244]. Therefore, regular long-term follow-up by experienced transplant physicians is essential in order to detect complications or graft dysfunction early and reassure adherence to the immunosuppressive regimen. Complications of immunosuppression occur frequently including specific complications of the different drugs as well as over immunosuppression (namely opportunistic infections and malignancy) [243, 244]. The risk of cancer and cardiac disease is several-fold higher in transplanted patients than in the general population. Cancer is a cause of significant morbidity and mortality in the transplanted population [243, 376, 377]. Cardiovascular disease is the most frequent cause of death in renal allograft recipients [243, 378, 379]. Other important long-term problems are non-adherence, the development of anti-HLA antibodies, recurrence of the original disease and CNI associated nephrotoxicity [243, 244].

3.1.12.1 Chronic allograft dysfunction/interstitial fibrosis and tubular atrophy
Many patients lose their grafts due to chronic allograft dysfunction [243, 244, 380]. Histology will usually reveal a chronic process of interstitial fibrosis and tubular atrophy (IF/TA) [381]. Some patients will have immunological chronic ABMR [382], as discussed in section 3.1.11.3. Interstitial fibrosis and tubular atrophy takes months or years to develop and is heralded by proteinuria and hypertension, with a simultaneous or delayed rise in serum creatinine level over months [243, 380, 381]. It is likely that IF/TA is more common in patients who have had early attacks of acute rejection or infection. The main differential diagnosis is chronic nephrotoxicity [383], which is common in patients receiving CNIs, and pre-existing and/or aggravated chronic kidney damage from a marginal donor kidney [243, 380, 381].

Diagnosis is by renal biopsy [243, 380]. In patients diagnosed early, particularly if there is evidence for CNI toxicity, disease progression may be slowed by conversion to a CNI-free regimen [201-203, 263, 264]. Conversion to m-TOR inhibitors is an option for patients without significant proteinuria (< 800 mg/day), but moderate renal function [242-244]. Alternatively, successful conversion to a mycophenolate based regimen has been described, especially in patients beyond the first three years post-transplant [242, 244, 278]. If there is intolerance to m-TOR inhibitors or MPA, conversion to belatacept or an azathioprine-based regimen may be successful, though the higher risk of rejection warrants close surveillance [357]. If the risk of rejection seems too high, another option is substantial reduction of CNI under the protection of MPA [244, 278].

In patients with proteinuria, intervention with an angiotensin converting enzyme inhibitor, or angiotensin II receptor blocker [243, 380] together with tight blood pressure control may slow down renal progression. Other supportive measures include the treatment of hypertension, hyperlipidaemia, diabetes, anaemia, acidosis, and bone disease [243]. However, ultimately, the patient will require another transplant (if fit enough to go on the transplant waiting list) or dialysis therapy.

</tbody>
</table>
Regularly monitor (approximately every four to eight weeks) serum creatinine, estimated glomerular filtration rate, blood pressure, urinary protein excretion, immunosuppression and complications after renal transplantation. Changes in these parameters over time should trigger further diagnostic work-up including renal biopsy, a search for infectious causes and anti-HLA antibodies.

Perform an ultrasound of the graft, in case of graft dysfunction, to rule out obstruction and renal artery stenosis.

In patients with interstitial fibrosis and tubular atrophy undergoing calcineurin inhibitor (CNI) therapy and/or with histological signs suggestive for CNI toxicity (e.g. arteriolar hyalinosis, striped fibrosis) consider CNI reduction or withdrawal.

Initiate appropriate medical treatment, e.g. tight control of hypertension, diabetes, proteinuria, cardiac risk factors, infections, and other complications according to current guidelines.

    11.3.2.1 Flow-rate analysis during follow-up after urethral surgery 73
    11.3.2.2 Post-void residual ultrasound measure during follow-up after urethral
    surgery 73
    11.3.2.3 Symptoms questionnaires during follow-up after urethral surgery 73
  11.3.3 Quality of life assessment, including disease specific questionnaires during
    follow-up after urethral surgery 74
11.4 Ideal follow-up interval after urethral surgery 74
11.5 Length of follow-up after urethral surgery 75
11.6 Risk stratified proposals during follow-up after urethral surgery 75
11.7 Follow-up protocol proposal after urethroplasty 75
  11.7.1 Surgeries with low risk of recurrence 75
  11.7.2 Surgical management options with standard risk of recurrence 76

12. REFERENCES 78
13. CONFLICT OF INTEREST 108
14. CITATION INFORMATION 108
1. INTRODUCTION

1.1 Aims and scope
The European Association of Urology (EAU) Urethral Strictures Guidelines aim to provide a comprehensive overview of urethral strictures in male, female, and transgender patients. The Panel is aware of the geographical variations in healthcare provision.

It must be emphasised that guidelines present the best evidence available to the experts; however, following guideline recommendations will not necessarily result in the best outcome. Guidelines can never replace clinical expertise when making treatment decisions for individual patients, but rather help to focus decisions - also taking personal values and preferences/individual circumstances of patients into account. Guidelines are not mandates and do not purport to be a legal standard of care.

1.2 Panel composition
The EAU Urethral Strictures Guidelines panel consists of an international multidisciplinary group of clinicians with particular expertise in this area. All experts involved in the production of this document have submitted potential conflict of interest statements which can be viewed on the EAU website: http://www.uroweb.org/guideline/urethral-strictures/.

1.3 Available publications
Alongside the full text version, a quick reference document (Pocket Guidelines) is available in print and as an app for iOS and Android devices. These are abridged versions which may require consultation together with the full text version. All documents can be viewed through the EAU website: http://www.uroweb.org/guideline/urethral-strictures/. A list of supplementary tables supporting this text can also be found online, along with an appendix of abbreviations specific to this text: https://uroweb.org/guideline/urethralstrictures/?type=appendices-publications.

1.4 Publication history
This document is a new Guideline first published in 2021. Additional information can be found in the general Methodology section of this print, and online at the EAU website: http://www.uroweb.org/guideline/. A list of associations endorsing the EAU Guidelines can also be viewed online at the above address.

1.5 Summary of Changes
This 2022 guideline represents a limited updated of the original 2021 text. References have been updated and now refer the reader to the final versions of the Panel's summary and systematic review papers. Minor grammatical and formatting issues have also been addressed.

2. METHODOLOGY

2.1 Methods
For the 2021 Urethral Strictures Guidelines, new and relevant evidence was identified, collated, and appraised through a structured assessment of the literature. A broad and comprehensive literature search, covering all sections of the Guidelines was performed. Databases searched included Medline, EMBASE, and the Cochrane Libraries, covering a time frame between 2008 and 2019 and restricted to English language publications. The panel defined by consensus inclusion and exclusion criteria for each topic before the scope search. Detailed search strategies are available online: https://uroweb.org/guideline/urethral-strictures/.

Relevant literature prior to the 2008 scope search cut-off was allowed if it was estimated to be of exceptional value by the panel. Relevant literature after the 2019 scope search cut-off was searched for by the panel member dedicated to a specific topic.

For each recommendation within the guidelines there is an accompanying online strength rating form, the basis of which is a modified GRADE methodology [1, 2]. Each strength rating form addresses a number of key elements namely:

1. the overall quality of the evidence which exists for the recommendation, references used in this text are graded according to a classification system modified from the Oxford Centre for Evidence-Based Medicine Levels of Evidence [3];
2. the magnitude of the effect (individual or combined effects);
3. the certainty of the results (precision, consistency, heterogeneity and other statistical or study related factors);
4. the balance between desirable and undesirable outcomes;
5. the impact of patient values and preferences on the intervention;
6. the certainty of those patient values and preferences.

These key elements are the basis which panels use to define the strength rating of each recommendation. The strength of each recommendation is represented by the words ‘strong’ or ‘weak’ [4]. The strength of each recommendation is determined by the balance between desirable and undesirable consequences of alternatives.

The Panel wants to highlight that “success” in urethral stricture treatment is poorly defined and subjective. “Success” is usually defined as urethral patency, either subjective by the absence of voiding symptoms or objective by imaging or urethral calibration. Despite urethral patency, the patient themselves might not consider the treatment as successful because of functional consequences (e.g., post-void dribbling, erectile/ejaculatory dysfunction, altered genital appearance). In this Guideline, the Panel agreed to avoid the term “success”. Instead, the term “patency rate” or “stricture recurrence rate” will be used to clarify that only stricture recurrence was taken into consideration (as assessed by the authors).

The Panel would like to stress that patency after urethral surgery is dependent on the general principles of wound healing. These principles have stood the test of time and need to be respected [5]. Some examples:

- An anastomosis should be made between healthy urethral ends and without any tension.
- A graft requires a well-vascularised graft bed with a close contact between the graft and graft bed to promote imbibition and inosculation.
- If the full circumference of the urethral mucosa is destroyed, spontaneous regeneration will not take place.
- Contraction and fibrosis in a wound only stops after it is covered by its epithelium.

The Panel conducted two systematic reviews (SR) to support guideline recommendations, which were published in 2021:

- What is the role of single-stage oral mucosa graft urethroplasty in the surgical management of Lichen Sclerosus-related stricture disease in men? A systematic review [6];
- Free Graft Augmentation Urethroplasty for Bulbar Urethral Strictures: Which Technique Is Best? A Systematic Review [7].

The results of these reviews are included in the 2022 Urethral stricture guidelines.

In addition, the panel drafted three summary papers of the guidelines which were published in European Urology and European Urology Focus:

- EAU guidelines on urethral stricture disease (part 1): management of male urethral stricture disease [8];
- EAU Guidelines on urethral stricture disease (part 2): diagnosis, perioperative management, and follow-up in males [9];
- EAU guidelines on urethral stricture disease (part 3): management of strictures in females and transgender patients [10].

2.2 Review
The Urethral Strictures Guidelines were peer reviewed prior to initial publication in 2021.

2.3 Future goals
A further SR was conducted in 2021 and will see publication in 2022:

- Is a course of intermittent self-dilatation (ISD) with topical corticosteroids superior at stabilising urethral stricture disease in men and improving functional outcomes over a course of ISD alone?

An update of the strictures guideline will be conducted when deemed necessary, but at latest after five years. Further SRs will be conducted after approval of the Guidelines Office.
3. DEFINITION, EPIDEMIOLOGY, AETIOLOGY AND PREVENTION

3.1 Definitions
In males, a urethral stricture refers to a narrowed segment of the anterior urethra due to a process of fibrosis and cicatrisation of the urethral mucosa and surrounding spongious tissue (“spongiofibrosis”) [11, 12]. In the male posterior urethra, there is no spongious tissue and at this location the terms stenosis is preferred [11, 12]. The definition of meatal stenosis is generally accepted as a short distal narrowing at the meatus, without involvement of the fossa navicularis [12].

There is no universal definition for what constitutes a female urethral stricture (FUS). Female urethral stricture is defined by most authors as a ‘fixed anatomical narrowing’ causing reduced urethral calibre [13, 14]. This reduced urethral calibre is variously defined as between < 10 Fr to < 20 Fr [15, 16] with the majority of series defining < 14 Fr as diagnostic, compared with a ‘normal’ urethral calibre of 18-30 Fr.

In transgender patients, the term stricture is also used to define a narrowing of the reconstructed urethra despite the absence of surrounding spongious tissue.

3.2 Epidemiology
In males, a sharp increase in incidence is observed after the age of 55 years, with a mean age of 45.1 [17, 18]. Overall, the incidence is estimated to be 229-627 per 100,000 males [17]. The anterior urethra is most frequently affected (92.2%), in particular the bulbular urethra (46.9%) [18].

In females, 2-29% of patients presenting with refractory lower urinary tract symptoms (LUTS) have bladder outflow obstruction (BOO) [19-22] of whom 4-20% will have a urethral stricture [21-23]. True FUS therefore occurs in 0.08-5.4% of women with refractory LUTS. There is a markedly increased incidence in women over 64 years of age [24].

In children, most strictures are traumatic: related to iatrogenic causes in 27.8-48% and external trauma in 34-72% [25]. Less frequent congenital (13%), inflammatory (4%), or post-infectious strictures (1%) are seen. The bulbular urethra is the most frequently affected part of the urethra [25].

After hypospadias repair, meatal stenosis and urethral strictures are reported in 1.3-20% of cases, depending on the severity of the hypospadias and the technique used [26]. There is a significantly higher incidence of this type of strictures in well-resourced countries due to a higher surgical repair rate [27].

Up to 18% of all urethral strictures have been reported to involve the meatus or fossa navicularis, usually due to failed hypospadias repair (FHR), lichen sclerosus (LS), trauma/instrumentation or idiopathic causes [28-31].

Meatal stenosis post-circumcision has been reported in less than 0.2% of children undergoing circumcision as neonates [17].

In female-to-male (FtM) transgender patients (“trans men”), approximately 51% will suffer a urethral stricture [32]. Strictures almost exclusively arise at the neomeatus in male-to-female (MtF) transgender patients (“trans women”) and occur in 14.4% of cases [33].

3.3 Aetiology and prevention
Stricture aetiology differs significantly throughout different regions in the world, due to differences in healthcare quality and environmental and practice patterns [27]. Regardless of geography, urethral stricture disease adversely impacts physical health and quality of life (QoL) [34, 35], notwithstanding costs associated with the treatment of primary and recurrent disease [36, 37]. The rationale for preventing urethral strictures is to avoid morbidity to the individual and costs to society. Prevention of urethral strictures encompasses reducing the causes of stricture (e.g., infection, trauma, iatrogenic injury) and where this is not possible, mitigating the risk.

3.3.1 Aetiology and prevention in males
a. Sexually transmitted infection
Urethritis due to sexually transmitted infection (STI), in particular gonorrhoea, was previously a major cause of urethral strictures in well-resourced countries accounting for 40% of all cases [38]. The wide-scale promotion of safe sexual practices and easier access to sexual health services, resulting in timely treatment with
antimicrobials, is thought to have led to the considerable reduction in the problem [38]. Infective urethritis now accounts for 0.9% to 3.7% of cases in contemporary series from well-resourced countries [38, 39] but continues to be the major cause of strictures in low-resourced countries comprising 41.6% of all strictures [40].

### Summary of evidence LE

</table>

### b. Inflammation

Lichen sclerosus involves the urethra in 20% of cases [41] and is the most common cause of panurethral stricture disease (48.6%) [18]. The aetiology of LS has not been fully elucidated but is thought to have an autoimmune origin [42]. Lichen sclerosus may be associated with environmental factors and non-autoimmune comorbidities. Uncircumcised men are far more likely to suffer LS than circumcised men (age-adjusted odds ratio [OR] of 53.55; 95% confidence interval [CI]: 7.24-395.88) [43]. Lichen sclerosus is also associated with higher mean body mass index (BMI), diabetes mellitus, coronary artery disease, tobacco usage, hyperlipidaemia, and hypertension [44-46].

### c. External urethral trauma

External trauma to the urethra is the second most common cause of stricture formation in adults [38]. The urethra is vulnerable to trauma during certain activities including sport, driving a vehicle, sexual intercourse and during combat. The bulbar urethra is the site most frequently affected by blunt trauma [12], usually as a result of straddle injuries or kicks to the perineum. Penile fracture is associated with a urethral injury in 15% of cases [47]. Motor vehicle accidents are the main cause of blunt injuries to the posterior urethra associated with pelvic fractures [48]. Penetrating injuries of the urethra are uncommon during non-combat situations [49].

### d. Iatrogenic urethral injury

Iatrogenic injury to the urethra is one of the most common causes of strictures in well-resourced countries [18, 38] accounting for 32-79% of all strictures [38, 50]. In children, specifically iatrogenic causes were identified in 6.7-25% of cases [51]. Preventing iatrogenic urethral injury represents the main way in which urologists can prevent urethral strictures. Iatrogenic urethral injury most commonly results from urethral instrumentation (e.g., catheterisation, cystoscopy), surgery for benign prostatic obstruction (BPO), surgery for prostate cancer, or radiotherapy [39].

#### d.1 Urethral catheterisation

Urethral strictures are a recognised complication of urethral catheterisation accounting for 11.2-16.3% of all strictures [18, 38]. In a meta-analysis by Hollingsworth et al., the pooled percentage of patients who developed urethral stricture or erosion after short-term catheterisation (< 3 weeks) in higher-quality studies was 3.4% (CI: 1-7%) [52]. In studies comprised mainly of men with spinal cord injury with indwelling urethral catheters, the pooled estimate of urethral stricture or erosion was 8.7% (CI: 0.0-18.7%) [52].

Urethral strictures following catheterisation may arise as a consequence of injury during attempts at insertion or during the period a catheter remains in situ. During insertion, the urethra may be injured by formation of a false passage by the catheter tip (29.7%) or inflation of the balloon within its lumen (70.3%) [53]. The rate of urethral injuries due to catheterisation was found to be 3.2 per 1,000 inpatients [54]. A six-month prospective multicentre study found that of 37 patients with catheter-related urethral trauma referred to urologists, 24% continued to perform ISD once weekly and 11% required at least one urethral dilation for urethral stricture [55]. In another follow-up study of 37 patients with catheter-related urethral trauma, 78% of patients developed urethral stricture [53]. The most common locations of trauma are the bulb and posterior urethra [56].

Catheter-related trauma can be prevented through several measures [57]. Studies have indicated around 25% of all indwelling catheterisations in hospitals were unnecessary and inappropriate [58, 59]. Implementation of guidelines [60, 61] and specific criteria [62] have been shown to reduce catheterisation rates. Several studies have identified deficits in the knowledge of urethral catheterisation amongst resident doctors [63, 64]. This is postulated to be a factor in catheter-related trauma [64]. A targeted training program on urethral catheterisation
for nursing staff was shown to be effective in reducing iatrogenic urethral injuries in a prospective single institution study [54].

In addition to guidance and education, another approach to safer catheterisation is modification of the standard Foley catheter. A novel catheter balloon pressure valve safety system was developed to prevent balloon inflation injury though this has not been assessed in comparative studies [65, 66]. Bugeja et al., studied the use of urethral catheterisation device (UCD) incorporating a guidewire, in prospective observational cohort study that included 174 patients. The incidence of adverse events was 7% with standard Foley catheterisation vs. 0% with the UCD (no statistical analysis was performed) [67]. A further prospective observational study found that Seldinger technique catheterisation could be used successfully by non-urology trained doctors [68]. These technologies need to be further assessed in prospective randomised controlled trials (RCTs), incorporating cost-benefit analysis.

Catheter diameter is suggested as a possible contributing factor to urethral stricture due to a pressure effect on the urethral wall [69]. Decreasing the catheter size from 22 Fr to 18 Fr significantly decreased the risk of fossa navicularis strictures (6.9% vs. 0.9%, p=0.02) after radical prostatectomy (RP) [70]. Catheter material may also have an influence on the occurrence of stricture. In the 1970s/80s several comparative studies in patients undergoing cardiac surgery demonstrated that non-coated latex catheters were associated with a greater incidence of urethritis and more stricture formation than silicone catheters [71-73]. Other studies showed no difference [74-76]. Modern latex catheters have polymeric coatings [77] due to the concern with regards to stricture alongside the risk of hypersensitivity and the demonstrable in vitro toxicity of latex. Prolonged urethral catheterisation has also been implicated in the aetiology of stricture (e.g., poly-trauma, burns patients) [50].

Summary of evidence

| A significant proportion of catheter insertions in hospitalised patients were considered unnecessary. | 2b |
| Educational programs can reduce the incidence of catheter-related urethral injury. | 2a |
| Larger catheter size was associated with a greater risk of navicular fossa strictures. | 3 |
| Non-coated latex catheters are associated with a greater degree of urethritis and possibly a greater risk of urethral strictures, than non-latex catheters or coated latex catheters. | 1a |

Recommendations

| Avoid unnecessary urethral catheterisation. | Strong |
| Implement training programmes for physicians and nurses performing urinary catheterisation. | Strong |
| Do not use catheters larger than 18 Fr if urinary drainage is the only purpose. | Weak |
| Avoid using non-coated latex catheters. | Strong |

d.2 Transurethral prostate surgery

Urethral stricture following transurethral prostate surgery occurs in between 4.5-13% of patients [78], whereas bladder neck stenosis (BNS) occurs in between 0.3-9.7% [79]. Transurethral surgery is the most common cause of iatrogenic urethral stricture accounting for 41% of all causes [50]. The most common location for urethral stricture is the bulbomembranous urethra, followed by the fossa navicularis and penile urethra [80, 81]. Postulated mechanisms include friction at the penoscrotal junction, lack of adequate lubrication, repetitive ‘in and out’ movement of the resectoscope, breach of mucosal integrity leading to urine extravasation and monopolar current leak due to inadequate resectoscope insulation [82]. Bladder neck stenosis may be related to excessive and/or circumferential resection and the use of relatively large resection loops which may generate excessive heat in small intraurethral adenomas leading to scarring [79, 83]. Stenoses of the posterior urethra may also be due to a prolonged period of post-operative inability to void [84].

d.2.1 Risk factors for development of urethral stricture and bladder neck stenosis

Several risk factors for the development of urethral stricture and BNS following transurethral prostate surgery have been identified. Both prostatic inflammation (OR: 4.31) and operative time > 60 min (OR: 4.27) were found to be independent predictors of stricture after monopolar transurethral resection of prostate (TURP) [85]. In terms of bipolar TURP, slower resection rate (OR: 0.003), intraoperative urethral mucosa rupture (OR: 2.44) and post-operative infection were shown to be independent predictors (OR: 1.49) [86, 87]. A larger-calibre endoscopic sheath (26 Fr vs. 24 Fr) was associated with a greater risk of bulbular urethral stricture following monopolar TURP (11.4% vs. 2.9%, p=0.018) [88]. Room temperature irrigation solution was associated with a greater risk of urethral stricture following combined transurethral resection and vapourisation of the prostate compared to body temperature irrigation (21.3% vs. 6.3%, p=0.002) [89].
Bladder neck stenosis is known to occur more frequently in smaller prostate glands after both monopolar and bipolar TURP [90, 91]. Lee et al., found that adenoma weight was an independent risk factor for BNS after monopolar TURP [91]. Meanwhile, Tao et al., found total prostate volume (< 46.2 g) (OR: 1.5), but not resected gland weight, to be an independent risk factor [86].

d.2.2 Incidence of urethral stricture and bladder neck stenosis with different energy modalities

A SR and meta-analysis by Cornu et al., showed no significant differences in urethral stricture and BNS rates by energy modality (monopolar, bipolar, holmium laser enucleation, photoselective vapourisation) [78]. In another meta-analysis assessing outcomes of thulium (Tm:Yag) laser and bipolar TURP, no difference in urethral stricture and BNS rates were found between the two modalities [92]. The presence of potentially confounding factors such as endoscopic sheath diameter, energy setting used, procedural length and length of follow-up make inter-study comparisons between energy modalities problematic. Overall, there is no strong evidence that any single modality is associated with a clinically significant higher incidence of urethral stricture and BNS than others. Selection of modality should be based on a comprehensive evaluation of clinical safety and efficacy. A summary of incidences of urethral stricture and BNS with different modalities is presented in Table 3.1.

d.2.3 Interventions to prevent urethral stricture and bladder neck stenosis

Sciarra and colleagues conducted a single-blind RCT (n=96) to assess the use of rofecoxib for stricture prevention following TURP. At twelve months follow-up a urethral stricture was found in 17% and 0% of cases in the placebo and rofecoxib groups, respectively (p=0.0039) [93]. Chung et al., conducted a single blinded RCT (n=180) evaluating the effect of urethral instillation of hyaluronic acid (HA) and carboxymethylcellulose (CMC). Urethral stricture on urethrography was diagnosed in 1.25% and 8.64% of patients in the treatment and placebo group respectively (p=0.031). Further RCTs are needed to confirm these findings and the safety of the pharmacological interventions.

Several earlier comparative studies assessed whether routine preliminary urethrotomy with an Otis urethrotome prevented the incidence of stricture following TURP [94-97]. Only one of these reported at least twelve-month follow-up, finding no significant difference in stricture rate in patients undergoing TURP alone vs. Otis urethrotomy followed by TURP (21% vs. 14%) [98]. Others have suggested performing internal urethrotomy where there are pre-existent meatal or urethral strictures [99].

Adjunctive transurethral incision of the prostate (TUIP) at the end of TURP to reduce the rates of BNS was studied by Lee et al. [91]. A total of 1,135 patients of whom 667 underwent TURP and 468 underwent TURP plus TUIP were retrospectively studied. At median follow-up of 38 months, the incidence of BNS was 12.3% for the TURP group vs. 6.0% for the TURP plus TUIP group (p < 0.001). In glands < 30 g, the incidence of BNS in the TURP vs. the TURP plus TUIP group was 19.3% and 7.7%, respectively (p < 0.05). The clinical efficacy and safety of additional surgical interventions to prevent urethral stricture and BNS need to be confirmed in larger prospective RCTs before their use can be recommended.

Summary of evidence

An RCT with more than twelve months follow-up failed to demonstrate a significant reduction in stricture rate using routine urethrotomy prior to TURP.

1b
d.3 Radical prostatectomy
Radical prostatectomy has been associated with vesico-urethral anastomosis stricture (VUAS) in 0.5-30% of patients [79], though most modern series report it in the range of 1-3% [100]. The risk of stricture formation after salvage RP is notably higher (22-40%) [101]. Most VUAS develop within the first two years [101, 102]. A 2012 meta-analysis by Tewari et al., showed no significant difference in VUAS between open-, laparoscopic and robotic RP [103]. In contrast, a more recent analysis of a national cohort in the UK found that VUAS rate after robotic RP was 3.3%, which is significantly lower than following laparoscopic (5.7%) or open RP (6.9%) [104]. These findings are consistent with an earlier similar study conducted in the USA [105]. The difference in VUAS rates may be explained by the level of experience and surgical volume of surgeons [106]. The cohort studies represent “real world” data, including all levels of surgical experience and surgical volumes whereas the meta-analysis is based on clinical studies. Thus, the better outcomes for robotic RP in the population studies may be related to the shorter learning curve [107].

d.3.1 Risk factors for development of vesicourethral anastomosis strictures
These include higher grade cancer, more advanced stage, higher prostate volume, coronary artery disease, obesity, hypertension, diabetes mellitus, previous bladder outlet surgery and older age [100, 108, 109]. Surgical factors include the use of non-nerve-sparing technique, anastomotic urine leak, increased operative time and increased estimated blood loss [100, 108, 109]. In addition, low-volume surgeons (< 40/year) were shown to have higher VUAS rates, 27.7%, compared to high-volume surgeons (> 40/year), 22% [110].

d.3.2 Interventions to prevent vesicourethral anastomosis strictures
Srougi et al., studied bladder neck mucosal eversion in a prospective RCT of 95 patients. No significant difference was found in rates of VUAS at twelve months follow-up [111]. A meta-analysis by Kowelewski et al., comparing interrupted vs. continuous vesico-urethral anastomosis suturing found no difference in VUAS rates [112]. Another SR by Bai et al., compared barbed sutures to conventional sutures, and although heterogeneity across studies precluded meta-analysis, no patients developed VUAS with either approach [113].

d.4 Prostate radiation and ablative treatments
Urethral strictures occur in 1.5% of patients undergoing external beam radiation therapy (EBRT), 1.9% having brachytherapy (BT) and 4.9% who receive combination EBRT-BT at around four years follow-up [114]. These strictures typically occur in the bulbomembranous urethra [115]. As opposed to RP, stricture incidence after irradiation increases with time [101, 114]. For the ablative treatments, the stricture incidence after cryotherapy and high-intensity focused ultrasound (HIFU) is 1.1-3.3% and 1-31%, respectively [101]. The use of these treatment modalities in the salvage setting is associated with increased risk of stricture formation: 3-10% after salvage EBRT, 5-12% after salvage cryotherapy and 15-30% after salvage HIFU [101]. Due to the increasing utilisation of prostate irradiation (EBRT, BT) and ablative treatments (cryotherapy, HIFU), an increasing number of respectively radiation-induced and ablative treatment-induced strictures are expected [116].

d.4.1 Risk factors for the development of radiation strictures
Awad et al., performed a multivariate meta-regression analysis including 46 studies, finding combining EBRT + BT and length of follow-up to be significant predictors of urethral stricture following prostate radiation [114]. Factors not shown to predict urethral stricture included biochemical equivalent dose, age, and androgen deprivation therapy [114]. Previous TURP was not included in the analysis, but has been found to be an independent predictor of stricture (HR: 2.81) in a previous multivariate analysis from a single institution [117] as well as PSA level < 10 ng/ml (HR: 0.47) [118].

d.4.2 Interventions to prevent radiation induced urethral strictures
Delaying adjuvant or salvage EBRT by nine months is associated with lower rates of urethral stricture (HR: 0.6) [119]. This has to be balanced with risk of delaying treatment in terms of cancer control [79]. In BT, it has been reported that downward movement of needle applicators occurs between fractions [120]. This may explain why strictures occur below the prostatic apex [118] in the so called “hot spot” [121]. Several measures taken together are thought to have contributed to a reduction in urethral stricture formation with BT including reduction of dosing to the “hot spot”, more careful needle placement, avoiding midline insertion and the introduction of plastic needles rather than steel [114].

e. Failed hypospadias repair.
Although urethral strictures after hypospadias repair are sometimes considered as iatrogenic [38], they are a very specific subtype and should be considered as a separate entity. The main reasons for this are the absence of spongyous tissue at different levels within the penile urethral segment, and the lack of high-quality local tissues for urethral reconstruction [122].
f. Congenital
The diagnosis of a congenital urethral stricture can only be made in the absence of other possible aetiology, such as iatrogenic, inflammatory, and traumatic causes [25]. Congenital strictures are thought to be consequent to incomplete or incorrect fusion of the urethra formed from the urogenital sinus with the urethra formed following closure of the urethral folds. They typically have a deep bulbar location and are usually short. In general, congenital strictures are diagnosed at a young age (Moorman’s ring or Cobb’s collar).

g. Idiopathic
Idiopathic strictures are seen in 34% of all penile strictures and in 63% of all bulbar strictures [123]. Unrecognised trauma is thought to be a possible aetiology of idiopathic urethral strictures [27].

3.3.2 Aetiology in females
The cause of FUS was idiopathic in 48.5%, iatrogenic in 24.1%, resulting from prior urethral dilations, difficult/traumatic catheterisation with subsequent fibrosis, urethral surgeries (mainly diverticulum surgery, fistula repair and anti-incontinence procedures) and trauma (mainly following pelvic fracture) in 16.4% [124-136]. Radiation therapy and infections are rare causes of FUS [137]. The most common segment of urethra affected is the mid- or mid-to-distal (58%). Panurethral strictures are rare (4%) [15, 124, 126, 127, 129-131, 136, 138].

For further information see online supplementary Tables S3.1 and S3.2.

4. CLASSIFICATIONS

4.1 According to stricture location
Classification according to stricture location is important as this will affect further management.

4.1.1 In males
4.1.1.1 Anterior urethra
The anterior urethra runs from the meatus to the urogenital diaphragm and is surrounded in its entire length by the corpus spongiosum [11, 139]. Further subdivision is made in three different areas (from distal to proximal) [12):

Meatal strictures: these strictures are located at the external urethral meatus and may extend into the fossa navicularis of the glans.

Penile strictures: these are located in the segment between the fossa navicularis and the bulbar urethra. Externally, the penile urethra begins approximately at the balanopreputial sulcus and continues to the penoscroetal junction. The whole penile urethral segment lies in the groove ventral to corpora cavernosa and is surrounded by a thin layer of corpus spongiosum.

Bulbar strictures: the bulbar urethra starts at the penoscroetal junction and is surrounded by the bulbospongious muscle. It ends in the membranous urethra proximally at the level of the urogenital diaphragm. The bulbar urethra can be subdivided into a proximal and distal part. The proximal bulbar urethra is defined as the segment within 5 cm of the membranous urethra; the urethra lies eccentrically in this part with abundant ventral spongious tissue. The distal bulbar urethra is defined as the adjoining segment extending to the penoscroetal junction [140]. Strictures extending towards the membranous urethra are termed bulbomembranous strictures (BMS).

Penobulbar strictures: these extend from the penile urethra into the bulbar segment, compromising long segments of urethra.

The difference between penobulbar strictures and multifocal strictures should be noted. The latter are defined by two or more narrowed segments, either in the same or different subdivision of the urethra but preserving healthy lengths of urethra between them (e.g., iatrogenic strictures related to TUR procedures which typically affect the fossa navicularis and the penoscroetal junction with healthy urethra in between).

4.1.1.2 Posterior urethra
The posterior urethra is approximately 5 cm long, with three different segments [12]:
- The membranous urethra is the area of the urethra traversing the urogenital diaphragm, between the proximal bulbar and the distal verumontanum.
• The prostatic urethra runs through the prostatic gland, starting at the proximal membranous urethra and extending to the bladder neck.
• The bladder neck is surrounded by the internal urinary sphincter and is the junction between the prostatic urethra and the bladder. Stenosis (or contracture) of the bladder neck implies a prostate in situ (i.e., after TURP or simple prostatectomies). If the narrowing or obliteration appears at this level but after a RP, the correct term is VUAS [12].

4.1.2 In females
The female urethra is approximately 4 cm long and arbitrarily divided in an upper, mid, and lower part [15, 124, 126, 127, 129-131, 136, 138].

4.2 According to stricture tightness
The definition of low- vs. high-grade strictures remains debatable [141-143]. A urethral plate less than 3 mm is considered a high-grade or tight stricture [144]. It has been demonstrated with a normally functioning bladder that flow rate will not diminish until the urethral lumen has a diameter below 10 Fr [142].

Table 4.1 presents a suggested classification for male patients with a normal functioning bladder. This classification was developed by the EAU Urethral Stricture Panel based on a consensus process.

4.3 Strictures in transgender men and woman
4.3.1 Trans women
After MtF gender confirming surgery, the penile urethra has been resected. Meatal strictures are defined as strictures occurring at the neomeatus, which is formed between the junction of the distal bulbar urethra and the neovagina. The other segments (bulbar and posterior) are the same as in a biological man.

4.3.2 Trans men
Four different areas can be identified in the urethra after FtM gender confirming surgeries [145]:
• The native urethra is the female urethral segment which remains preserved during surgery. It goes from the bladder neck to the original external meatus.
• The fixed part (pars fixa) or perineal urethra follows the native urethra, starting at the original external meatus. This segment is reconstructed using local tissues, typically vestibular mucosa, or anterior vaginal mucosa. Its course is similar to the bulbar urethral segment in males, but without being covered by spongiosal tissue.
• The anastomotic part is the area where the pars fixa joins the neophallus.
• The phallic urethra is the segment located within the neophallus or the metoidioplasty and is usually made of skin tube. Its course is similar to the penile urethra in males, but without being covered by spongiosal tissue.

5. DIAGNOSTIC EVALUATION

A comprehensive diagnostic evaluation of urethral stricture disease encompasses clinical history and examination, urinalysis (+/- culture), uroflowmetry and post-void residual (PVR) assessment, radiography, and endoscopy.
5.1 Patient history
The purpose of history taking is to assess symptoms including severity and duration, possible aetiology, prior treatments, complications, associated problems, and patient factors that may impact upon surgical outcome.

The clinical presentation of urethral stricture disease is varied. In a retrospective analysis of 611 patients with an endoscopically confirmed diagnosis of urethral stricture, LUTS were the most common presentation (54.3%) followed by acute urinary retention (22.3%), urinary tract infection (UTI) (6.1%) and difficult catheterisation (4.8%) [146]. In a retrospective study of 214 patients who underwent anterior urethroplasty, weak stream was reported as the most common individual LUTS (49%) followed by incomplete emptying (27%) and urinary frequency (20%) [147]. A further retrospective series of 614 patients undergoing anterior urethroplasty found post-void dribble to be present in 73% [148].

Genitourinary pain is a common feature, affecting 22.9-71% [34, 146]. Pain may be felt in the bladder and/or urethra, is associated with more severe LUTS, is more likely to be felt by younger men and resolves in most following reconstruction [34]. Other complaints include spraying (9%), visible haematuria (3.1-5%), urethral abscess/necrotising fasciitis (2.3%), urgency (14%) and incontinence (1-4%) [146, 147].

To establish aetiology, an enquiry about a history of pelvic, genital, or perineal trauma, prior instrumentation, prior surgeries, irradiation or focal therapies and urethritis should be made. It is important to document prior surgical approaches and date of the most recent intervention (e.g., dilatation) as this may impact upon the timing of radiological evaluation or surgical treatment.

Problems of sexual function are common in patients with urethral stricture disease [149, 150] and sexual function may be impacted upon by surgical intervention [151, 152]; therefore, the status of erectile and ejaculatory function should be established and documented using validated tools.

The performance status of the patient should be determined as it may influence the choice of treatment (curative or palliative). A past medical history should assess for factors that may impact upon tissue healing including diabetes, immunosuppression, and smoking. Oral tobacco use or the chewing of betel leaves may increase the risk of morbidity at the harvest site or render oral mucosa too poor for use. Prior harvest of oral mucosa should be noted as alternative sources for tissue transfer may need to be considered [153] or alternative surgical approaches (e.g., perineal urethrostomy [PU]).

5.2 Physical examination
The abdomen should be examined for the presence of a palpable bladder. The location of any suprapubic tube should be noted to assess its potential utility for antegrade cystoscopy or the placement of a sound (to facilitate repair) [154]. Examination of the genitalia should note the presence of foreskin, the position and size of the meatus as well as any evidence of scarring suggestive of LS. Pre-operative biopsy to confirm LS may be performed if this alters management and is essential if malignancy is suspected [155].

The presence of penile or perineal fistulae should be noted. The urethra should be palpated to assess for induration suggestive of significant fibrosis. Rarely a mass may signify a urethral carcinoma. A rectal examination to assess for prostatic pathology, which may be the cause of urinary symptoms, should be undertaken. In patients with posterior urethral stenosis rectal adherence to the prostate and the mobility of the surrounding tissues should be assessed [156]. The oral cavity should be examined for the suitability of oral mucosa. Measurement of BMI will identify obese individuals who are at greater risk of leg compartment syndrome when placed in the lithotomy position for a prolonged time period [157]. Assessing hip mobility is important when considering an exaggerated lithotomy position as some patients may have limited hip flexion due to unresolved orthopaedic problems [154].

5.2.1 Further diagnostic evaluation
5.2.1.1 Patient reported outcome measure (PROM)
The first validated urethral stricture surgery PROM (USS-PROM) was reported in 2011 [158]. It consists of six LUTS questions derived from the International Consultation on Incontinence Questionnaire Male LUTS (ICIQ-MLUTS) module, a LUTS-specific QoL question, the Peeling voiding chart and the EQ-5D to assess overall health-related QoL (HRQoL). The post-operative questionnaire contains an additional two questions to assess overall patient satisfaction. This PROM has been validated in several other languages (German, Spanish, Italian, Dutch, Turkish, Polish, Japanese) and is increasingly used in research studies as well as clinical practice. A further PROM is in development in North America but requires validation [159] (see section 11. Follow-up).

5.2.1.2 Urinalysis and urine culture

Urinalysis is an essential component of the work up of patients with LUTS. If infection is suggested, urine culture should be performed to confirm the diagnosis and identify the causative organism and sensitivity to antibiotics. Bacteriuria should be treated prior to surgical intervention to prevent peri-operative sepsis [160] (see section 10. Peri-operative care).

5.2.1.3 Uroflowmetry and post-void residual estimation

A reduced maximum flow rate with a prolonged plateau is characteristic of the constrictive obstruction caused by urethral stricture. However, interpretation of flow patterns is subjective and is not considered a reliable screening tool for the detection of stricture [161]. To overcome this, a statistical model based on uroflowmetry parameters was developed and was found to predict urethral stricture with a sensitivity of 80–81% and a specificity of 77–78% [161]. Uroflowmetry is usually combined with ultrasound (US) estimation of PVR to identify patients with urinary retention who may require emergent bladder drainage. Uroflowmetry parameters can also be used for monitoring patients and in the assessment of treatment response (see section 11. Follow-up).

Urodynamic studies are not indicated in the vast majority of patients with urethral stricture disease. In patients with suspected bladder dysfunction (e.g., severe storage LUTS, history of irradiation or neurological disease), an assessment of bladder function may help surgical decision making and patient counselling. Similarly, when there is concern that flow impairment or increased PVR are due to detrusor underactivity or an acontractile detrusor, a urodynamic study may help predict the likelihood that the patient would need to perform intermittent self-catheterisation (ISC) post-operatively. The only urodynamic parameter found to distinguish a diagnosis of urethral stricture from BPO is urethral closure pressure which is lower in the former due to the constrictive nature of the obstruction (22.07 vs. 28.4 cm H2O, p=0.0039, r=0.61, BPO vs. stricture) [162].

5.2.1.4 Urethrography

Retrograde urethrography (RUG) has widely been used as the investigation of choice for evaluating the stricture presence, location, length, and any associated anomalies (e.g., false passages, diverticula) [163].

The reported sensitivity and specificity of RUG in the diagnosis of strictures is 91% and 72%, respectively [164]. The positive predictive value (PPV) was 89% and the negative predictive value (NPV) was 76% [164]. Most reports suggest that RUG underestimates stricture length [165, 166]. Interpretation of RUG findings by urologists were found to be more accurate at predicting urethral stricture location and length as compared to evaluation by an independent physician [167].

Limitations of RUG include difficulty assessing very distal strictures and assessing the proximal extent of strictures which are too narrow to permit passage of adequate contrast. Combining a RUG with voiding
cystourethrography (VCUG) can allow adequate visualisation of the urethra proximal to the stricture and a more accurate assessment of stricture length in (nearly) obliterative strictures, stenoses and gap in pelvic fracture urethral injury (PFUI) [168, 169]. In addition, urethrography provides only a two-dimensional assessment of stricture and the results may be affected by the amount of penile stretch [170], degree of pelvic rotation and patient body habitus [171]. Risks of the procedure include infection, discomfort [162], contrast reaction from intravasation of contrast [172] in addition to the risk of radiation exposure. Urethographic clamp devices (Brodny, Knutson) are available and were found to be less painful than using the Foley catheter technique [173].

5.2.1.5 Cystourethroscopy

Cystourethroscopy allows for accurate visual detection of a suspected stricture or can rule out a stricture as cause of obstructive voiding [164]. It can detect narrowing of the urethral lumen before changes in uroflowmetry and symptoms [143]. Cystourethroscopy can also assess the presence of LS or other pathology but cannot usually assess stricture length as the calibre of most cystoscopes is greater than most symptomatic strictures [174]. To overcome this, use of smaller calibre ureteroscopes (6.5 Fr and 4.5 Fr) has been reported [174]. This also allows an assessment of the bladder prior to surgery and may identify other pathology such as bladder stones. Cystourethroscopy is particularly helpful for diagnosing proximal BMS which may be missed on RUG [175].

Retrograde urethroscopy combined with antegrade cystoscopy via the suprapubic tract may be used to evaluate PFUI and plan the surgical approach. It allows an assessment of the length of the defect, the competence of the bladder neck, the involvement of the bladder neck in scarring in addition to identifying the presence of bony spicules or other abnormalities (e.g., fistulae, stones) [176]. Combined retrograde and antegrade cystoscopy was found to provide similar estimates of length of urethral defect in patients with PFUI as combined retrograde and antegrade cystourethrography, but was more likely to detect fistulae, false passages, and calculi [176].

5.2.1.6 Ultrasound

Ultrasound of the urethra or sonourethrography (SUG) provides a non-invasive three-dimensional assessment of anterior urethral stricture disease; including stricture location, length, and the degree of associated spongiosfibrosis [177].
Several studies have compared SUG to RUG and cystoscopic or intraoperative findings. Sonourethrography was found to be more accurate at diagnosing stricture presence compared to RUG [173, 178]. Sonourethrography was also found to more accurately estimate stricture length (94% correlation with intraoperative findings) than RUG (59% correlation with intraoperative findings) (p < 0.001) [166]. A further study showed similar findings and found that the closest correlation for stricture length at operation was for strictures in the penile urethra [165]. Intraoperative sonourethrogram findings have also been found to change the planned reconstructive approach (based on pre-operative retrograde urethrogram) in 19% of men undergoing anterior urethral reconstruction [171]. Sonourethrography incorporating real-time elastography can provide a qualitative and quantitative assessment of spongiofibrosis [179, 180]. The clinical relevance of assessing the degree of spongiofibrosis pre-operatively remains to be established. Three-dimensional reconstruction of sonographic images is investigational at present [181].

The advantages of SUG are that it can be performed in the outpatient setting, provides information on the degree of spongiofibrosis and its relatively low cost [177]. Limitations of the technique include lower sensitivity for detection of strictures in the bulbar urethra, operator dependency, and the need for urethral distension requiring intraurethral anaesthesia. Sonourethrography requires specialised training in the use of US and is currently not in widespread usage.

### 5.2.1.7 Magnetic resonance imaging

Magnetic resonance imaging (MRI) has been used to image PFUIs, posterior urethral stenoses and anterior urethral strictures.

Several studies have compared MRI urethrogram to RUG and intraoperative findings. Magnetic resonance imaging urethrogram was found to be as accurate as RUG at detecting stricture site in anterior urethral strictures [182]. In terms of stricture length both MRI urethrogram and RUG reliably correlated with intraoperative findings [182]. On the other hand, a further study of patients with anterior urethral strictures found MRI urethrogram stricture length to correlate more closely with surgical findings than RUG [183].

In a mixed group of anterior urethral strictures and posterior urethral stenoses, MRI urethrogram was as accurate (sensitivity = 100%, specificity = 91.7%) as combined RUG and sonourethrography (sensitivity = 100%, specificity = 91.7%) at diagnosing strictures [184]. There was no significant difference in the measurement of stricture length [184]. In a further study of patients with posterior urethral stenosis, MRI estimation of stenosis length correlated more closely with operative findings compared to RUG [185]. In patients with PFUI, MRI measurement of pubo-urethral stump angle (angle between long axis of pubis and line between the distal end of the proximal urethral stump and lower border of inferior pubic ramus) was predictive of an elaborated approach on multivariate analysis [186].
Magnetic resonance imaging was also found to be more accurate at diagnosing associated pathologies e.g., diverticula, tumours, fistulae, and stones [184]. In cases of fistulation between the urinary tract and pubic symphysis after irradiation for prostate cancer, the fistula tract can be clearly demonstrated on MRI [187]. Other imaging modalities, including computed tomography (CT), may fail to identify the tract and the problem may be misdiagnosed as isolated osteomyelitis of the pubic bone leading to medical management with antibiotics rather than surgical excision [187].

The main advantage of MRI is greater anatomical detail, which is countered by the expense of the procedure and the greater complexity in interpreting images. The technique is not commonly used for routine situations, but it may be helpful in diagnosing associated pathologies which may alter patient management.

MRI = magnetic resonance imaging; n = number of patients; RUG = retrograde urethrography; SUG = sonourethrography; VCUG = voiding cystourethrogram.

**Summary of evidence LE**

Magnetic resonance imaging is more accurate than retrograde urethrography and voiding cystourethrogram at determining length of posterior urethral stenoses and can detect alternative associated pathologies e.g., diverticula, fistulae.

**Recommendation**

Consider magnetic resonance imaging urethrography as an ancillary test in posterior urethral stenosis.

6. DISEASE MANAGEMENT IN MALES

6.1 Conservative options

6.1.1 Observation

A stricture will usually result in diminution in flow once the calibre of the urethral lumen is ≤ 10 Fr [142]. In other strictures (> 10 Fr), the diagnosis is often made by coincidence in asymptomatic patients because of a urologic examination for other reasons (e.g., cystoscopy, need for urethral catheterisation) [142]. Purohit et al., performed observation and repeated cystoscopic evaluation of 42 subclinical, incidentally encountered strictures (≥ 16 Fr). After a median follow-up of 23 months, only five (12%) strictures progressed to a low-grade stricture (11-15 Fr). No patient developed symptoms and none of them needed surgical intervention [142]. These patients are candidates for observation although no evidence exist on the long-term evolution of these strictures.

In a series of anatomic stricture recurrence (≤ 16 Fr) after urethroplasty, only 65% of patients were symptomatic [143]. Some asymptomatic patients refused further intervention because they had experienced substantial improvement after their primary urethroplasty. These patients were considered as functional “success” [143]. A multicentric study of the Trauma and Urologic Reconstructive Network of Surgeons observed an important discrepancy between cystoscopic recurrence and need for further intervention [141]. Patients with a large calibre (> 16 Fr) recurrence had a one and two-year need for intervention rate of 4% and 12%, respectively. Of note, patients with small-calibre (≤ 16 Fr) recurrence had a one and two-year need for intervention rate of only 41% and 49%. Patients who needed intervention had poorer PROMs suggesting clinical symptoms and
bother. There is no information on long-term complications in patients with recurrences who did not undergo intervention. In cases of an asymptomatic stricture recurrence, it might be an option not to intervene but to perform regular follow-up.

Care must be taken about the term “asymptomatic” stricture (recurrence) as patients might conceal their bother and symptoms by different means (not drinking, social avoidance) and might only search for medical help once concealment is no longer tenable [188].

6.1.2 Suprapubic catheter
Radiation-induced urethral strictures are a difficult to treat population as stricture-free rates for urethral reconstruction are lower compared to those in non-irradiated patients [189]. Fuchs et al., evaluated 75 patients who were initially treated by suprapubic diversion for radiation-induced isolated BMS [190]. Only 51% eventually decided to undergo urethroplasty after a mean follow-up period of 25 months. Although there was no significant difference in overall performance status between patients with a chronic suprapubic catheter vs. those undergoing urethroplasty, all patients with a poor performance score remained with a suprapubic catheter. Patients with concomitant stress urinary incontinence (SUI) opted more often to keep their suprapubic catheter as the SUI improved in 61% of cases. On the other hand, patients who kept their suprapubic catheter suffered from catheter-related complications in 27% of cases. Urinary diversion by ileal conduit was performed in 30% of patients who remained with a suprapubic catheter while this was only the case in 8% who underwent urethroplasty.

A suprapubic catheter is also an option in frail patients not able to undergo surgery or in patients who do not want (further) urethral surgery and are willing to accept the complications of a suprapubic catheter [191].

6.2 Endoluminal treatment of anterior urethral strictures in males
The ability to treat the majority of strictures by less invasive and time-consuming means, offers obvious benefits particularly when specialist surgical services are not available, or patients simply prefer a more pragmatic immediately available solution.

6.2.1 Direct vision internal urethrotomy
In contemporary practice, direct vision internal urethrotomy (DVIU) is commonly performed as a first-line treatment of urethral strictures [192]. It is usually performed under general or spinal anaesthesia in well-resourced countries but shown to be well tolerated under local anaesthesia with or without sedation [193-195].

6.2.1.1 Indications of “cold knife” direct vision internal urethrotomy

6.2.1.1.1 Direct vision internal urethrotomy for primary stricture treatment
In the only high-level evidence study, Steenkamp et al., randomised 210 patients with seemingly comparable non-obliterative strictures at all locations of the urethra to either filiform dilatation vs. DVIU with local anaesthesia on an outpatient basis [196]. They collected objective data with RUG performed at seven follow-up visits (3, 6, 9, 12, 24, 36 and 48 months). This unique study showed that urethral dilatation is equally effective as DVIU but both procedure modalities become less effective with increasing stricture length (see section 6.2.1.1.3.1).

A Cochrane review in 2012 could not identify a single prospective RCT comparing DVIU (or dilatation) with urethroplasty at the anterior urethra [197]. Since then, the randomised Open-label Superiority Trial of Open Urethroplasty vs. Endoscopic Urethrotomy (OPEN) prospectively randomised patients with a recurrent bulbar stricture between open urethroplasty and DVIU but this was for recurrent bulbar strictures only and not as primary treatment [198] (see section 6.2.1.1.2). A retrospective cohort series in boys with bulbar stricture reported a patency rate of 53% for DVIU and 80% for urethroplasty. No statistical analysis was performed and no information on stricture length was available in both cohorts which makes direct comparison hazardous [199].
Patency rates vary considerably between 8% and 77% after DVIU (predominantly without prior urethroplasty) in retrospective cohort studies with minimum follow-up of one year [69, 199-208] (Table 6.1). Median time to recurrence was less than twelve months in most series [69, 200-202, 204-206]. This large variation in patency rate can be in part explained by the heterogeneous nature of the strictures and various definitions of patency used by the authors in these series. Indication to perform DVIU is dependent on various stricture characteristics that are prognostic for a successful outcome.

DVIU = Direct vision internal urethrotomy; IQR = interquartile range; N = number of patients; NR = not reported; SD = standard deviation; TTR = time to recurrence.
6.2.1.1.2 Direct vision internal urethrotomy for recurrent strictures and as salvage treatment after failed urethroplasty

In the OPEN trial, a recurrent stricture was defined as at least one previous failed intervention (endoscopic urethrotomy, urethral dilatation, urethroplasty) [209]. The previous intervention was predominantly DVIU. Despite poor recruitment, 108 and 112 patients were randomised to urethroplasty and DVIU respectively in a 24-month study protocol. Both groups had a similar improvement in voiding score symptoms after intervention. However, patients undergoing urethroplasty had 2.6 higher odds of experiencing an improvement of ≥ 10 ml/s in their maximum urinary flow compared to those undergoing urethrotomy (p=0.001) [209]. Need for re-intervention was observed in 13.8% vs. 25.9% of cases respectively allocated to urethroplasty and DVIU resulting in a 48% lower risk for re-intervention with urethroplasty (HR: 0.52; 95% CI: 0.31-0.89; p=0.017) [209]. Of note, self-dilatation was not considered a re-intervention [209]. Direct vision internal urethrotomy is also used as salvage treatment for recurrent strictures after urethroplasty. Brown et al., used DVIU for stricture recurrence (mean length: 4 cm; range: 1.5-7 cm) after excision and primary anastomosis (EPA), buccal mucosa grafts (BMG) urethroplasty and penile skin graft urethroplasty [210]. Patency was obtained in thirteen out of 37 cases (35%) after a single DVIU. After free graft urethroplasty (FGU), a short, veil-like stricture (or “diaphragm”) might develop at the distal or proximal end of the graft. Rosenbaum et al., used DVIU to a selected cohort of 43 patients with a short (<1 cm), veil-like stricture after BMG urethroplasty [211]. After a mean follow-up of twelve months, patency rate was 51%. Farrell et al., performed DVIU with mitomycin C (MMO) injection in seventeen patients with a short (median 2 cm; interquartile range [IQR] 1-2.5 cm) recurrence after bulbar urethroplasty (no details on technique available) and patency was achieved in twelve (71%) patients [212].

6.2.1.1.3 Predictors of failure of “cold knife” direct vision internal urethrotomy

Several groups tried to identify prognostic factors to predict which patients are most likely to fail initial treatment (Table 6.2).

6.2.1.1.3.1 Stricture length

Stricture length was identified as an important predictive factor for recurrence in several series. For bulbar strictures, Pansadoro et al., found a 71% and 18% patency rate for < 1 cm and ≥ 1 cm strictures respectively (p < 0.001) [201]. In the series of Al Taweel et al., no patient with a stricture > 1 cm who achieved patency was stricture-free, whereas this was 27% for strictures < 1 cm (p < 0.001) [204]. Barbagli et al., reported an estimated five-year patency rate of 71%, 51% and 39% for 1–2 cm, 2–3 cm and 3–4 cm strictures respectively (p < 0.00001) [203]. Pal et al., reported no patency in case of strictures > 1 cm [205]. In their prospective study, Steenkamp et al., reported that for each 1 cm increase in the length of the stricture the risk of recurrence was increased by 1.22 (95% CI: 1.05-1.43) [196]. In a paediatric series, a 0% patency rate was obtained for strictures > 2 cm [206]. Redon-Galvez et al., reported a 25% patency rate for strictures > 1 cm, whereas strictures ≤ 1 cm had a 71% patency rate (p=0.006). This difference remained statistically significant in the multivariable analysis, when adjusted for stricture location (HR: 1.75; p=0.025) [207]. A SR of case series calculated a weighted average patency rate of 71.2% vs. 23.2% for strictures less and more than 1 cm respectively (p < 0.0001) [213].

6.2.1.1.3.2 Stricture tightness (calibre)

Pansadoro et al., reported a patency rate of 69% and 34% for strictures more than and less than 15 Fr in calibre, respectively (p < 0.001) [201]. Using pre-operative maximum urinary flow (pQmax), as surrogate for urethral calibre, Barbagli et al., stratified patients into three groups (pQmax < 5 vs. 5–8 vs. > 8 ml/s) and reported an estimated five-year patency rate of 31% vs. 53% vs. 83%, respectively (p < 0.00001) and the importance of pQmax was confirmed in multi-variate analysis [198]. Kluth et al., could not confirm the significance of pQmax on the outcome of DVIU [202].

6.2.1.1.3.3 Number of strictures

Pansadoro et al., reported poorer patency rates in case of DVIU for multiple strictures compared to a single stricture at both the bulbar (18% vs. 50%; p < 0.001) and penile urethra (8% vs. 35%; p=0.013) [201]. Pal et al., reported a 0% patency rate in case of multiple strictures whereas this was 35% for a single stricture (p=0.03) [205].

6.2.1.1.3.4 Stricture aetiology

Harraz et al., identified idiopathic stricture aetiology as an independent risk factor for failure (HR: 3.11; p=0.035) [208]. On the other hand, stricture aetiology was not a predictive factor in many other series [201, 205, 206].
6.2.1.3.5 Stricture location
Several series have reported a better patency rate for bulbar strictures compared to penile stricture or penobulbar strictures [196, 201, 204]. Kluth et al., could not identify stricture location as an independent prognostic factor but only 12% of patients had a stricture at the penile urethra [202].

6.2.1.3.6 Previous interventions
Pansodoro et al., [201], Al Taweel et al., [204] and Heyns et al., [214] found a 0% patency rate after two or more prior failed DVIU, whereas this occurred after three and four prior failed DVIUs in the series of Santucci et al., [200] and Launonen et al., [206], respectively. Kluth et al., identified secondary DVIU for a recurrent stricture as an independent risk factor for stricture recurrence (HR=1.78; 95% CI: 1.05-3.03; p=0.032) [202]. Pal et al., found significantly better patency rates after a 1st DVIU compared to a 2nd or 3rd DVIU [205].

6.2.1.3.7 Other factors
Two series could not identify age, diabetes, hypertension, obesity and smoking as independent predictive factors [202, 203]. However, Harraz et al., identified that older age at presentation and obesity are independent predictors of failure after DVIU [208].

In the absence of well-designed, adequately powered multi-centre trials it is difficult to answer the question as to which clinical factors are predictive of failure of DVIU in men with urethral strictures. However, based on the predictors evaluated above and further supported by consensus papers [215-217], one can summarise that the best candidates are previously untreated patients with a single, short (max. 2 cm) bulbar stricture. In a selected group of patients (n=60), a patency rate of 77% was reported for a single, short, primary bulbar stricture with a minimum follow-up of five years [201]. This is confirmed by a more contemporary cohort of patients with untreated short (1-2 cm) bulbar urethral strictures, in which the estimated five-year patency rate was 71% [203].

DVIU = Direct vision internal urethrotomy; NA = not applicable; NR = not reported; pQmax = pre-operative maximum urinary flow.

*patency rates are reported after repetitive treatments.

6.2.1.2 Indications of “hot-knife” direct vision internal urethrotomy

6.2.1.2.1 Laser urethrotomy

Lasers available for urological applications, including Neodymium:YAG, Argon, Holmium:YAG, Potassium titanyl phosphate (KTP) and Tm:Yag, have been used for the treatment of urethral strictures. A SR identified four RCTs comparing laser urethrotomy and the “cold knife” urethrotomy. All studies were limited by short-term outcome evaluation and none of these four studies specified the results based on the location of the stricture. Two of these studies reported specific recurrence rates and meta-analysis showed a RR for recurrence of 0.55 (95% CI: 0.18-1.66; p=0.29), 0.39 (95% CI: 0.19-0.81; p=0.01) and 0.44 (95% CI: 0.26-0.75; p=0.003) in favour of laser urethrotomy after three, six and twelve months respectively [218]. Jin et al., performed a SR including 44 case series on laser urethrotomy or “cold knife” DVIU [213]. This included nineteen articles on laser urethrotomy and 25 articles on “cold knife” DVIU. The overall weighted average stricture-free rate was 74.9% (371/495) and 68.5% (1874/2735) for laser vs. “cold knife” DVIU, respectively (p=0.004). Although statistically significant, the results must be interpreted with caution because of heterogeneity and because no details are provided on follow-up duration. Specifically looking at first DVIU, laser and “cold knife” DVIU obtained a stricture-free rate of 58.6% and 42.7% respectively and the difference was no longer statistically significant (p=0.09). At the bulbar urethra, laser and “cold knife” DVIU yielded a stricture-free rate of 52.9% and 60%, respectively (p=0.66) [213].

After publication of this SR, the EAU Guideline Panel scope search identified two additional RCTs [219, 220] and one retrospective cohort series [221]. In the RCT of Yenice et al., patients with a primary, bulbar stricture were randomised either to “cold knife” DVIU (n=29) or holmium:YAG laser urethrotomy (n=34). After twelve months follow-up, no significant difference in patency rate was identified (79% for “cold knife” DVIU vs. 68% for laser urethrotomy, p=0.3) [220]. In their RCT, Chen et al., reported a better patency rate after one year with laser (n=24) compared to “cold knife” (n=22) DVIU (respectively 88% vs. 18%; p < 0.05). However, after two years the benefit for laser disappeared and after five years both techniques showed a low patency rate: 9% for “cold knife” DVIU vs. 12% for laser DVIU (p > 0.05) [219]. In both these RCTs, operation time was slightly but significantly longer with laser DVIU as compared to “cold knife” DVIU [219, 220]. Holzhauer et al., evaluated in a retrospective comparative study “cold knife” (n=127) with laser (n=65) DVIU at a mean follow-up of sixteen and eighteen, respectively. They reported patency rates of 42% for “cold knife” DVIU vs. 31% for laser DVIU (p=0.1) [221].

6.2.1.2.2 Plasmakinetic (bipolar) urethrotomy

Cecen et al., conducted an RCT comparing plasmakinetic with “cold knife” DVIU (n=136) [222]. They reported patency rates for plasmakinetic and “cold knife” urethrotomy at nine months in respectively 86% and 70% of cases (p=0.025). At eighteen months, patency rates for plasmakinetic and “cold knife” urethrotomy were 63% and 67%, respectively (p=0.643) [222]. A prospective cohort study on primary strictures < 2 cm reported a patency rate at twelve months in 23/30 (77%) cases for plasmakinetic DVIU vs. 19/30 (63%) cases with “cold knife” DVIU (p=0.04) [223]. A retrospective case series (n=27) reported a 74% patency rate for short (1-2.5 cm) strictures after a mean follow-up of fourteen months [224]. They reported negligible blood loss during the procedure and no post-operative incontinence.

Based on the conflicting results described above and considering the heterogeneity of series and absence of long-term follow-up, overall, the available studies do not support the efficacy of one technique of DVIU over another. Given the similar complication rates between techniques (see section 6.2.1.3), no recommendation can be made in favour of one technique over another.

6.2.1.3 Complications of direct vision internal urethrotomy

6.2.1.3.1 Complications of “cold knife” direct vision internal urethrotomy

An overall complication rate of 6.5% was reported in a SR of Jin et al., based on twelve articles including 1,940 patients [213] (Table 6.3).
Notably, erectile dysfunction (ED) was reported in 5.3% of cases in this review [213]. In addition, Graversen et al., reported ED in eleven out of 104 (10.6%) patients [225]. This risk appears higher in strictures located in the penile urethra and, in addition to the poor patency rates, the use of DVIU in the penile urethra must be discouraged [217, 225].

6.2.1.3.2 Complications of “hot knife” direct vision internal urethrotomy
The SR of Jin et al., reported a total complication rate of 11.8% (39/330) [213] (Table 6.3).

6.2.1.3.3 Complications of “cold knife” vs. “hot knife” direct vision internal urethrotomy
In a SR of RCTs comparing “cold knife” DVIU vs. laser DVIU, only 1/4 series reported complications [218]. In the laser group, an 8.9% complication rate was found due to contrast extravasation to the perineum and stricture recurrence. For the “cold knife” DVIU, a 15.5% complication rate was reported related to bleeding [218]. Two later RCTs reported similar rates of urinary extravasation [219, 220] and urinary incontinence (UI) [219] with both techniques.

The SR of retrospective case series of Jin et al., found no significant differences in the incidence rates of UI, urinary extravasation and UTI between laser and “cold knife” DVIU [213]. However, urinary retention and haematuria were more frequent with laser compared to “cold knife” DVIU [213]. Conversely, in the series of Yenice et al., haematuria was only reported after “cold knife” DVIU but not after laser DVIU (p=0.6) [220] (Table 6.3).

DVIU = direct vision internal urethrotomy; NA = not applicable; NR = not reported.

6.2.1.3.4 Complications of direct vision internal urethrotomy vs. dilatation
A Cochrane review found no significant differences for overall intra-operative complications (single dilatation vs. DVIU respectively 14% vs. 11%; RR: 0.75; 95 CI: 0.36-1.55) nor for individual complications (difficulty urinating, haematuria, false passage, pain, knotting/breaking/bending filiform leader) [196, 197]. The low rate of false passage for both DVIU and dilatation (respectively 0.96 and 0.94%) might be explained by the systematic use of a filiform leader in both groups which was inserted endoscopically in the dilatation group followed by coaxial dilators [196, 197].

A small retrospective study comparing balloon dilatation (n=31) with DVIU (n=25) showed less urethral bleeding (6.5 vs. 32%; p=0.017) and UTI (3.2 vs. 24%; p=0.037) with balloon dilatation [226].

Apart from acute peri-operative complications described above, the stricture length was reported to increase after DVIU treatment requiring complex urethral reconstruction, but the authors of this retrospective study clearly state the limitations of the study design in the absence of consistent baseline investigations [200]. Other
authors mention that repeat urethral manipulations (DVIU and/or dilatation) can increase stricture complexity and delays time to urethroplasty [227, 228].

6.2.1.3.5 Complications of “cold knife” direct vision internal urethrotomy vs. urethroplasty

The OPEN-trial reported adverse events of any type in 61% and 26.1% after urethroplasty (all types) and DVIU respectively [209]. In the urethroplasty group, mouth pain (related to oral mucosa graft [OMG] harvesting) and wound infection was noted as complication in respectively 14.6% and 4.9% of cases. Erectile dysfunction was 4.9% and 2.6% after urethroplasty and DVIU, respectively. Serious adverse events were reported in 8.5% and 8.7% after urethroplasty and DVIU respectively [209].

6.2.2 Single dilatation

6.2.2.1 Modalities of dilatation and results

Dilatation can be done in the office, under local anaesthesia and without complex resources [216, 229]. With dilatation, the urethral mucosa at the stricture site is stretched and the scarring is disrupted. This is opposed to DVIU where the stricture is incised. However, both treatment modalities use the same principle to achieve urethral patency: a breach of the urethral mucosa at the site of the stricture in which re-epithelialisation should occur faster than wound contraction [197].

When dilators are used to dilate bulbar urethral strictures, considerable experience is required to avoid accidental perforation of the urethra at the level of the stricture. In order to reduce the risks (esp. false passage, spongiosal perforation, urethral bleeding) of “classic” blind dilatation with rigid sounds [229], other strategies have been developed and evaluated in which the dilatation is visually controlled:

- endoscopic/fluoroscopic guidewire placement and progressive dilatation with Amplatz renal dilators [229, 230];
- endoscopic/fluoroscopic guidewire placement and balloon dilatation [226, 231];
- endoscopic/fluoroscopic guidewire placement and S-curved coaxial dilators [232].

Although no direct comparative studies of blind vs. visually controlled dilatation are available, several studies have reported a low complication rate with visually controlled modifications of dilatation. The recurrence rate with short follow-up largely varies between 7.7-64.5% (Table 6.4). Chhabra et al., identified focal/short (< 1.5 cm) strictures and strictures at the bulbar urethra as predictors for a favourable outcome [231].

DVIU = direct vision internal urethrotomy; FU = follow-up; ISD = intermittent self-dilatation; mo = months; N = number of patients; NA = not applicable; NR = not reported; UTI = urinary tract infection; yr = year.

6.2.2.2 Effectiveness of dilatation compared with direct vision internal urethrotomy

A SR identified only one prospective RCT comparing dilatation with DVIU and failed to detect any differences [196, 197]. In a small (n=56) retrospective cohort study, the three-year estimated stricture recurrence-free survival was 35.5% and 28% for respectively balloon dilatation and DVIU (p=0.21) [226].

At present, there is lack of evidence to support the claim that dilatation is superior to DVIU (or vice versa) and therefore, the indications for single dilatation are the same as for DVIU.

Repetitive dilatation/DVIU with curative intent (see also section 6.2.1.3.6 Previous interventions) should be avoided as no long-term freedom of recurrence can be expected [216] and because of the significant risk of increasing stricture length and complexity [227, 228] and prolonging the time to urethroplasty (which has better patency rates) [228].

6.2.3 Post-dilatation/direct vision internal urethrotomy strategies

Several strategies have been developed and evaluated to prevent wound contraction, improve the stricture-free rate and time to stricture recurrence after dilatation or DVIU.

It is noteworthy that these strategies tend to stabilise the stricture rather than to keep the patient stricture-free and the reported outcomes should be understood in this respect.
6.2.3.1 Intermittent self-dilatation

### Results

A SR identified six randomised and quasi-randomised trials comparing ISD with no ISD with a follow-up between eight and 24 months [233]. Stricture recurrence was reduced in men performing ISD (85/197, 43%) vs. those who did not (128/207, 62%) (RR: 0.70; 95% CI: 0.48-1.00; p=0.05). There was significant heterogeneity, and the quality of included studies was very low, which led the authors to conclude there is uncertainty about the estimate [233]. This review found no significant difference in adverse events between ISD and no ISD (RR: 0.60; 95% CI: 0.11-3.26; p=0.56) [233]. One trial containing 48 patients found no significant difference in six vs. twelve months duration of ISD (RR: 0.67; 95% CI: 0.12-3.64) and another trial (n=59) found no significant difference from using a low-friction hydrophilic vs. a polyvinyl chloride catheter (RR: 0.32; 95% CI: 0.07-1.40) [233]. Other studies have been published after this SR of 2014. Chhabra et al., reported that patients complying with ISD after dilatation had a lower need for re-intervention than those who did not, 12.3% vs. 20.5% respectively (p=0.2) [231]. After a mean follow-up of 25 months, Greenwell et al., found a need for subsequent intervention in 13/31 (42%) men performing ISD vs. 47/95 (49%) who did not (p=0.46). The number of reoperations in patients with need for subsequent intervention was lower in the group performing ISD vs. those who did not (2.6 vs. 3.4). No major complications were reported in both groups [234].

### Complications

The potential benefit of ISD in stabilising the stricture must be balanced against the drawbacks. Commonly reported complications are urethral bleeding (7.1%) [235] and UTI/epididymitis (4.7-18.1%) [236, 237]. A multicentric prospective study (n=85) reported that respectively 35% and 26% of patients had moderate to severe difficulties in catheterisation and respectively 32% and 17% of patients suffered moderate to severe pain while performing ISD. This had a serious impact on QoL which was rated moderate and poor in 32% and 55% of patients, respectively [35]. Younger age was identified as predictor for poor QoL, and QoL was more impaired in proximal stricture location (posterior and bulb) [35]. In a study of 286 patients (mainly > 60 years old) performing ISD, 20% experienced problems with ISD and 33% had at least one infection annually. After a mean follow-up of 58 months 67% still continued with ISD [238]. Khan et al., reported eight “drop-outs” of 30 (26.7%) men randomised to ISD [237]. Of these eight “drop-outs”, two were unable to perform ISD and one stopped because of pain.

As mentioned above, repetitive dilatation (including ISD) increases stricture complexity and delays time to urethroplasty [227, 228].

6.2.3.1.3 Intermittent self-dilatation combined with intra-urethral corticosteroids

To delay wound contraction at the stricture site, intra-urethral corticosteroids (as a catheter lubricant) have been used to improve the results of ISD. In 2014, a SR identified three prospective RCTs comparing ISD and local steroid (triamcinolone) ointment vs. ISD without local steroid ointment [239]. These three studies included a total 67 and 68 patients randomised to local steroid, or not, with a follow-up ranging between twelve and 36 months. There were fifteen (22.4%) recurrences in the steroid group and 25 (36.7%) in the control group (OR: 0.51; 95% CI: 0.24-1.10; p=0.09) [239]. Time to recurrence was longer in the steroid group vs. the control group (weighted mean difference = 0.29; 95% CI: 0.08-1.00; p=0.05). There was no difference in adverse events between groups [239].

Since 2014, two additional RCTs have been published. Ergun et al., evaluated patients after DVIU for primary short (< 2 cm), bulbar (82%) or posterior (18%) strictures that were further randomised between ISD (n=30) and ISD + triamcinolone ointment (n=30) for six weeks. Stricture recurrence rate after 24 months was not significantly different between ISD and ISD + triamcinolone (respectively 33.3 and 30%) [240]. On the other hand, Regmi et al., found a lower stricture recurrence rate (22% vs. 46%, p=0.04) in patients performing ISD + triamcinolone (n=27) vs. ISD alone (n=28) [241]. In this study, median time to recurrence was 7.4 ± 4.5 months vs. 11.9 ± 3 months in respectively ISD alone and ISD + triamcinolone (p=0.16). Both studies reported no complications related to ointment of triamcinolone [240, 241].

In a small (n=28) cohort with LS-related strictures, an intra-urethral steroid regimen was successful (no need for subsequent escalation of therapy) in 25 (89%) patients after a mean follow-up of 25 months [155]. This regimen consisted of applying clobetasol cream 0.05% as lubricant on a calibration device (10-16 Fr catheter or dilator) twice a day during a minimum of two months. As most of these patients further continued with instillation of steroids on a calibration device, this high “success” rate must be viewed with caution and should be considered as a stabilisation of the stricture rather than a cure. Eventually, twelve (42.8%) patients could reduce the interval of instillation/dilatation and three (10.7%) of them could finally stop the treatment [155].

6.2.3.2 Intralesional injections

The rationale of adjuvant intralesional injections is to reduce fibroblast proliferation and excessive urethral scarring [215].

6.2.3.2.1 Steroids

A 2014 SR identified five studies comparing intra-urethral submucosal steroid injection vs. no intra-urethral submucosal steroid injection after DVIU, of which two were RCTs [239]. Meta-analysis of these two RCTs with 57 and 58 patients in, respectively, the steroid and control group showed no statistical difference in recurrence rate (OR: 0.53; 95% CI: 0.25-1.13; p=0.10).. Time to recurrence was significantly longer in the steroid group (weighted mean difference = 4.43; 95% CI: 2.77–6.09, p < 0.00001). There were no significant differences regarding adverse events (infection, bleeding, extravasation) between both groups (weighted mean difference = 1.59; 95% CI: 0.71–3.58, p=0.26).

6.2.3.2.2 Mitomycin C

An RCT (n=40) by Moradi et al., reported that MMC hydrogel significantly reduced recurrent stricture formation (10% with MMC vs. 50% without MMC; p=0.001) at one year in patients with anterior strictures < 1.5 cm and no or mild spongiformosis on US [242]. The authors reported no significant complications related to MMC injection [242]. Another RCT (n=151) with eighteen months follow-up in predominantly bulbar strictures reported a stricture-free rate of 86% and 63% after DVIU with and without MMC, respectively (p=0.002) [243]. The mean stricture length was less than 2 cm in both groups. No significant complications, such as necrosis of the urothelium, extravasation, or systemic absorption, were recorded in the MMC group [243].

Farrell et al., conducted a retrospective study in 44 patients with recurrent bulbar and BMS with a median stricture length of 2 cm (IQR: 1-2.5 cm) [212]. They reported patency in 75% after a median follow-up of 26 months. No long-term complications attributed to MMC were observed.

In a prospective case-series (n=103), Kumar et al., evaluated adjuvant intralesional injections of a cocktail of triamcinolone, MMC and hyaluronidase after DVIU for predominantly (78%) bulbar strictures with a median follow-up of fourteen months. A stricture-free rate of 81% was reported and none of the patients suffered local or systemic side effects related to the injection [244].

Despite the encouraging results reported with MMC, the use of MMC in urethral stricture management is still off-label and not widespread. Severe complications with MMC injection are possible. Redshaw et al., reported in a multi-institutional series that 4/55 (7%) patients experienced serious complications with osteitis pubis, rectourethral fistula and necrosis of the bladder floor when MMC was injected after endoscopic incision to treat BNS [245]. Given this safety concern and in the absence of well-conducted and adequately powered RCTs, MMC adjuvant to DVIU should only be used in the framework of a clinical trial.

See supplementary Table S6.1 for further information.

6.2.3.2.3 Platelet rich plasma

Rezaei et al., conducted an RCT comparing DVIU + platelet rich plasma (PRP) (n=44) vs. DVIU + saline (n=43) in primary, bulbar strictures < 1.5 cm in length [246]. The two-year stricture-free rate was 78% vs. 56% after DVIU with or without PRP, respectively (p=0.034). Complications were frequent but not significantly different between both groups (DVIU + PRP: 70%; DVIU + saline: 79%). All complications (urethral bleeding, haematuria, urethral pain, pelvic pain, urinary leakage and genitoperineal swelling) were classified as grade 1 according to the Clavien-Dindo system. Further validation of this treatment is needed before general clinical implementation.

### 6.2.3.3 Urethral stents

Urethral stents are designed with the aim to oppose wound contraction after dilatation or DVIU [247, 248]. Stent insertion is a short procedure (< 60 minutes) that can be done under local or spinal anaesthesia as “one-day” surgery [247, 249, 250]. Urethral stents are classified as permanent or temporary (removable, after six to twelve months).

#### 6.2.3.3.1 Results

Permanent stainless-steel mesh stents are no longer commercially available. An RCT comparing dilatation/DVIU only vs. dilatation/DVIU followed by temporary stent insertion for bulbar strictures reported a significantly longer stricture-free survival time in favour of dilation/DVIU followed by stent (median 292 vs. 84 days; p < 0.001) [251]. Only 20.6% of patients treated with a stent developed a recurrent stricture within one year vs. 82.8% in the control group. These results are corroborated by a prospective series of Wong et al., who found a median stricture-free survival of two months after DVIU alone vs. 23 months after DVIU followed by temporary (three months) stent for bulbar strictures [248].

Failure and need for re-intervention are frequent (30-53%) and are usually because of stricture recurrence, stent encrustation, stent migration and urethral hyperplasia. Other complications include recurrent UTI, recurrent haematuria and genito-perineal pain (Table 6.5). Although stents are mainly used to treat bulbar strictures, they have been used for posterior stenoses as well. Stents used in the posterior urethra have a high risk (82-100%) of causing UI and this is most pronounced in patients with previous irradiation and/or strictures extending into the membranous or bulbar urethra [252]. In the bulbar urethra, the risk of UI is higher if stent placement is adjacent to the external sphincter [253]. The use of stents in the penile urethra is anecdotal. Jung et al., reported stent failure in 4/7 (57%) patients with a penile stricture after a mean follow-up of eight months. Of those patients who failed, no patient with distal or pan-penile strictures was rendered stricture-free [254]. In their series, stricture recurrence after stenting of the penile urethra was significantly higher when compared to the bulbar urethra [254]. Although no direct comparison is available, temporary stents tend to have fewer and less severe complications compared to permanent stents (Table 6.7).

DVIU = direct vision internal urethrotomy; FU = follow-up; NR = not reported; UI = urinary incontinence; UTI = urinary tract infection; VUAS = vesico-urethral anastomotic stricture; \(Q_{max}\) = maximum flow rate.
6.2.3.3.2 Treatment of stent failure

In the case of stent failure, subsequent urethroplasty (usually with stent removal) is possible, but this urethroplasty is very likely to be more complex than it would have been had it been performed initially [255-257]. Due to the fact that the stainless-steel wires are fully embedded into the urethral wall, over time the urethral spongiosum is severely damaged. Horiguchi et al., found that a history of urethral stenting was an independent significant predictor of increased stricture complexity (OR: 13.7; 95% CI: 1.7-318.3; p=0.01) and need for more complex urethroplasty (OR: 6.9; 95% CI: 1.1-64.5; p=0.04) [227]. The majority (62%) of patients in this study had a permanent stent and tend to be difficult to remove because they are epithelialised, usually within six months [227]. The type of urethroplasty required depends on the length of the stricture and quality of local tissues [256]. In the majority of cases, it is possible to preserve the urethral plate and to perform a one-stage substitution urethroplasty [255, 256, 258]. The patency rates after different types of urethroplasty vary greatly between 16.7-100% [255-258] and this variation probably reflects variation in complexity of the stricture, rather than that the superiority of one technique of urethroplasty over another (for further information see supplementary Table S6.2). Due to these limitations, the use of stents should be avoided if subsequent urethroplasty is considered [247, 257]. Urethral stents are not a first-line treatment for urethral strictures but can be considered in co-morbid patients who have a recurrent stricture after DVIU/dilatation and are unable to have more complex urethroplasty or who refuse urethroplasty [247, 251, 252].

Summary of evidence LE

| Permanent urethral stents have a high complications and failure rate and make subsequent urethroplasty more challenging if they fail. | 3 |
| Stents have a higher failure rate in the penile urethra. | 3 |
| Temporary stents after DVIU/dilatation at the bulbar urethra prolong time to next recurrence compared to DVIU/dilatation alone. | 1b |

6.3 Open repairs (urethroplasty): site and aetiology (clinical scenario) treatment options

6.3.1 The role of urethroplasty in the management of penile urethral strictures

Due to the specific aetiology and the associated problems, strictures related to failed hypospadias repair and LS will be discussed separately. However, many series reporting on the outcome of penile strictures have a mixed aetiology also including failed hypospadias repair and/or LS [259, 260]. Due to their specific location, distal penile strictures will be discussed separately.

6.3.1.1 Staged augmentation urethroplasty

Classically called “two-stage” urethroplasty, this approach may become a multi-stage urethroplasty as revision (usually due to graft contracture) after the 1st stage has been reported in 0-20% of cases [260-263]. Therefore, the term “staged” should be used instead [264]. Revision rates before 2nd stage were 0-20%, stressing that a two-stage urethroplasty might become a multi-stage urethroplasty. In general, reconstructive urologists tend to follow this approach in men with more complex urethral stricture disease (multiple interventions in the past, unfavourable clinical findings such as significant spongiosis or scarring that requires excision, poor quality of the urethral plate). An interval of at least four to six months has been proposed before proceeding to the tubularisation of the urethra, provided that the graft has healed uneventfully [265-267].

A SR by Mangera et al., has shown an average patency rate of 90.5% with the use of all types of grafts for staged penile urethroplasties with an average follow-up of 22.2 months [268]. Patency rates of staged OMG urethroplasty in specific locations vary between 73.3 and 100% [259, 260, 262, 263]. Post-operative urethrocataurose fistula (UCF) rates were 17.2% and 2.6% in the studies of Ekerhult et al. and Joshi et al., respectively, and either not reported or unclear in the remaining studies [259, 260].

6.3.1.2 Single-stage augmentation urethroplasty

Single-stage urethroplasty offers the option for reconstruction of the stricture without the need for multiple operations, the associated peri-procedural risks, and the cosmetic and functional implications that by definition follow the first part of staged urethroplasties [269-271]. There is some evidence to suggest a considerable
number of patients (50% or more in some studies) who were offered 1st stage urethroplasty never returned for the 2nd stage because they were either satisfied with their functional status after the 1st stage (this particularly applied to older men or patients with multiple failed procedures in the past) or they were disappointed with the need for another operation [269, 270].

In the SR of Mangera et al., overall patency rate for all types of single-staged graft urethroplasties is 75.7% with an average follow-up of 32.8 months [268].

The patency rate for different one-stage techniques in specific are:
- dorsal OMG (n=190): 70-100% [263, 272-277];
- ventral OMG (n=47): 55-92.6% [278, 279];
- dorsal + ventral OMG (n=10): 80% [276];
- double (dorsal + ventral) onlay with penile/scrotal skin graft /OMG (n=14/8/4): 88.5% [273];
- dorsal penile skin graft (n=44): 62-78% [273, 274];
- penile skin flap (n=315): 67-100% [273-275, 280, 281].

No high-level evidence exists to state that one technique is superior to another, but it seems that the dorsal graft location is more commonly used compared to the ventral one. Mangera et al., reported that the patency rate was better with OMG compared to other grafts (mainly penile skin) [268]. Jiang et al., showed that combined (dorsal + ventral) BMG onlay had significantly better stricture-free rates for penoscrotal strictures (patency rate 88.9% vs. 60.9% with single-onlay approach); however, follow-up was significantly shorter in the double-onlay group [282]. Few studies have reported dedicated results on sexual function parameters that do not appear to be significantly impaired post-operatively [262, 283, 284].

A critical factor with respect to single-staged procedures is the careful selection of patients, as men with long and complex strictures might not be good candidates for single-stage reconstruction and attempts to offer single-staged operations in these patients might lead to higher recurrence rates. Sometimes, this selection can only be done based on intra-operative findings. Therefore, any scheduled single-staged procedure might be converted into a staged one [269, 285]. Palminteri et al., highlighted the fact that single-stage augmentation urethroplasties in men with LS-related strictures enlarge rather than remove the diseased segment of the urethra; therefore, there is always a risk of recurrence in the future [286]. The role of previous interventions (especially multiple urethrotomies or history of previous urethroplasties) remains unclear as several studies on single-staged operations do not provide information on previous procedures, or excluded patients with operations in the past [275, 284]. Although favourable outcomes in patients with previous history of urethrotomies/urethroplasties were reported by Barbagli and Kulkarni, in the study by Pfalzgraf et al., all recurrences post-previous urethroplasty took place in the single-stage group while Ekerhult et al., identified prior history of urethral operations as a risk factor for recurrence in the group of single-stage procedures [259, 262, 263, 273]. In addition to previous urethral surgery, high BMI has also been identified as a poor prognostic factor after single-stage penile urethroplasty [259].

6.3.1.3 Anastomotic urethroplasty in men with penile urethral strictures

Historically, the use of anastomotic urethroplasty in the management of urethral stricture disease has been discouraged due to the risk of chordee post-operatively [267, 287]. Nevertheless, it has been performed in selected patients with very short strictures (usually < 1 cm) with a 93% patency rate, with satisfactory QoL and sexual function and without any case of chordee [288].

**6.3.1.4 Specific considerations for failed hypospadias repair-related strictures**

The term “failed hypospadias repair” (FHR) includes a wide range of abnormalities after previous attempts for reconstruction, such as glans deformity, recurrent urethral stricture, glans/urethral dehiscence, UCF and penile chordee [289-291]. The management of FHR is challenging as the urethral plate, penile skin and dartos fascia are often deficient/non-existent. Management of these patients is often made more difficult due to incomplete health records and a lack of critical information (original meatal site, number, and type of previous repairs) [265, 292]. In addition, multiple operations might need to be offered to reach satisfactory outcomes [289]. As a result, FHR should always be considered as a complex condition and it is advised that FHR management takes place in high-volume centres [290, 291, 293, 294].

“Hypospadias cripples” is a term widely used to describe the group of men with multiple previous failed attempts to correct the condition resulting in unfavourable results such as severe scarring, penile deformity and shortening, hair or stones in the urethra, UCF, chordee and functional disorders (e.g., urinary, or sexual dysfunction). This term should be avoided and a more neutral one should replace it as it further stigmatises men with hypospadias who have been shown to have reduced self-esteem and confidence due to unsatisfactory cosmesis, and problematic urinary and sexual function. Moreover, it has been reported that FHR patients experience high rates of disappointment after failure of attempted repair and a sense of helplessness as they are frequently advised that their failed hypospadias is too complex to correct and they should not pursue further repair [290-292, 295, 296].

Two main approaches are applicable: single-stage or staged procedures. In general, it is advised that staged procedures should be followed when the urethral plate is inadequate for a single-stage operation. Surgeons should consent patients for both types of urethroplasty as the surgical approach might need to be modified intra-operatively depending on favourable/unfavourable intra-operative findings. Besides poor-quality of the urethral plate, these unfavourable findings include high degree of scarring and presence of concomitant LS, UCF and/or chordee. It is not uncommon for men with FHR to have scarred skin or concurrent LS and thus, skin grafts or flaps should be avoided as the risk of recurrence due to LS is very high (90% in long-term follow-up as reported by Depsaquale et al. [41]) [297, 298].

Staged repairs (using mainly BMG) reported patency rates ranging from 71-95% [261, 295, 297, 299, 300], while single-stage repairs had patency rates from 80-100% [297, 299, 301-304]. It needs to be highlighted that, as FHR is an umbrella term that covers various clinical conditions apart from urethral stricture disease only (such as UCF, chordee, penile deformity), “success” rates as reported by the authors in their studies do not represent urethral patency rates only. Unfortunately, the number of previous operations is either not reported or refers to the whole FHR study group collectively rather than to the subgroups of staged/single-staged procedures.

A comparative analysis is reported by Barbagli et al., in 345 FHR patients at five-year follow-up. Overall failure-free survival rate was 48% for all urethroplasties, and in sub-analysis, staged techniques had significantly lower treatment failure-free survival rates compared to single-stage techniques [305]. However, it is unclear whether these groups were comparable in terms of baseline characteristics such as age, length of stricture, number of procedures, comorbidities etc. [305]. If the patients in the staged group had a more unfavourable background, this on its own could explain the final outcome rather than the surgical approach itself.

Kozinn et al., reported a 16% and 14% revision rate after the 1st and 2nd stage, respectively, and observed that these revision rates were higher in the FHR group compared to non-FHR patients with penile strictures [261]. There is conflicting evidence whether FHR as aetiology is a poor prognostic factor in the outcome of urethroplasty for penile strictures [259, 306-308]. Concomitant UCF can be successfully managed at the same time of urethroplasty [305].
For further information see supplementary Table S6.3.

### Summary of evidence

| Men with FHR have history of multiple interventions, and poor-quality tissues, and might require complex procedures for a satisfactory functional and cosmetic outcome. | LE 4 |
| Men with FHR may have low self-esteem due to urinary and sexual dysfunction and unsatisfactory cosmesis. | LE 2b |
| Men with FHR can have scarred penile skin or concurrent LS and outcomes with skin grafts or flaps can be unsatisfactory. | LE 3 |

### Recommendations

| Men with failed hypospadias repair (FHR) should be considered complex patients and referred to specialist centres for further management. | Strength rating Weak |
| Propose psychological and/or psychosexual counselling to men with unsatisfactory cosmesis and sexual or urinary dysfunction related to FHR. | Strength rating Weak |
| Do not use penile skin grafts or flaps in failed FHR patients with lichen sclerosus or scarred skin. | Strength rating Strong |

### 6.3.1.5 Specific considerations for lichen sclerosus-related penile urethral strictures

Given the fact that LS affects the skin, the use of genital skin as a flap or graft is not advised as the risk of disease recurrence has been reported to be high (50-100%) and while most of recurrences tend to occur within the first two to three post-operative years, late recurrences have been reported [309].

Main strategies are single-stage or staged oral mucosa graft urethroplasty.

The EAU Urethral Strictures Guidelines Panel conducted a SR [6] to explore the role of single-stage oral mucosa graft urethroplasty in the management of LS-related urethral strictures and to compare its outcomes with alternative management options (surgical dilatations +/- ISD; surgical dilatations + local steroids +/- ISD; staged oral mucosa urethroplasty; penile skin urethroplasty; meato(hypo)plasty; urethrotomy [Otis, DVIU]; perineal urethrostomy; urinary diversion [e.g., suprapubic catheterisation]).

In total, fifteen studies met the inclusion criteria, recruiting a total of 649 patients (366 from five non-randomised comparative studies and 283 from ten, single-arm retrospective observational studies). Single-stage OMG urethroplasty resulted in success rates ranging from 65-100% after twelve to 67 months mean or median follow-up. For staged OMG urethroplasty, the most commonly reported comparator, the success rates were somewhat lower and varied between 60-79%. Methodological issues (mainly selection bias) could explain the difference in success rates rather than the intervention itself. Complications were uncommon (0-12%) and mainly comprised Grade 1-3 events.

Due to the overall very poor quality of evidence, the SR did not provide a clear answer as to whether single-stage OMG urethroplasty is superior to other management options, although careful patient selection is highlighted. In the absence of adverse local tissue conditions, a single-stage approach could lead to high success rates with an improvement in voiding symptoms and QoL.

### Summary of evidence

| Lichen sclerosus is a skin condition that can lead to scarring, and recurrence rates after skin graft/flap augmentation urethroplasties have been reported to be high (50-100%). | LE 4 |
| Single-stage OMG urethroplasty provides patency rates between 65-100% and is not inferior to staged OMG urethroplasty. | LE 3 |

### Recommendations

| Do not use genital skin in augmentation penile urethroplasty in men with lichen sclerosus (LS) related strictures. | Strength rating Strong |
| Perform single-stage oral mucosa graft urethroplasty in the absence of adverse local conditions in men with LS related strictures. | Strength rating Weak |
6.3.1.6  Distal urethral strictures (meatal stenosis, fossa navicularis strictures)

Open repair of distal urethral strictures can be in the form of Malone meatoplasty, skin flap meatoplasty or graft (skin [SG]/OMG) urethroplasty.

For short distal meatal strictures, the Malone meatoplasty (dorsal + ventral meatotomy) provides a technique with patency rates up to 100%, and 83% patient-reported satisfaction with the cosmetic results [310].

Skin flap meatoplasty showed excellent patency rates ranging from 85-100% based on three studies comprising 53 patients [311-313]. In addition, based on their results, patient satisfaction with post-operative outcomes and cosmesis was high, there were no cases of ED and functional complaints were minimal (mainly spraying of the urine flow). Barbagli et al., in their study from 2008, had lower success (57%) with the use of skin flaps; however, this was in only seven patients [273].

Patency rates with the use of grafts (OMG or SG) ranged from 69-91% in 85 patients overall [273, 302, 312, 314]. Where reported, patients were satisfied with cosmesis, and mild spraying of the urine flow self-resolved. Although tubularised grafts in a single-stage procedures are not routinely recommended (see also section 9. Tissue transfer), one series reported an 89.9% patency rate for this approach (“two-in one approach”) in selected patients with mainly distal penile strictures [315].

For further information see supplementary Table S6.4.

### Summary of evidence LE

| Post-meatoplasty/urethroplasty patency rates in men with meatal stenosis or fossa navicularis/distal urethral strictures range between 57-100% depending on type of surgical intervention with high patient satisfaction and minimal complications. | 3 |

### Recommendation Strength rating

| Offer open meatoplasty or distal urethroplasty to patients with meatal stenosis or fossa navicularis/distal urethral strictures. | Weak |

6.3.2  Urethroplasty for bulbar strictures

6.3.2.1  “Short” bulbar strictures

The length of a “short” bulbar stricture is poorly defined. In general, “short bulbar strictures” are those amenable to stricture excision and subsequent tension-free anastomotic repair. The limit is usually around 2-3 cm but can be longer depending on the patient’s anatomy and stricture location within the bulbar urethra [316].

In fit patients, the choice of urethroplasty is between EPA (transecting or non-transecting) and FGU.

6.3.2.1.1  Excision and primary anastomosis

6.3.2.1.1.1 Excision and primary anastomosis with transection of corpus spongiosum (transecting EPA)

Transsecting EPA (tEPA) is based on the full thickness resection of the segment of the bulbar urethra where the stricture and surrounding spongiofibrosis is located. Reconstruction is performed by a tension-free spatulated anastomosis.

6.3.2.1.1.1.1 Patency rates

The International Consultation on Urological Diseases (ICUD) performed an extensive review of the literature and reported a composite patency rate of 93.8% for tEPA [317]. Based on this, they endorsed tEPA as treatment of choice for short bulbar strictures if other techniques have an expected patency rate below 90%. However, ED was not taken into account for this advice and as discussed below, ED is a concern with tEPA.

After publication of the ICUD review, several other series have been published and the reported patency rates (76-97%) are in line with the findings of the ICUD review [318-330].

Usually, no need for further intervention is used to evidence that the urethra is patent. In the few studies using an anatomic definition for failure (an inability to pass a 16 Fr endoscope) tEPA urethroplasty achieves a similar patency rate, ranging between 85.5-97% [143, 323, 329, 331] (Table 6.12). The median time for recurrence after tEPA is between 3.5 and thirteen months [143, 320, 321].
Several authors suggested that tEPA is the technique of choice for short post-traumatic bulbar strictures with complete obliteration of the urethral lumen and full thickness spongiosfibrosis [317, 331]. These strictures are a specific entity and usually the result of a straddle injury with complete or nearly complete rupture of the bulbar urethra. These obliterations are predominantly short and can be treated with tEPA yielding a patency rate of 98.5% as reported in the series of Horiguchi et al. [333]. They also reported an improvement in erectile function after urethroplasty measured one year post-operatively. Straddle injury (and perineal trauma) are a common aetiology in papers published about tEPA; however, separate data on the outcomes for this specific aetiology is usually lacking.

For further information see supplementary Tables S6.5 and S6.6.

6.3.2.1.1.2 Complications
Granieri et al., [322] specifically focused on complications after bulbar urethroplasty. Peri-operative complications (haematoma, neuralgia), infectious complications, anatomic complications and voiding complications were not significantly different between EPA, augmented anastomotic repair (AAR) and FGU. Erectile dysfunction after bulbar urethroplasty is usually transient, with improvement after three to six months [334]. Chordee is one of the complications attributed to EPA urethroplasty but is rarely reported. A large case series (n=352), reported an incidence of 0.3% [331]. Another large case series (n=94), reported five cases (5.3%), with a mean stricture length of 2 cm (range 1.5-4) in patients with this complaint [318].

Other complications of tEPA are a cold feeling in the glans (1.6-3.2%) and decreased glandular tumescence (6%) [334, 335]. These latter complications (as well as ED) might be attributed to complete transection of the corpus spongiosum at the level of the stricture, thereby disrupting the antegrade blood flow of the urethra and corpus spongiosum. To spare this, the non-transecting EPA (ntEPA) has been described [336] and later modified [337].

6.3.2.1.1.2 Non-transecting excision and primary anastomosis
6.3.2.1.1.2.1 Patency rates
Except for straddle injuries that are usually associated with complete obliteration of the lumen and full thickness scarring of the corpus spongiosum [317, 331], ntEPA is a good alternative for short bulbar strictures of all other aetiologies. With median follow-ups ranging between 17.6 and 37.1 months, the patency rates reported are 93.2-99%; with the lack of further intervention as success criteria [330, 332, 338]. Even with the anatomic criteria (16 Fr cystoscopy passage) the success rate achieved was 97.9% at twelve months [331] (see supplementary Table S6.7).

Two comparative analyses evaluated tEPA vs. ntEPA. Waterloos et al., reported patency rates of 88.4% and 93.2%, respectively, for tEPA and ntEPA (p=0.33) but with significantly longer follow-up for tEPA (118 vs. 32 months, p < 0.001). Of patients scheduled for ntEPA, 11.1% were converted to tEPA, highlighting that ntEPA is not always possible. Chapman et al., using anatomic success criteria (16 Fr cystoscope passage), reported patency in 93.8% of tEPA vs. 97.9% of ntEPA. Follow-up was also significantly shorter at 74.1 (SD: 45.4) months for tEPA vs. 37.1 (SD: 20.5) months for ntEPA (p < 0.001) [331].

6.3.2.1.1.2.2 Complications
When erectile function after urethroplasty was assessed (at six months), ntEPA had significantly lower ED rates (a decrease of > 5 points on the sexual health inventory for men [SHIM] scale) compared to tEPA (4.3 vs. 14.3%, respectively) [331]. Urethral transection performed during tEPA was the only factor associated with sexual dysfunction in a multivariate analysis [331]. Other series reported ED lasting for more than six months in 2-6% of cases after ntEPA [332, 338, 339]. Grade ≥ 2 Clavien-Dindo complications were 3.6-8.1% vs. 4.3-6.8%, respectively, for tEPA and ntEPA, without reaching statistical significance [330, 331].

To date, no trials comparing ntEPA with FGU have been published to report on comparative patency outcomes and complications.

6.3.2.1.2 Free graft urethroplasty
Despite the very high patency rates of EPA, FGU has been performed for short bulbar strictures as well. This is mainly driven by reports of ED after EPA. A meta-analysis of ten papers [340] comparing tEPA with BMG FGU for short strictures, found that tEPA is better than BMG FGU in terms of patency rates (91.5% vs. 70%), whilst BMG FGU has less erectile complications (9% vs. 25%). However, the methodology of this meta-analysis must be disputed as it was performed on cohort studies without risk of bias assessment and without further specification of timing of assessment of ED. On the other hand, two prospective, non-randomised papers
[143, 341] comparing tEPA with BMG FGU, found no significantly different patency rates for EPA compared to BMG FGU (87-90% vs. 84-87%, respectively) and no significant differences in erectile complications for tEPA compared to BMG FGU (6.7% vs. 2.2%, respectively). However, the operation technique used was dependent upon the length of the stricture, with tEPA utilised for shorter strictures (< 2 cm) and BMG for longer (> 2 cm) [341] or when a tension-free anastomosis was not possible [143]. Appropriate choice of procedure for stricture length and other patient and stricture parameters appear to equalise outcomes. Another prospective trial [342] involving both penile and bulbar strictures could not find any influence on erectile function of urethral transection. A prospective study on ejaculatory function following different urethroplasties by Erickson et al., [343] found no overall difference in ejaculatory score pre- and post-operatively, although patients with a poor score preoperatively improved significantly and those with a good score pre-operatively did not decrease post-operatively.

Dogra et al., [283] looked prospectively at sexual function in 87 patients after different urethroplasties (EPA, penile/bulbar substitution) and found a 20% reduction in sexual function in all groups, which resolved after six months.

Details on where to place the graft during FGU are discussed below.

6.3.2.2 “Longer” bulbar strictures
6.3.2.2.1 Free graft urethroplasty
For strictures not amenable to EPA, FGU is the technique of choice and buccal mucosa is, at the moment, the most widely used graft. Other grafts (and flaps) are possible and discussed in the tissue transfer chapter. Patency rates of FGU of the bulbar urethra are 88-91% with twelve to 40 months follow-up [268, 344].

During bulbar urethroplasty, the bulbospongiosus muscle is usually separated at the midline which may cause damage to the muscle and perineal nerves. This might subsequently provoke post-void dribbling and ejaculation disorders. In order to reduce this, the muscle and nerve-sparing perineal approach has been introduced [345]. Although it is mostly used in graft urethroplasty, this approach is also possible for EPA as well [346]. Elkady et al., [339] randomised 50 patients between a muscle and nerve-sparing perineal approach vs. a classic perineal approach and found no difference in operative time (100 vs. 105 min), but significantly less dribbling (4% vs. 36%, p=0.01), and significantly less ejaculatory changes (8% vs. 40%, p=0.02) in the nerve and muscle-sparing group. Fredrick et al., [346] did the same in 50 patients in a multicentric study with bulbar urethroplasty but could not find a statistical difference regarding post-void dribbling and ejaculatory changes. Due to the limited and conflicting evidence, no recommendation can be made about the routine use of nerve and muscle-sparing modification during bulbar urethroplasty.

See supplementary Table S6.8 for further information.

6.3.2.2.2 Augmented anastomotic repair
Augmented anastomotic repair is also an option for these strictures. It has been mainly performed in cases where the stricture was just too long (+/- 2-4 cm) for tension-free EPA [328]. It can also be performed for longer strictures with a shorter (nearly) obliteratorive segment [347]. In this case, only the most oblitterative segment is excised, the urethral plate is anastomosed, and the urethra is further reconstructed with an onlay graft [347]. Patency rates after AAR vary between 91.1 - 91.9% with twelve to 28 months follow-up [322, 328] (see supplementary Table S6.9).
A non-transecting alternative has also been described to overcome the previously mentioned inconveniences related to spongiosal transection (augmented non-transecting anastomotic bulbar urethroplasty [ANTABU]). With this technique, Bugeja et al., [348] reported a 100% patency rate in sixteen patients after a median follow-up of thirteen months. One patient (6.7%) suffered permanent ED.

6.3.2.2.3 Location of the graft during urethroplasty for bulbar strictures

The best location for graft positioning into the bulbar urethra remains to be determined. There are many techniques described with ventral, lateral, dorsolateral, or dorsal graft as an onlay or an inlay. Onlay means from the outside onto the urethra, inlay means from the inside after opening the urethra.

Regarding the site of graft placement, the Panel has conducted a SR assessing the literature from 1996 onwards, including studies with at least 20 patients and a minimum of twelve months follow-up [7]. This yielded one RCT, four non-randomised comparative series and 36 case series comprising 3,683 patients. The RCT of Vasudeva et al., compared ventral (n=40) with dorsal (n=40) onlay BMG urethroplasty and reported a patency rate of 90 - 92.5% respectively at twelve months follow-up (p=0.51) [344]. The non-randomised comparative studies could not identify any significant differences in patency rates for dorsal onlay vs. ventral onlay, dorsal inlay vs. ventral onlay or dorsal onlay vs. ventral onlay vs. dorsolateral onlay. Case series reported a patency rate of 62.1-98.3% for dorsal onlay, 74.3-94.4% for ventral onlay and 78.4-92% for dorsal inlay. There are no arguments to assume a higher risk of ED with one of the four techniques. Post-void-dribbling was reported in 0-28.1% with dorsal onlay and in 20-21% with ventral onlay. Other complications were also similar in incidence between techniques. Urethrocutaneous fistula and urethral diverticulum were only reported with the ventral onlay technique although this consisted of only two and one cases, respectively.

Double ventral-dorsal onlay, proposed by Palminteri et al., [144] for high-grade strictures, yielded a patency rate of 91% after 22 months follow-up.

6.3.2.3 Staged urethroplasty for bulbar urethral strictures

6.3.2.3.1 Indications

Staged urethroplasty may be considered when:

- there are locally adverse conditions such as fistula, false passage, abscess, cancer [285, 349, 350];
- there has been a previously unsuccessful complex urethroplasty including failed hypospadias repair [261, 349];
- there is a lack of certainty on behalf of the surgeon regarding the most appropriate form of urethroplasty for the patient [349];
- the stricture is radiotherapy induced [261];
- the stricture is consequent to LS [261] (this is controversial and for some groups LS is a contraindication for a staged urethroplasty [307]; Kozinn et al., recommend leaving at least ten months between 1st stage and 2nd stage re-tubularisation in patients with LS to allow graft complication to develop) [261];
- there is severe spongiofibrosis [351].
6.3.2.3.2 Outcomes

Patency rates of 33.3-94.6% at mean follow-up of 11.2-50 months have been described for staged urethroplasty in series which include men with bulbar urethral stricture disease [261, 307, 329, 351-353]. Grafts (mesh graft, preputial skin, oral mucosa) can be used in staged augmentation as well as marsupialisation [329, 351]. In patients affected by LS, a 52.2% patency rate for staged urethroplasty was reported whereas this was 86% for single-stage buccal mucosa urethroplasty (p < 0.01) [307]. It is highly likely that different stricture and patient characteristics contributed to the differences reported and this should be kept in mind when interpreting the data. Of note, 19-45.5% of patients planned for staged urethroplasty declined to proceed to 2nd stage re-tubularisation [261, 352].

Early complications after staged procedures include wound dehiscence, UTI, epididymitis, scrotal abscess, and penile numbness. Specific to 2nd stage Johanson urethroplasty UCF occurs in 3-15%. The actual incidence of UCF is probably higher as many small fistulae close spontaneously with conservative management and are not formally reported [307, 329, 351].

Late complications of 1st stage urethroplasty include a need for revision in up to 19% - as a consequence of recurrence of LS in graft(s) (8.8%), graft contracture (6.6%) and stomal stenosis (3.3%) [261]. Late complications of 2nd stage urethroplasty include post-micturition dribble in 14-18%, SUI in up to 16%, penile curvature in up to 9%, ED in up to 4%, urethral diverticulum formation in 1% and cold glans [307, 351, 353]. Stress urinary incontinence, penile curvature and ED appear to be particularly associated with mesh graft stage urethroplasty [351, 353].

After their procedure, 86% and 96.6% of men with, respectively, mesh graft and buccal mucosa graft staged urethroplasty were satisfied. The patient groups included in the review were too small to detect significant differences [351]. All are retrospective series – with heterogenous indications, stricture locations (not exclusively bulbar), stricture lengths and patient groups. It is consequently difficult to draw meaningful conclusions from the little data that are available.

See supplementary Table S6.10 for more information.

6.3.2.4 Risk factors for adverse outcomes

In four series specifically dedicated to risk factors for failure after urethroplasty using multivariate analysis, there is conflicting evidence about several factors (aetiology, comorbidity, stricture length, prior therapy) that might be predictive for failure after urethroplasty (Table 6.6). Advanced age does not appear to be a risk factor for urethroplasty failure in the majority of studies, with the exception of Viers et al., 2017 [354] retrospective case series which found that the risk for recurrence was significantly higher beyond the age of 60 (< 50 yrs 94%, > 70 yrs 74%) in 184 patients having a wide variety of urethroplasties. Previous radiation therapy was also found to be a risk factor for stricture recurrence in both Viers’ [354] retrospective case series and Ahyai’s 2015 series [355] – with only a 71% patency rate at a median follow-up of 29 months in those with previous radiotherapy. Based on these data, a clear and evidence-based recommendation cannot be formulated.

6.3.2.5 Management of recurrence after bulbar urethroplasty
Kahokehr et al., [328] followed nearly 400 patients after urethroplasty and found a recurrence rate of 6% (n=25). Ninety-two percent of the failed cases were treated successfully with DVIU and only 8% needed another open reconstruction. However, they did not mention characteristics of the recurrent cases nor the duration of follow-up.

Rosenbaum et al., [359] and Javali et al., [360] retrospectively analysed the outcomes of BMG FGU for ReDo urethroplasty in 51 and 21 patients, respectively, using the other cheek as donor side. Patency rates were 82-86%, which is in the range of primary cases.

Vetterlein et al., [361] compared primary (no previous open urethroplasty) vs. ReDo (previous open urethroplasty with BMG) vs. secondary (previous open urethroplasty without use of BMG) cases in a retrospective series of 534 patients with BMG FGU. The patency rates in primary and ReDo cases were comparable (87%) whilst the outcome in secondary cases was worse (71%).

A small series (n=37) reported on the use of EPA for revision surgery after failed urethroplasty in strictures of 2.1 (range 1-3.5) cm length on average. Patency rates using EPA after failed primary EPA (51%) and after any other technique of urethroplasty (49%) were 95 and 94% respectively with a mean follow-up of 30 months [321].

6.3.3 Urethroplasty for penobulbar or panurethral strictures
The possibilities for reconstruction are various and often include combinations of different techniques or grafts other than OMG. The patency rates are usually lower than in shorter reconstructions (Table 6.7). Hussein et al., [362] performed a RCT comparing skin grafts vs. skin flaps in strictures of mean length 15 cm and found no difference in patency rates (72% vs. 79%) or complications.
Warner et al., [307] performed a multi-institutional review in 2015 including 466 patients with stricture length > 8 cm and found an overall patency rate of 77.5%.

As discussed previously, Kozinn et al., [261] reported on the outcome of staged urethroplasty in a cohort of which 54.9% had panurethral strictures (Table 6.7).

Kulkarni et al., [363] proposed a one-stage completely perineal approach with invagination of the penis and one-sided urethral dissection. After 59 months the overall patency rate was 83.7% in 117 men with a mean stricture length of 14 cm.

Another option in patients refusing or unfit for complex reconstructive surgery is PU (see section 6.3.4 Perineal urethrostomy).

**Summary of evidence**

Publications about panurethral urethroplasties generally come from high volume centres. 4

Different materials and techniques might be needed for reconstruction. 3

**Recommendations**

Offer panurethral urethroplasties in specialised centres because different techniques and materials might be needed. Weak

Combine techniques to treat panurethral strictures if one technique is not able to treat the whole extent of the stricture. Weak
6.3.4 Perineal urethrostomy

6.3.4.1 Indications
Perineal urethrostomy offers a permanent or temporary solution for restoration of voiding in men with complex urethral stricture disease in whom:

- there are no further options to restore urethral patency either due to multiple previous failed urethroplasties [307, 349] or multiple co-morbidities precluding a more expansive surgical undertaking after failed endoscopic management [370];
- there is a lack of certainty on behalf of the surgeon regarding the most appropriate form of urethroplasty for the patient;
- following urethrectomy and/or penectomy for cancer [371].

6.3.4.2 Types of perineal urethrostomy
Johanson described an inverted anterior scrotal funnel PU in 1953. This was later modified by Gil-Vernet and Blandy to utilise a posteriorly based scrotal flap. Both these techniques utilise an inverted U or lambda incision. The Gil-Vernet-Blandy PU has been further modified with the addition of dorsal and/or ventral free OMG augment to allow use of PU in men with strictures consequent to radiotherapy [372] or LS [263] and/or in men with PU stenosis or stricture extending into the proximal bulbar or membranous urethra (“augmented Blandy”) [370].

More recently, the ‘7 flap’ PU utilising a unilateral posteriorly based scrotal flap has been developed for use in the very obese, or in men of all BMI with stricture extension into the proximal bulbar or membranous urethra [373]. Initially this was performed with transection of the distal bulbar urethra but latterly the technique has been modified to a non-transection technique with loop mobilisation of the bulbar urethra (“loop PU”) [374]. The “7-flap” utilises a midline incision – which has been shown to have a significantly reduced side-effect profile in terms of superficial wound infection (1.9% c.f. 18.6%) and superficial wound dehiscence (11.9% c.f. 23.3%) than the inverted U or lambda incision [375, 376] and may be associated with improved urethroplasty (and by inference PU) outcomes, at least in the short term (0% failure c.f. 6.2% failure at six months) [375]. Operative time is similar for all types of PU with mean operative time varying between 97.2 minutes to 112 minutes [371, 377].

The utilisation of PU is increasing [378] – constituting 4.5% of 403 procedures for complex urethral stricture disease in a tertiary centre in 2008 and 38.7% in 2017 [379]. Perineal urethrostomy patients are generally older than those having urethroplasty with a median of 62.6 years of age for men having PU in Fuchs et al., 2018 series compared with a median of 53.2 years for men having anterior urethroplasty [379]. Between 18.7% and 73.4% of men having staged urethroplasty for complex anterior urethral stricture decline to proceed to 2nd stage re-tubularisation after a successful 1st stage and remain voiding from the PU of their 1st stage urethroplasty [261, 349, 352].

6.3.4.3 Outcomes
6.3.4.3.1 Patency rates
Patency rates of 70-95% at mean/median follow-up of 20–63 months have been described [307, 349, 354, 370-372, 374, 377, 379]. All reports are retrospective series – all of which are heterogenous in terms of indications and patients. There is consequently little data available to determine which is the best technique for PU.

McKibben et al., reported a patency rate of 92.9% in 42 patients for “7-flap” PU at median follow-up of 53.6 months, whilst they had a 100% patency rate with loop PU in twenty patients at a median follow-up of thirteen months [374].

Lumen et al., in 2015 reported a 74.3% patency rate for Johanson PU compared with an 87.5% patency rate for Gil-Vernet-Blandy PU (p=0.248), but with a significantly longer follow-up after Johanson PU (median 36 vs. nine months) [371]. Barbagli et al., published the largest series of PU patients to date – including 173 men (all of whom had been planned to have a staged urethroplasty for their complex anterior urethral stricture disease and 127 (73.4%) of whom declined to proceed with 2nd stage re-tubularisation). The median follow-up in this series was 62 months and the patency rate was 70% - confirming that patency rates for PU (and indeed for all urethroplasty [274, 326]) reduce with time [349].

See supplementary Table S6.11 for further information.

6.3.4.3.2 Complications
Perineal urethrostomy complications occur in 2.5-11.4% and include superficial wound dehiscence, scrotal abscess, UTI and urosepsis, bleeding, and transient scrotal pain and numbness [307, 371, 380]. The majority of
complications are Clavien-Dindo grades 1 (2.9-18.8%) and 2 (0-2.9%). Grade 3 complications are rare and only occur in 5.7-6.2%. In the medium-term 22.2-30.8% of men with PU report post-micturition dribble [371].

6.3.4.3.3 Patient reported outcomes
Barbagli et al., reported that 168/173 (97.1%) of men were satisfied or very satisfied with the outcome of their Gil-Vernet-Blandy PU and would have the procedure again at median 62 months follow-up. Of these, 166/173 (95.9%) felt they had excellent or good results from their Gil-Vernet-Blandy PU, 145/173 (85%) felt it caused them no problems and 141/173 (82%) felt it caused their partner no problems [349]. The Trauma and Urologic Reconstructive Network of Surgeons (TURNS) collaborative found no significant change in sexual function and a significant improvement in urinary symptoms following PU in a small group of patients [381], whilst Lumen et al., found satisfactory or acceptable International Prostate Symptom Score (IPSS) outcomes in 26/32 (81.25%) of men with Johanson or Gil-Vernet-Blandy PU at a median follow-up of 32 months and nine months, respectively.

McKibben et al., found a mean patient global impression of improvement (PGI-I) of 1.3 in nineteen patients with either loop PU or “7-flap” PU [374] at median 31 months follow-up.

6.3.4.3.4 Risk factors for patency failure of the perineal urethrostomy
Lichen sclerosus, trauma and infection urethral strictures have poorer outcomes from PU, with PU patency failure in 36.7-67% at a median 62 month follow-up [349, 380]. Worse outcomes were also observed in patients with previous failed urethroplasty and multiple previous endoscopic and open treatments [349, 371, 372].

Barbagli et al., found that stricture length was inversely related to PU patency, as was patient age [349]. Conversely Viers et al., found outcomes worsened with age, reporting patency rates of 100% in men < 50 years old compared with 83% in men aged 60-69 years old [354]. Lopez et al., found increased risk of PU failure in men with ischaemic heart disease which makes sense and would be a putative explanation for the age-related worsening of outcomes noted by Viers et al. [380].

Failure of PU is most commonly treated with surgical revision of PU using V-Y plasty, augmentation or complete ReDo but can also be managed with periodic dilatation or urinary diversion [349, 370, 371].

For further information see supplementary Table S6.11.

6.3.5 Posterior urethra
6.3.5.1 Non-traumatic posterior urethral stenosis
6.3.5.1.1 Treatment of non-traumatic posterior urethral stenosis
Several treatment modalities including conservative management (see section 6.1 Conservative options), endoluminal, open or minimally invasive surgical procedures are currently available, depending on patient’s goals and health status.
6.3.5.1.2 Endoluminal management of non-traumatic posterior urethral stenosis

6.3.5.1.2.1 Dilatation of non-traumatic posterior urethral stenosis

This can be done under loco-regional anaesthesia [382-386]. Dilatation is used for VUAS [382-387] or radiation-induced BMS [117, 388] and in the majority of reported cases, patients were not previously treated for their stricture (see supplementary Table S6.12). Patency rates vary widely between 0-89% [117, 382-388]. The risk of de novo UI was low (0-11%) and no other complications were reported. It is of note that most series report on visually controlled dilatation [382-386] in VUAS without complete obliteration.

6.3.5.1.2.2 Endoscopic incision/resection of non-traumatic posterior urethral stenosis (Table 6.8)

Incisions can be performed at multiple locations according to surgeon’s preference [389]. However, aggressive incisions at the six and twelve o’clock positions should be avoided because of the risk of, respectively, rectal injury and uroscopyhymal fistulation [187, 390-392]. The risk of uroscopyhymal fistulation is especially a concern after previous radiotherapy [393]. Direct vision internal urethrotomy is mainly performed in patients with primary or recalcitrant VUAS although one series performed it in a mix of patients with VUAS and BNS [394] and two series reported it for radiation-induced BMS [117, 388]. Direct vision internal urethrotomy/dilatation for non-irradiated BMS are usually included in series reporting on anterior strictures (see section 6.2 Male endoluminal treatment of anterior urethral strictures). Patency after a 1st “cold/hot knife” DVIU ranges between 25-80% [382, 385, 387, 389, 394-399]. Laser incision yields a 69-100% patency rate [385, 387, 400, 401]. In a retrospective and unbalanced series, LaBossiere et al., found better patency rates for laser incision as compared to dilatation, “cold knife” DVIU and transurethral resection (TUR) [385]. Redshaw et al., reported inferior patency rates for “cold knife” incision vs. “hot knife” incision followed by MMC for BNS (50 vs. 63%; p=0.03) [240] (see supplementary Table S6.13). Urinary incontinence largely varies between 0 and 53% but some series have not assessed urinary continence before DVIU [395, 397]. In series where pre-DVIU continence data were available, de novo urinary continence after DVIU ranges between 0% and 10% [382, 387, 396, 398, 400]. Noteworthy, of 21 patients that were incontinent pre-DVIU in the series of Giannarini et al., eleven (52%) patients became continent, and eight (38%) patients experienced improvement after DVIU [396]. In the series of Lagerveld, 1/5 (20%) patients noticed improvement of UI after DVIU [400]. As most recurrences will occur early [396, 397], it is advised to wait for three to four months after DVIU [389, 397, 402, 403] to proceed with incontinence surgery, if necessary, although others wait for twelve months [403]. The presence of recurrence must be ruled out by cystoscopy prior to incontinence surgery [389, 397, 402, 403].

Another option is to resect the stenosis. Popken et al., reported a 47% patency rate with TUR for untreated VUAS and no patient suffered de novo UI [398]. Kranz et al., compared the results of TUR in 87 and 60 patients with, respectively, VUAS after RP and BNS after TURP. After a median follow-up of 27 (range: 1-98) months, patency rate was 40.2% for VUAS and 58.3% for BNS (p=0.031). The rate of de novo incontinence was significantly higher in patients treated for VUAS compared to BNS (13.8 vs. 1.7%; p=0.011) [404]. Kravchick et al., reported a higher incontinence rate after TUR compared to “cold knife” DVIU and dilatation for VUAS (50% vs. 13% vs. 0%, respectively; p=0.005) [386]. However, the number of patients were small and a selection bias of more severe cases towards TUR might be possible [386]. Alternatively, thermal damage to the adjacent external sphincter during TUR (especially with monopolar current) might be the cause of incontinence [386]. Brodak et al., compared TUR by bipolar resection (n=22) with holmium laser incision and vaporisation (n=17). After a mean follow-up of 42 months, two (9.1%) and four (23.5%) patients suffered a recurrence with bipolar and laser resection respectively (p=0.37). After six months, patients treated with bipolar resection had a significant better Qmax compared to laser treatment (13 vs. 6.1 ml/s; p < 0.001) [401]. Bipolar plasma vaporisation produced an 82% patency rate at a mean 24-month follow-up in 28 patients with VUAS who previously failed endoscopic treatment [405].

Cut-to-the-light technique for a complete obliterative stricture is not advised because of the very-low likelihood of durable patency and for the risk of false passage towards the rectum [402, 406, 407].

Repetitive DVIU was often able to stabilise the stricture [117, 382, 385, 388, 394-396, 404], but ultimately 6-10% required urinary diversion [397] or chronic suprapubic cystostomy [388, 394].

Transurethral resection can be performed for prostatic obstruction due to sloughing after high-energy treatments (HIFU, cryoaiblation) [101]. Transurethral resection for obstructive necrotic debris after radiotherapy is possible but is of limited role. Risk of recurrence is 50% and risk of de novo UI is 15-25% [101].

BNS = bladder neck stenosis; DVIU = direct vision internal urethrotomy; FU = follow-up; ISD = intermittent self-dilatation; NR = not reported; TUR = transurethral resection; VUAS = vesico-urethral anastomosis stricture.

* patency rate after 1st endoluminal treatment evaluated in the study.
* requiring incontinence surgery (artificial urinary sphincter or male sling).
** slightly problematic urinary incontinence by questionnaire post DVIU (no data on pre DVIU continence).
***all incontinent pre-operatively.
6.3.5.1.2.3 Post-dilatation/direct vision internal urethrotomy strategies for non-traumatic posterior urethral stenosis

6.3.5.1.2.3.1 Intermittent self-dilatation for non-traumatic posterior urethral stenosis

As for anterior strictures, ISD can be offered to patients for recurrent posterior stenosis after dilation/DVIU to stabilise the stenosis. This is especially relevant for patients unfit/unwilling to undergo surgery or in patients with radiation-induced BMS [117, 385, 388, 408]. Although ISD may be acceptable to many urologists and patients, it usually is associated with a reduced QoL and poor patient compliance [35].

6.3.5.1.2.3.2 Intrallesional injections for non-traumatic posterior urethral stenosis

In order to stabilise the luminal fibrosis and consequently to reduce the risk of recurrence, injection of antifibrotic agents at the time of endoluminal treatment has been proposed. The majority of patients in these studies were patients with recalcitrant/recurrent non-obliterative VUAS/BNS. Two series used corticosteroids [386, 402], whilst the others used MMC [245, 403, 406-409]. Patency rates with corticosteroid injections range between 50-100% [386, 402]. Patency rates with MMC vary between 50-79% [245, 403, 406-409]. No trials comparing endoluminal treatment with or without adjuvant intrallesional injections were identified.

See supplementary Table S6.13 for further information.

Complications are low across most studies, but all studies were retrospective in nature. Redshaw et al., also reported grade 3 complications in four out of 55 (7%) patients, including osteitis pubis (n=2), bladder neck necrosis (n=1) and rectourethral fistula (n=1) in one multi-institutional study [245]. Three of these patients ultimately required urinary diversion with additional faecal diversion in one patient [245]. Given the severity of these complications, although rare, MMC should not be used outside the framework of a clinical trial [410].

6.3.5.1.2.3.3 Urethral stent for non-traumatic posterior urethral stenosis

Stents have been used anecdotally in the posterior urethra [252, 253, 385]. Patency rates are relatively low (47-60%) [252, 253, 385] at the cost of a high-risk for UI (19-82%) [252, 253].

6.3.5.1.3 Lower urinary tract reconstruction for non-traumatic posterior urethral stenosis
If endoluminal treatment (repeatedly) fails or in case of a completely obliterated posterior stenosis [406, 407, 411, 412], lower urinary tract (LUT) reconstruction may be considered in fit patients motivated to undergo surgery (Figure 6.1). The choice of LUT reconstruction will depend upon the length, location, calibre and aetiology of the stenosis, continence status, bladder function, previous radiotherapy, patient’s preference, and surgeon’s expertise.

Figure 6.1: Options for lower urinary tract reconstruction of non-traumatic posterior urethral obstruction (stenosis/stricture)

6.3.5.1.3.1 Redo vesico-urethral anastomosis for vesico-urethral anastomotic stenosis after radical prostatectomy
After excision of the stenosis, ReDo vesico-urethral anastomosis (ReDo VUA) can be performed. This may be performed via a retropubic, perineal, combined abdominoperineal or robot-assisted approach. Nikolavsky et al., proposes a retropubic approach for VUAS involving the bladder neck, a perineal approach for short VUAS with intact bladder neck and an abdominoperineal approach for long segment (> 3 cm) VUAS with bladder neck involvement [411]. The ReDo VUA must be performed in a tension-free fashion which can be achieved either by mobilisation of the bladder (retropubic approach), mobilisation of the bulbar urethra with corporal splitting and inferior pubectomy if necessary (perineal approach) or both (abdominoperineal approach) [411, 413]. Dinerman et al., reported a robot-assisted abdominoperineal approach in a case with 4.5 cm long complete obliteration [414]. Kirshenbaum et al., reported a pure robot-assisted abdominal approach. Regardless of the approach, the procedure is technically demanding due to the location deep under the pubic symphysis, and the proximity of the external sphincter [413]. As a consequence, surgical morbidity must be considered. As most patients with VUAS were healthy enough to undergo RP, most patients will likewise remain fit and eligible for VUAS surgical reconstruction [411, 413].

FU = follow-up; NR = not reported; RT = radiotherapy; UTI = Urinary tract infection.

* incontinent before ReDo VUA.

** de novo incontinence in four out of eleven patients.

***social continent (1 pad/day).

ReDo VUA in non-irradiated patients yields patency rates of 60-91% (Table 6.9) [411-413, 415-417]. Prior radiotherapy is a risk factor for failure [413, 415]. In addition, radiation-induced bladder toxicity might provoke reduced bladder capacity, low bladder compliance, bladder spasms and pain, and urethral necrosis making reconstruction futile (see below) [393, 413, 418]. ReDo VUA should only be done in patients with adequate bladder function and in the absence of (peri)-urethral pathology (urethral necrosis, calcification, fistulation). Flaps (gracilis flap, peritoneal flap) to support and protect the anastomosis may be beneficial in irradiated patients [411].

With the transperineal approach, UI is inevitable, as this approach disrupts the external sphincter [412, 413, 415, 417]. With the retropubic approach, Pfalzgraf et al. reported de novo incontinence in only four out of eleven (36%) patients [416]. In the series of Nikolavsky et al., where a retropubic approach was predominantly used, incontinence rate was 58% [411]. Kirshenbaum et al., reported no incontinence in five patients treated by robot-assisted retropubic approach [412]. Giudice et al., reported incontinence in one out of four patients treated with the retropubic approach [417]. Therefore, some authors [101, 411, 412] have proposed a preference for the retropubic approach in patients with good pre-operative urinary continence, although both approaches have never been directly compared for UI. In addition, the lack of perineal dissection by a retropubic approach will preserve the perineal anatomy and vascularisation which makes subsequent artificial urinary sphincter (AUS) less demanding [412]. Artificial urinary sphincter implantation should be deferred because of the risk of VUAS recurrence and difficulty of treating any recurrent VUAS with the cuff of the AUS in place [397, 413]. The exact timing of AUS placement is not consensual in the literature but most advise waiting at least three to six months to ensure stability of the VUA patency [393, 410, 413, 415, 416].

Due to the complexity of this pathology the EAU Urethral Strictures Panel advises that VUAS reconstruction should be performed only in experienced high-volume centres, particularly after prior radiotherapy or other energy ablative treatments.

6.3.5.1.3.2 Posterior stenosis after surgery for benign prostatic obstruction

6.3.5.1.3.2.1 Bladder neck reconstruction for bladder neck stenosis after surgery for benign prostatic obstruction

The bladder neck is augmented by advancement of local bladder flaps (Y-V or T-plasty) with or without resection of scar tissue. They are used for BNS refractory to endoscopic treatments [412, 419-421]. Patency rates vary between 83-100% with fourteen to 45 months follow-up [412, 419-421]. There is a trend to perform bladder neck reconstruction by minimally invasive approach (laparoscopic, robot-assisted) [412, 420, 421]. De novo incontinence rate ranges from 0-14% [412, 419-421]. Satisfaction among patient is high with 88.5% of patients stating that they are pleased with the surgery, with an improvement of QoL in 75% of patients [419, 421]. Recently, a robot-assisted augmentation technique with subtrigonal buccal mucosa inlay has been successfully reported in a case report, but this technique requires further investigation [422].

See supplementary Table S6.14 for further information.

6.3.5.1.3.2.2 Bulbomembranous strictures after surgery for benign prostatic obstruction

Bulbomembranous urethral strictures (BMS) after TURP or simple prostatectomy are managed as bulbar strictures and can be treated by EPA or augmentation urethroplasty with a graft, taking into account the length and tightness of the stricture [84, 423]. As reconstruction is in the proximity of the external sphincter and the bladder neck was already damaged during BPO surgery, the risk of incontinence (up to 25%) is present [84].

6.3.5.1.3.3 Radiation/high-energy induced posterior strictures

6.3.5.1.3.3.1 Bulbomembranous strictures secondary to radiation/high energy sources

The major challenge in treating radiation-induced strictures is the consequent tissue damage with impaired healing capacity, involving not only the stricture itself but also the adjacent proximal and distal areas of the scar [413, 424]. Additionally, proximity of the stricture to the external sphincter can further complicate surgery [84]. Due to these challenges, patients with radiation-induced BMS have long been considered poor candidates for urethral reconstruction and have been treated with urinary diversion if endoscopic treatments failed or were not possible [413].
Most radiation-induced BMS are short and in these cases, EPA is possible [84, 189, 425, 426]. Reported patency rates vary between 67-95% [84, 189, 426, 427]. De novo UI was reported in 33-36% of cases [84, 189, 426, 427] and this seems to be higher compared to the rates reported for bulbar and traumatic-posterior strictures (see sections 6.3.2 and 6.3.5). Chung et al., reported de novo incontinence in twelve out of 36 (33%) patients with EPA for radiation-induced BMS vs. four out of 33 (12%) patients with EPA for PFUI (p=0.05) [427].

Excision and primary anastomosis has the advantage of avoiding the use of a graft or a local flap in an area of poor vascular health. However, EPA will not be possible for BMS with a long bulbar segment and in these cases, augmentation urethroplasty will be necessary despite the aforementioned concerns [189, 426, 428, 429]. Glass et al., used a cut-off of 2.5 cm to proceed with augmentation urethroplasty, whilst this was 2 cm by Meeks et al. [426, 429]. Some authors have even used augmentation urethroplasty as their standard technique for radiation-induced BMS [355]. Both dorsal [423, 428] and ventral onlay [355, 429] have been described to treat radiation-induced BMS. In the absence of a robust vascular graft bed, the support by a gracilis flap has been proposed during ventral onlay graft urethroplasty [429, 430]. Patency rates with augmentation urethroplasty vary between 50-83% [189, 355, 426, 428] with de novo incontinence ranging between 11-50% [189, 355, 428](see supplementary Table S6.15). Rourke et al., reported a patency rate of 91% vs. 75% for EPA and augmentation urethroplasty, respectively, but this difference did not reach statistical significance (p=0.31) [428]. Of note, strictures treated with augmentation urethroplasty were significantly longer compared to those treated by EPA (respectively 6.1 vs. 2.1 cm; p < 0.001). They reported no significant differences in de novo UI (26 vs. 25%; p=1), new onset ED (35 vs. 0%; p=0.06) or other adverse events (30% vs. 33%; p=1) [428].

6.3.5.1.3.3.2 Prostatic strictures secondary to radiation/high energy sources

Radiotherapy and high-energy modalities (cryoablation, HIFU) might provoke prostatic necrosis, sloughing and obstruction [101]. Cases refractory to TUR and with good bladder capacity might be salvaged by prostatectomy taking into account the morbidity associated with salvage RP (rectal injury, VUAS, incontinence) [101, 424]. Mundy et al., treated nine patients with patency in six, (67%) and one (11%) needing an AUS for severe incontinence [413].

Cases with impaired bladder function, urethral necrosis and/or peri-urethral pathology should be considered for supravesical diversion, especially if a suprapubic catheter is not tolerated due to bladder pain or spasms [393, 410, 413, 418].

Recently, a “pull-through” procedure has been reported as an alternative to cutaneous diversion for reconstruction of the devastated posterior urethra associated with a defunctionalised bladder after radiation where tissue vascularity and quality is poor [431]. This novel technique of total LUT reconstruction combines salvage cystectomy, ileal neobladder formation and urethral pull-through. An AUS was implanted in a 2nd stage. All eight patients maintained a patent posterior urethra after a median follow-up of 58 (range 16-84) months. Five patients experienced low-grade complications after the 1st stage, but no high-grade complications were reported. Four out of eight (50%) patients experienced cuff erosion with need for removal and subsequent reimplantation. After a median of two revision surgeries (range 0 to 4), all patients achieved social continence enhancing QoL [431]. This technique requires further validation before its use can be recommended.

**Summary of evidence LE**

| Patency rates with EPA and augmentation urethroplasty are respectively 67-95% and 50-83% in case of radiation-induced BMS. | 3 |
| Radiation-induced BMS longer than 2-2.5 cm are rarely amenable for EPA. | 3 |
| De novo incontinence and new onset ED after urethral surgery for radiation-induced BMS are reported in respectively 11-50% and 0-35% of cases. | 3 |
| Salvage prostatectomy can achieve patency in 67% of patients for prostatic strictures after irradiation or high-energy treatments but morbidity is substantial. | 4 |

| **Recommendations** | **Strength rating** |
| Use either excision and primary anastomosis or augmentation urethroplasty for short (< 2.5 cm) radiation-induced bulbomembranous strictures (BMS) refractory to endoscopic treatment depending on surgeon’s experience. | Weak |
| Perform augmentation urethroplasty for long (> 2.5 cm) radiation-induced BMS. | Weak |
Warn patients about the risk of de novo incontinence and new onset erectile dysfunction after urethroplasty for radiation-induced BMS.  
Offer salvage prostatectomy in motivated and fit patients with adequate bladder function in case of a prostatic stricture due to irradiation or high-energy treatment.

### 6.3.5.1.4 Exirpative surgery and urinary diversion for non-traumatic posterior urethral stenosis

In complex and/or recurrent cases [411], LUT reconstruction is not possible or not indicated due to severe necrosis, calcification and significant morbidity, especially severe pain [410]. Intractable haematuria or fistulation might be other reasons to abandon the urethral outlet. Typically, the patient has a history of pelvic irradiation or high energy prostate cancer treatment and several previous attempts to achieve cure. Moreover, and equally important, any of the options used to deal with a devastated posterior urethra are dependent upon good bladder capacity, compliance and function allowing for bladder preservation as well as healthy distal ureters [393, 410]. The last resort therapeutic option is urinary diversion (continent or incontinent) with or without cystectomy [413, 418]. Different techniques have been described and the choice between them largely depends on the bladder capacity, presence of local symptoms, performance status and expectations of the patient. Cystectomy during urinary diversion is able to palliate symptoms of intractable bladder pain, spasms and haematuria which are especially prevalent after pelvic radiotherapy [432-435]. The satisfaction rate was reported to be 100% and the overwhelming majority of patients would have undergone this exirpative surgery an average of thirteen months sooner in a study of fifteen patients by Sack et al. [436]. In a report by Faris et al., 27% of the patients also required bowel diversion due to intractable gastrointestinal morbidity, highlighting the complexity of this pathology [418].

### 6.3.5.2 Post-traumatic posterior stenosis

The acute and early management of PFUIs is discussed in the EAU Guidelines on Urological Trauma. A non-obliterative stenosis is the result of a partial injury at the membranous urethra or occurs after unsuccessful early realignment of a partial or complete injury. An obliterative stenosis is the consequence of a complete injury with a distraction defect between the ruptured urethral ends. The gap between these ends fills up with dense fibrotic tissue [11].

The deferred management of PFUI is at earliest three months after the trauma. After that period, the pelvic haematoma has nearly always resolved, the prostate has descended into a more normal position, the scar tissue has stabilised [437] and the patient is clinically stable and able to lie down in the lithotomy position [437, 438].

#### 6.3.5.2.1 Endoluminal treatment for post-traumatic posterior stenosis

Endoluminal treatment (dilation, DVIU) of an obliterative stenosis using the cut-to-the light principle will not be successful [48] and has a risk of creating a false passage towards the bladder base or rectum [439]. For a non-obiterative, short (≤ 1.5 cm) stenosis, one attempt of endoluminal treatment (endoscopic incision or dilation) can be performed. Kulkarni et al., reported a 92.3% and 96.5% stricture-free rate with “cold knife” and holmium laser urethrotomy, respectively (median follow-up respectively 61 and 57 months) [440]. These results are challenged by Barbagli et al., who reported a 51% stricture-free rate with holmium laser urethrotomy but with no data on length of follow-up available [441]. Cai et al., compared patient outcomes between bipolar plasma vaporisation and “cold knife” DVIU in 53 patients with posterior traumatic (80%) and iatrogenic (20%) urethral strictures with significantly different stricture-free rates of 81.5% vs. 53.8% at a mean follow-up of 13.9 months, respectively [442]. No severe complications were reported in either group. A statistically significant shorter operative time was found in the bipolar group [442]. Barratt et al., calculated a composite stricture-free rate of 20% after all types of endoscopic treatments (but with a mix of obiterative and non-obiterative
steno...s) [48]. De novo UI was reported in 4% of cases [48]. Repetitive endoluminal treatments are unlikely to be curative and must be discouraged as this delays the time to definitive cure and can lead to more complications [443, 444].

6.3.5.2.1.2 Endoluminal treatment after failed urethroplasty for post-traumatic posterior stenosis
In case of a non-obliterative and short (≤ 1 cm) recurrence after failed urethroplasty, endoluminal treatment can be performed [445, 446]. Although a 1st and 2nd DVIU can be successful with a stricture-free rate of 22.9-77.3% and 0-60% respectively, three or more incisions are never successful (see supplementary Table S6.16) [445-449]. Therefore, repetitive endoluminal treatments (dilations and/or endoscopic incisions) can only be considered as a palliative option [446, 450].

6.3.5.2.2 Urethroplasty for post-traumatic posterior stenosis
In view of the complexity and difficulty of urethroplasty and the fact that the best results are obtained with its first attempt, this surgery must be performed in high-volume centres [451-453]. It has been calculated that to achieve and maintain sufficient experience in the reconstruction of PFUI, one centre per twelve million inhabitants is sufficient (for well-resourced countries) [452].

6.3.5.2.2.1 First urethroplasty for post-traumatic posterior stenosis
6.3.5.2.2.1.1 Indication and technique of urethroplasty for post-traumatic posterior stenosis
Progressive perineal EPA is the standard treatment for an obliterative stenosis and for a non-obliterative stenosis as first attempt, or after failure of primary endoluminal treatment [48, 454].

Although both a midline and inverted U-incision are possible to gain access to the posterior urethra, a midline incision is associated with a significant reduction in trauma to the superficial perineal and posterior scrotal nerves and vessels, in the rate of surgical site infections (3.1% vs. 16.4%) and reduced length of hospitalisation [376].

A combined transpubic abdomino-perineal approach is only necessary in complicated cases such as those with associated para-urethral bladder base fistula, trauma-related recto-urethral fistula, and bladder neck injury [439]. Total pubectomy during transpubic abdomino-perineal reconstruction has a higher complication rate (bleeding, pelvic instability, dead space) compared to partial (superior or inferior) pubectomy with no gain in surgical exposure [455]. Although also considered complex situations, iatrogenic recto-urethral fistula (after misdirected endoscopic treatment), traumatic recto-urethral fistula < 5 cm from the anus, UCF and urinoma cavity can usually be corrected by a progressive perineal approach only [439, 456].

6.3.5.2.2.1.2 Patency rate after urethroplasty for post-traumatic posterior stenosis
The overall patency rate after deferred EPA is 85.7% [48]. Complete excision of scar tissue is a strong predictor for freedom of stricture whereas number (3-5 vs. 6-7) and size (3.0 vs. 4.0 cm) of sutures are not [457]. One retrospective cohort study showed a significantly improved patency rate if dorsal anterior urethral spatulation was performed compared to ventral anterior urethral spatulation [458]. Another retrospective study showed an improved patency rate after eversion of the urethral mucosa of both urethral ends before anastomosis (“valgus urethral mucosa anastomosis”) [459]. The findings of both studies have yet to be confirmed in a prospective fashion.
To preserve the antegrade arterial inflow of the bulbar urethra and reduce the surgical trauma of “classic” deferred EPA, bulbar artery sparing EPA has been described [460]. Initial patency rates vary between 88.5-100% with 20-45 months of follow-up (see supplementary Table S6.17) [460-462]. Xie et al., only used this technique for distraction defects less than 2.5 cm [462]. No evidence exists to date whether bulbar artery sparing EPA is superior to the “classic” EPA in terms of patency rate and potency and continence rates.

In case of a very deep location of the proximal urethral end that makes anastomotic suturing impossible, Badenoch described a pull-through technique which has a 33.3-96.5% patency rate after 43-126 months of follow-up (see supplementary Table S6.18 for further information) [440, 463, 464]. With the aim to reduce stricture recurrence, Wong et al., advise a 1.5 cm segment overlap of the bulbar stump within the prostatic urethra during the pull-through technique [463]. To facilitate the suturing at the proximal part of the urethra located deep under the pubic bone, the robotic approach is under exploration but there is no evidence so far of improved outcome with this approach [465].

Patency rate in children varies between 75-89.8% (Table 6.10). The statement that EPA in children is associated with poorer results [466] cannot therefore be generally accepted [467].

6.3.5.2.2.1.3 Sexual function, urinary continence, and rectal injury after urethroplasty for post-traumatic posterior stenosis

Regarding erectile function, a prospective study by Hosseini et al., found no significant difference before, and three or six months after EPA for posterior traumatic stenosis [472]. Another prospective study by Tang et al., also demonstrated no significant overall change in ED after urethroplasty. However, in the subgroup of patients with pre-operative non-vascular ED, a significant post-operative increase in ED was observed [473]. A meta-analysis of retrospective studies showed a significant decline of the rate of ED from 43.27% before to 24.01% after posterior urethroplasty (p < 0.001) [474]. Assessment of erectile function and its definitive treatment (e.g., penile prosthesis) should be performed two years after the trauma because of the potential return of normal erectile function within that time [475, 476].

After deferred EPA, antegrade ejaculation is present in 98.3-100% of cases [477, 478]. Decreased ejaculatory volume and/or diminished ejaculatory force were reported in 17.2-18.7% of cases but it cannot be assessed whether this is due to the trauma or due to the surgery [477, 478].

Continence after PFUI and urethroplasty is generally attributed to a competent bladder neck [48]. On the other hand, as most ruptures occur at the bulbomembranous junction just below the external sphincteric mechanism, at least a part of the external sphincter mechanism can be spared during urethroplasty [479]. Therefore, incontinence is rare with deferred EPA (6.8%) and is usually due to incompetence of the bladder neck although an incompetent bladder neck will not necessarily result in incontinence after urethroplasty [48, 479].

Rectal injury is a relatively rare (0-10.2%) but severe complication after deferred EPA (see supplementary Table S6.19) [437, 449, 455, 458, 480-484]. The risk of rectal injury tends to be higher in complicated cases or cases with previous urethral manipulations [437, 480, 485].

6.3.5.2.2.2 ReDo-urethroplasty for post-traumatic posterior stenosis

In case of a recurrent stenosis, a repeat (“ReDo”) urethroplasty is possible. In the majority of cases, especially if not all consecutive length-gaining manoeuvres have been used during the 1st EPA, another EPA can be performed [468, 480, 481, 486, 487]. The Badenoch pull-through technique is again an option if no adequate mucosa-to-mucosa suturing is possible (See supplementary Table S6.18) [463, 464]. In case of excessive dead space after resection of the fibrosis, gracilis muscle [485] or omental flaps (laparoscopically harvested if urethroplasty was performed using perineal approach only) [439, 483] have been advised to fill up this space.
and support the anastomosis. These flaps, or alternatively bulbospongious muscle or local subcutaneous dartos flaps, are also useful to separate the suture lines in case of a concomitant recto-urethral fistula [439, 451, 456, 485]. If the urethra cannot be anastomosed in a tension-free fashion, despite the aforementioned manoeuvres, or in cases of ischemic narrowing/necrosis of the bulbar urethra, options are a tubed preputial island flap, staged BMG urethroplasty with flap, staged buccal mucosa dartos flap, radial forearm free flap urethroplasty or entero-urethroplasty [451, 481, 486, 488]. In case of entero-urethroplasty, the sigmoid colon is preferred above ileum (which is in turn better than stomach) because of the proximity of the vascular pedicle to the perineum. Entero-urethroplasty should only be done in the presence of a competent bladder neck because subsequent implantation of an AUS is nearly impossible [488].

Patency rate of different types of ReDo-urethroplasty varies between 37.5-100% (Table 6.11) [446, 451, 453, 480, 481, 483, 486-488]. An alternative is to abandon the normal urinary outlet and opt for Mitrofanoff-vesicostomy, PU (if local perineoscrotal skin is suitable) or permanent suprapubic diversion [481, 488].

</tr>
</tbody>
</table>
Total pubectomy during transpubic abdomino-perineal reconstruction has a higher complication rate (bleeding, pelvic instability, dead space) compared to partial (superior or inferior) pubectomy with no gain in surgical exposure.

By using the progressive perineal approach, a combined transpubic abdomino-perineal approach is usually not needed except for very long distraction defects and in case of complicated situations, which include associated para-urethral bladder base fistula, trauma-related recto-urethral fistula, and bladder neck injury.

If the urethra cannot be anastomosed in a tension-free fashion or in case of ischaemic narrowing/necrosis of the bulb urethra, options are a tubed preputial island flap, staged buccal mucosa graft urethroplasty with flap, staged buccal mucosa darts flap, radial forearm free flap urethroplasty or enterourethroplasty.

In case of excessive dead space after resection of the fibrosis, local flaps have been advised to fill up this space and support the anastomosis. These flaps are also useful to separate the suture lines in case of a concomitant recto-urethral fistula.

**Recommendations** | **Strength rating**
--- | ---
Perform open reconstruction for post-traumatic posterior stenosis only in high-volume centres. | Weak
Perform progressive perineal excision and primary anastomosis (EPA) for obliterative stenosis. | Strong
Perform progressive perineal EPA for non-obliterative stenosis after failed endoluminal treatment. | Strong
Perform a midline perineal incision to gain access to the posterior urethra. | Strong
Do not perform total pubectomy during abdomino-perineal reconstruction. | Strong
Reserve abdomino-perineal reconstruction for complicated situations including very long distraction defect, para-urethral bladder base fistula, trauma-related recto-urethral fistula, and bladder neck injury. | Weak
Perform another urethroplasty after 1st failed urethroplasty in motivated patients not willing to accept palliative endoluminal treatments or urinary diversion. | Weak
Use a local tissue flap to fill up excessive dead space or after correction of a concomitant recto-urethral fistula. | Weak

7. DISEASE MANAGEMENT IN FEMALES

7.1 Signs and symptoms of female urethral strictures

The symptoms of female urethral strictures are non-specific and therefore generally non-diagnostic. Female urethral stricture presents with mixed filling and voiding symptoms with frequency in 60.2%, urgency in 51%, poor flow in 42%, incomplete emptying in 42%, UI in 36% (stress, urge or mixed), nocturia in 26%, UTI in 20% and straining to void in 16%. It very rarely presents with urethral pain (3%), terminal dribble (1%), haematuria (1%) or renal failure (1%) (see supplementary Table S7.1) [15, 23, 124, 126, 132, 134, 136, 138, 489-492]. There is often a significant delay in diagnosis of FUS from time of development of symptoms with mean delays of 4.3-12 years described (range 1-30 years) [129, 136].

7.2 Diagnosis of female urethral strictures

Twenty-four studies detail investigations leading to a diagnosis of FUS (see supplementary Table S7.2) [13, 15, 124-127, 130-136, 138, 491-500]. In all cases a full history was taken, and a detailed pelvic examination was performed to assess for prolapse, masses, scars and vulval dermatological disorders such as LS, lichen planus or vulvo-vaginal atrophy. Flow rate and US PVR assessment was evaluated in eighteen (75%) and seventeen (71%) studies, respectively. Lateral VCUG was performed routinely in fifteen studies (63%) and as required in one study (4%). Cystourethroscopy was performed routinely in thirteen studies (54%) and as required in two studies (8%). Urodynamics (UDS) were performed routinely in four studies (17%) and as required in seven studies (30%) whilst video-urodynamics (VUDS) were performed routinely in three studies (13%) and urethral calibration (to < 14 Fr) also in three studies (13%). Pelvic MRI was performed as required in four series (17%) whilst transrectal US (TRUS) and renal US were each performed routinely in two series (8%) and intravenous urography (IVU) in ten (4%).
Flow rate and PVR assessment make inherent sense as initial non-invasive screening tools and allow for simple monitoring of effect of treatment. Voiding cystourethrography and/or VUDS will permit diagnosis of BOO [23, 499], visualisation of ballooning above the proximal end of the FUS [134], and delineation of alternate or co-existent diagnoses such as detrusor overactivity (DO) and SUI [127], although VCUG, VUDS and UDS require the ability to insert a 6 Fr catheter and may not be possible without preliminary urethral dilatation in all cases of FUS [492]. Likewise, passage of a cystourethroscopy will require a preliminary dilation in the majority of cases even when a paediatric uretero-renoscope is utilised [125]. Cystourethroscopy will allow for formal identification of the distal end of the FUS and will also allow for exclusion of a functional cause of BOO [134]. Magnetic resonance imaging is performed mainly to exclude alternate pathology such as urethral diverticulum and urethral carcinoma and also allows assessment of the degree of urethral fibrosis associated with FUS [492, 501]. Proponents of TRUS utilise it in lieu of MRI and for visualisation of the dilated urethra above the proximal end of the FUS [502].

7.3 Treatment of female urethral strictures

7.3.1 Minimally invasive techniques for treatment of female urethral strictures

Several minimally invasive treatments have been reported; these include urethrotomy, dilatation, meatotomy and meatoplasty. Meatotomy and meatoplasty are essentially the same procedure in the female urethra and the term ‘meatoplasty’ will be used throughout this document.

7.3.1.1 Urethrotomy for treatment of female urethral strictures

No papers were found detailing the use and outcomes of urethrotomy specifically for the management of FUS. Internal urethrotomy or dilatation was used by Massey and Abrams [503] to treat a variety of pathologies, including FUS, causing symptoms of obstructed voiding, and resulted in symptomatic improvement in 80% of patients. As this study included women with a variety of complaints and did not assess urodynamic parameters, the results in the patient subset with true urethral stricture are unclear. If utilised, urethrotomy in the female urethra involves incisions at three, nine and occasionally twelve o’clock [503].

7.3.1.2 Urethral dilatation for treatment of female urethral strictures

With this treatment, the urethra is dilated to between 30 Fr and 41 Fr. Some patients will continue with ISD. Romman et al., 2012 [491] and Popat & Zimmern [492] also described suture plication of bleeding areas of the meatus if required post-urethral dilatation.

Four studies described the results after twelve to 59 months follow-up of, in total, 183 patients having dilatation only. Patency rates ranges from 7.5-51% (see Table 7.1) [127, 128, 491, 492]. In another four studies that included, in total, 31 patients that continued to perform ISD, stabilisation of the stricture with “patency” was obtained in 37.3-100% of cases at twelve to 21 months of follow-up (see Table 7.1) [13, 132, 135, 497]. New onset SUI (0.8%) and other complications are very rare after dilation (see supplementary Table S7.3). Due to the low complication rate, the minimally invasive nature of the technique and the reasonable success rate, it is acceptable to start with urethral dilation as a first-line treatment for an uncomplicated FUS.

7.3.1.3 Meatoplasty for treatment of female urethral strictures

Meatal stenosis is extremely rare, with only 2/58 (3%) of females evaluated for voiding dysfunction found to have true meatal stenosis [504]. Only three meatoplasty papers were identified containing 60 patients (see supplementary Table S7.4): one [505] detailed meatoplasty outcomes in a series of 58 girls whilst the 2nd was from a study analysing outcomes of various forms of FUS treatment that included one case of meatoplasty [506], and the third was a case report [132]. The patency rate of meatoplasty in girls is excellent with 97% of the 58 girls in Hesing’s series having a successful outcome with no reported side effects at twelve months. Forty-eight of 50 patients experienced resolution of their recurrent UTIs and improved voiding symptoms one year after meatoplasty [505]. None of these studies reported incontinence or other acute complications. For short meatal strictures, meatoplasty is the first-line treatment option.

7.3.2 Urethroplasty for treatment of female urethral strictures

Twenty-five papers report the outcomes of urethroplasty for FUS disease in 231 patients in total after the scope search of the Panel. The Panel have analysed the outcomes of these urethroplasty according to flap or graft type as: vaginal graft, vaginal flap, labial/vestibular graft, labial/vestibular flap and buccal or lingual graft.

In female urethroplasty, a dorsal approach is via a stricturotomy at twelve o’clock, a ventral approach is via a stricturotomy at six o’clock and circumferential is a full circumference reconstruction.

7.3.2.1 Vaginal graft augmentation urethroplasty for treatment of female urethral strictures

There were four studies reporting vaginal graft urethroplasty including 37 patients [15, 495, 500, 507]. All
37 vaginal graft urethroplasties were performed via a dorsal approach in women with a mean/median age of 47.5-60.6 years (range 35-70). In these studies, patency rates of 73-100% were reported after 22-27 months follow-up (Table 7.1). No complications and no new onset UI were reported.

See supplementary Table S7.5 for further information.

7.3.2.2 Vaginal flap augmentation urethroplasty for treatment of female urethral strictures
Vaginal flap urethroplasty was reported in 70 women and was always via a ventral approach, utilising an inverted U vaginal flap inlay in five studies (n=52) [126, 127, 130, 489, 490], a lateral C vaginal flap in three studies (n=17) [124, 132, 136] and one vaginal island flap urethroplasty in one patient [130]. At a mean/median follow-up time of 30-80.7 months, patency rates of 67-100% were reported (Table 7.1). Eight (11.4%) patients had a simultaneous pubo-vaginal sling (PVS), four (5.7%) had a simultaneous Martius fat pad flap interposition and one (1.4%) had a simultaneous excision of urethral diverticulum. Five (7.1%) patients developed new onset UI, two (2.9%) developed UTIs and two (2.9%) described temporary intravaginal direction of their urinary stream.

See supplementary Table S7.6 for further information.

7.3.2.3 Labial/vestibular graft augmentation urethroplasty for treatment of female urethral strictures
There were four papers detailing the outcomes of 31 patients having labial or vestibular graft urethroplasty (see supplementary Table S7.7); nineteen had ventral labial minora graft [131, 138, 494] and twelve had dorsal labial graft [135]. At a mean follow-up of fifteen to 24 months, patency rates of 75-100% were reported with ventral grafting whilst this was 100% with dorsal grafting at six to fifteen months follow-up (Table 7.1). One (5.2%) ventral graft patient developed a UTI post-surgery. There were no other complications (including UI).

7.3.2.4 Labial/vestibular flap urethroplasty for treatment of female urethral strictures
There were two papers detailing the outcomes of nineteen patients having labial/vestibular flap urethroplasty: two had a ventral labia minora flap [508] and seventeen had a dorsal vestibular flap [16]. At a follow-up of 24 months the two ventral flap patients (100%) remained stricture-free whilst fifteen (88%) dorsal flap patients remained stricture-free at a mean of twelve months follow-up (Table 7.1 and supplementary Table S7.8). There were no adverse short- or long-term effects reported in either group.

7.3.2.5 Buccal and lingual mucosal graft augmentation urethroplasty for treatment of female urethral strictures
There were twelve papers detailing the outcomes of 73 patients, all treated with BMG except in the series of Sharma et al., who used lingual mucosa graft (LMG) in fifteen patients at the dorsal urethra [125]; 44 patients with dorsal onlay oral (buccal or lingual) mucosa graft (DOOMG) [125-127, 130, 133, 493, 499, 507, 509]; 27 with ventral onlay BMG (VOBMG) [126, 134, 510, 511] and two with circumferential BMG urethroplasty [126]. At a mean/median follow-up of six to 28 months, 62.5-100% of DOOMG urethroplasty patients were stricture-free whilst 50-100% of VOBMG patients were stricture-free at a mean of ten to 24 months follow-up. Both circumferential BMG patients were stricture-free at a mean of 21 months follow-up (Table 7.1). Seven (15.9%) DOOMG patients suffered a low-grade short-term adverse effect and no patients in any subgroup developed sustained new onset UI.

For further information see supplementary Tables S7.9, S7.10 and S7.11.

7.3.2.6 Anastomotic urethroplasty
Anastomotic urethroplasty has only been described in two cases in the literature – both in women with very short mid-urethral stricture and both of whom were stricture-free at four and 24-months follow-up respectively. None of them suffered from UI post-operatively [126, 496] (see supplementary Table S7.12).

FU = follow-up; ISD = intermittent self-dilatation; N = number of patients; UI = urinary incontinence.

Summary of evidence

Female urethral stricture symptoms are long standing and non-specific, the most commonly reported are frequency, urgency, poor flow, incomplete emptying, and UI. It is important to exclude FUS in female patients with LUTS.

Urethral dilatation alone to 30-41 Fr provides low stricture-free rates of mean 35% at mean follow-up 36.3 months.

Urethral dilatation and ISC or planned repeat dilatation provides stricture-free rates of 75%.

Urethroplasty provides stricture-free rates of 81-92%. No one particular type of urethroplasty is superior to another.

Meatotomy/meatoplasty for short meatal strictures has a success rate of 95% at twelve months follow-up.

Recommendations

Perform flow rate, post-void residual and voiding cystourethrogram or video-urodynamics in all women with refractory lower urinary tract symptoms. Strong

Perform urethral dilatation to 30-41 Fr as initial treatment of female urethral stricture (FUS). Weak

Perform repeat urethral dilatation and start planned weekly intermittent self-dilatation (ISD) with a 16-18 Fr catheter for the 1st recurrence of FUS. Weak

Perform urethroplasty in women with a 2nd recurrence of FUS and who cannot perform ISD or wish definitive treatment. The technique for urethroplasty should be determined by the surgeon’s experience, availability and quality of graft/flap material and quality of the ventral vs. dorsal urethra. Strong

Treat meatal strictures by meatotomy/meatoplasty. Weak
8. DISEASE MANAGEMENT IN TRANSGENDER PATIENTS

8.1 Treatment of strictures in trans men

In trans men, stricture treatment depends on the time after neophallic reconstruction, stricture location, stricture length and quality of local tissues [512].

8.1.1 Management of strictures early after neophallic reconstruction

Urethral surgery on tissues in the acute phase of inflammation and wound healing is not indicated and should be postponed until any healing problems of the neophallus have been resolved and scar tissue formation in the urethra has been stabilised. This usually takes six months [32, 145]. Endoscopic incision for short (< 3 cm)
urethral strictures has been performed, mainly at the anastomotic site, with a maximum stricture-free rate of only 16.7% when performed within six months after neophallic reconstruction [513]. Insertion of a suprapubic catheter is the first-line treatment in cases of obstructive symptoms severely affecting the patient's QoL, recurrent UTI or retention. The alternative is perineostomy, which is a specialist procedure and should be performed by a urologist familiar with transgender urethral anatomy. The perineostomy may be closed at the time of formal urethral reconstruction [145].

8.1.2 Treatment of meatal stenosis in trans men
Intermittent urethral dilatation is an option, as palliative treatment, for low-grade meatal stenosis with the interval of dilatation depending on the interval of stricture recurrence. Patients with high-grade meatal stenosis, those who refuse ISD, or those who want a durable solution should be offered simple meatotomy. Patency is 75% (mean follow-up 39 months) but the drawback is that the meatus will be in a hypospadiac position [145]. Alternatively, a staged urethroplasty can be offered [145].

8.1.3 Treatment of strictures at the neophallic urethra
Endoscopic incision of a short stricture at the neophallic urethra has been reported but evidence is very scarce, and the long-term results seem to be disappointing (34% patency rate after median follow-up of 51 months) [513]. Single-stage graft urethroplasty is only possible if the graft can be supported and covered by the healthy surrounding fatty tissue of the neophallus. Experience is very limited and reported patency rate is 50% after a mean follow-up of 102 months [145].

The standard treatment for these strictures is staged urethroplasty with or without graft augmentation [145, 512] (BMG or full thickness SG) [32, 145]. A patency rate of 69.7% has been described with these techniques (mean follow-up: 25 months) [145].

For complex (e.g., fully obliterated) or recurrent strictures at the neophallic urethra, a complete urethral substitution of this part needs to be performed. Different suitable flaps have been described (radial forearm free flap, superficial circumflex iliac artery free flap, pedicled groin flap). Double-face grafts with the ventral graft supported by rotating a part of the neoscrotum or by a gracilis flap have been successfully reported in a very limited number of patients [512].

8.1.4 Treatment of strictures at the anastomosis neophallic urethra-fixed part of the urethra
Short, non-obliterative, strictures can be treated by endoscopic incision. A first endoscopic incision has a 45.5% patency rate, but this dropped to 0% in case of three or more attempts (median follow-up of 51 months) [513]. Therefore, repetitive endoscopic incisions should be discouraged unless with palliative intent.

For very short (< 1 cm) low-grade strictures, Heineke-Mikulicz urethroplasty is an option reporting a 57.9% patency rate after a mean follow-up of 44 months [145].

If endoscopic incision fails or if the stricture is nearly or completely obliterative, options are EPA or graft augmentation urethroplasty. In case of short (< 2-3 cm) strictures, EPA yields a 57.1% patency rate (mean follow-up of 35 months) [32, 145]. If EPA is not possible, usually for strictures longer than 2 cm, a ventral onlay BMG urethroplasty demonstrated a 50% patency rate (median follow-up of 9.5 months) [514]. In case of insufficient ventral tissue during graft urethroplasty, it is advised to support this graft by a local fasciocutaneous flap [515]. An alternative (especially after failure of the previous techniques) can be a staged approach, but no data are currently available [514].

8.1.5 Treatment of strictures at the fixed part of the urethra
This part of the urethra has a more reliable blood supply, and the dorsal part of the urethra is supported by the corporal bodies of the clitoris. Therefore, single-stage dorsal inlay graft urethroplasty is possible for strictures at this site. Experience however is very limited [145, 512].

Staged repair with or without a dorsal graft is a reliable treatment for these rare strictures [145].

8.1.6 Definitive perineostomy in trans men
The vast majority of trans men have a strong desire to void in a standing position [512]. Therefore, definitive perineostomy should only be offered to those with refractory strictures or to patients with strictures who do not wish to have complex reconstructive surgery [32, 145].
8.2 Peri-operative care after treatment of strictures in trans men
Anecdotally, after endoscopic incision and urethroplasty, the urethral catheter is maintained for two to three weeks [513, 514]. Peri-catheter urethrography is advised before catheter removal as it might be challenging to reinsert the urethral catheter in case of urinary extravasation [514].

8.3 Strictures in trans women
It is acceptable to start with dilation of a short and non-obliterative stricture in trans women although no long-term data about the effectiveness are available [33, 516]. If this is not possible or if it fails, a short (< 1 cm) meatal stricture can be treated by Y-V meatoplasty with an 85% stricture-free rate [517]. Somewhat longer (1-2 cm) meatal strictures can be treated by a neovaginal advancement flap (inverted U or “7-flap”) with no recurrence observed after 37 months median follow-up [518].

9. TISSUE TRANSFER

9.1 Comparison of grafts with flaps
One small RCT (LS excluded) comparing OMG with PSF found no significant difference in urethral patency rate [519]. Penile skin flaps had a higher urogenital morbidity (superficial penile skin necrosis, penile torsion, penile hypoesthesia, and post-void dribbling) and longer operation time compared to OMG. Furthermore, patient dissatisfaction was significantly higher with penile flaps [519]. Another small RCT (LS excluded) comparing penile skin grafts with PSF confirmed these findings with longer operation time and more superficial penile skin necrosis in the group of the flaps whereas the urethral patency rate was similar between both groups [362]. Several retrospective series also found a comparable urethral patency rate between PSF and grafts [273, 275, 280, 502] (Table 9.1).

Table 9.1: Comparative studies of grafts vs. flaps used in urethroplasty for anterior urethral strictures
Due to their robust vascular pedicle, flaps can be used as a tube as well as a patch in a single-stage approach [451]. Castagnetti et al., showed that grafts used as a tube have significantly higher complication rates as compared to onlay grafts (OR: 5.86; 95% CI: 1.5-23.4) [521]. A review by Patterson et al., also reported high (circa 50%) complication and recurrence rates for tubularised grafts [522]. Iqbal et al., have shown an encouraging 87% stricture-free rate in 23 patients who were offered single-stage circumferential skin flap urethroplasty [284]. Therefore, if there is a need to reconstruct a complete urethral segment with a tissue-transfer tube in a one-stage operation, flaps are usually the preferred option. As flaps carry their own vascular supply to the reconstruction site, they do not rely on the local vascularisation of the recipient site. Therefore, they need to be considered in case of poor urethral vascularisation (e.g., after irradiation or dense scarring after previous urethroplasty) [280, 523]. In addition, flaps survive well in the presence of active urinary infection [524].

Grafts and flaps should not be considered competitors in urethral surgery. A combination of a flap with a graft is possible for complex, multifocal or penobulbar strictures [280, 525, 526].

9.2 Comparison of different types of flaps

Different local flaps have been described. Penile skin flaps are generally hairless, although the ventral penile skin can be hair-bearing around the raphe in some ethnic groups/phenotypes. They can be harvested as a transverse preputial skin flap [527], a transverse distal PSF [365, 524, 528, 529] or as a longitudinal island flap [530]. Urethral patency rates vary between 74.2-100% [275, 365, 524, 527-530]. Complications include skin necrosis (0-3.8%), fistula (0-7%), penile deformity (0-7%), post-void dribbling (0-79%) and sacculation (0-16.5%) (see supplementary Table S9.1). As there are no direct comparative series available about these flaps it is not possible to determine which performs better.

Hair-bearing perineal and scrotal flaps have been described as well. Fu et al., demonstrated that PSF had a significantly better urethral patency rate compared to scrotal and perineal skin flaps (respectively 87.7%, 69% and 66.7%) [275]. The hair-bearing perineal and scrotal skin flaps are associated with hairball formation and chronic infection which may cause failure of the repair. A study of Blandy with long-term follow-up, reports 3% revision for calculi and 3% revision for diverticula [531].

An alternative is to epilate the needed scrotal skin prior to tissue transfer [532, 533] or to patch an OMG to the underlying dartos tissue of the scrotum after incision of the scrotal skin and use this patch as a flap in a second attempt [451].

9.3 Comparison of different types of grafts

Buccal mucosa is at present the most commonly used graft. Urethral patency rates of buccal mucosa vary between 75.6% and 91.7% with 16-75 months of follow-up (see supplementary Table S9.2) [534-540]. Penile skin is another popular graft, especially in uncircumcised men where the foreskin is an abundant source of graft material.

In case of LS, Trivedi et al., demonstrated a significantly higher urethral patency rate when using non-genital mucosal grafts for reconstruction (82.6%) compared to genital skin grafts (4%) [541]; therefore, the use of genital skin in LS cases is not indicated.

There is no RCT comparing buccal mucosa with penile skin. A secondary analysis of a meta-analysis comparing dorsal with ventral onlay graft urethroplasty found a superior urethral patency rate for buccal mucosa compared to penile skin (88.1% vs. 79%; p < 0.001). In this secondary analysis, no data were available about the stricture aetiology, stricture length, follow-up duration or other potential confounders between both groups [542]. A pooled analysis of non-RCTs comparing buccal mucosa (n=483) with penile skin (n=428) found a better urethral patency rate for buccal mucosa (respectively 85.9% vs. 81.8%). However, the results might be biased because of the longer follow-up time and longer stricture length in the penile skin group [543]. Lengthy skin grafts (up to 20 cm) can be taken from the foreskin in a spiroid fashion which is clearly more difficult with OMG.

The main disadvantage of BMG harvesting is the oral morbidity and because of this morbidity, lingual mucosa has been proposed as alternative. A SR and meta-analysis of comparative studies comparing LMG with BMG (four prospective, two retrospective studies) showed no significant differences in urethral patency rate and overall long-term complication rate [544-546]. These studies revealed that LMG was associated with more difficulties in eating/drinking, speaking, tongue protrusion and dysgeusia [544, 545]. In 13.8-20%, speaking problems remained after six months [544, 545]. A retrospective study of Xu et al., reported difficulties in tongue movements, numbness over the donor site and speaking difficulties in 6.2%, 4.9% and 2.5% of patients, respectively after twelve months [303]. On the other hand, BMG harvesting provoked more oral tightness which was present in up to 24% of patients after six months [544, 545]. Chauhan et al., showed that immediate and early donor site complications were more common in the BMG group, except for bleeding being more common in the LMG group. Numbness (61%), difficulty in chewing (54%), swelling (48%) and articulation (40%) were the most common problems during the first week. Late donor site complications were rare [547]. Pal et al., describes more short-term complications (difficulty in tongue movement and slurring of speech) in the LMG group, compared to the BMG group. Long-term complications (after three months) at the donor site (persistent pain, perioral numbness, tightness of mouth, salivary disturbance, scarring of the cheeks) were only seen in the BMG group [548]. For long strictures, buccal mucosa can be combined with lingual mucosa [503].

Beyond the oral mucosa and penile skin graft, a multitude of other autologous grafts have been described. These include: postauricular skin [526, 550], abdominal skin [367], split-thickness mesh graft from the thigh [351], inguinal skin [302] and colonic mucosa [551] (Table 9.2). Manoj et al., only used the postauricular skin when both genital skin and oral mucosa were not usable [550]. Marchal et al., used postauricular skin in addition to oral mucosa to reconstruct lengthy strictures [526]. Meeks et al., reported the use of abdominal skin graft mainly in patients with lengthy strictures where OMG harvesting would be insufficient, in case of prior OMG urethroplasty or if OMG was refused by the patient [367]. Pfalzgraf et al., reported a comparable urethral patency rate for split-thickness mesh graft and BMG (respectively 84 and 83%), but more penile deviation (9% vs. 0%) and lower satisfaction (83.3% vs. 96.7%) with split-thickness mesh graft [351]. Xu et al., used colonic mucosa for lengthy (> 10 cm) strictures. Urethral patency rate was 85.7% but graft harvest requires an abdominal procedure, and 1/35 (2.9%) patient developed a colonic-abdominal fistula [551]. Due to the limited experience with grafts other than oral mucosa and penile skin, they should only be considered if oral mucosa and penile skin are not available, indicated, or desired.

N = number of patients; NR = not reported.

Summary of evidence

- Patency rates of buccal mucosa and lingual mucosa are comparable. 1a
- Different types of oral grafts have distinct types of oral morbidity and some of the oral complications might last in the long-term. 1a
- Patency rates with penile skin grafts are 79-81.8% vs. 85.9-88.1% with buccal mucosa. 3
- In LS related strictures, the use of genital skin graft is associated with poor patency rates (4%). 3

Recommendations

- Use buccal or lingual mucosa if a graft is needed and these grafts are available. Weak
- Inform the patient about the potential complications of the different types of oral grafting (buccal vs. lingual vs. lower lip) when an oral graft is proposed. Strong
- Use penile skin if buccal/lingual mucosa is not available, suitable, or accepted by the patient for reconstruction. Weak
- Do not use genital skin graft in case of lichen sclerosus. Strong

9.4 Tissue engineered grafts

9.4.1 Cell-free tissue engineered grafts

These grafts are derived from cadaveric or animal sources (e.g., porcine small intestine submucosa [SIS], acellular bladder matrix, acellular dermal matrix), are completely cell-free and serve as a scaffold for host cell ingrowth [552]. The main advantage suggested for their use is the off-shelf availability [552].

A small RCT (n=30) comparing acellular bladder matrix with BMG reported a urethral patency rate of respectively 66.6% and 100%. The poorer results of acellular bladder matrix were the most apparent in cases of an unhealthy urethral bed [553]. Palminteri et al., reported a global urethral patency rate with SIS graft in 19/25 (76%) cases [554]. In this series SIS graft urethroplasty failed in all cases with a stricture length > 4 cm [554]. On the other hand, Xu et al., reported adequate urethral patency in 26/28 patients (92.8%) after a median follow-up of 25 months. Of note, only one patient in this series underwent previous urethroplasty suggesting only minor spongiofibrosis in the remaining patients [555]. Other series have included only a limited number of patients with short follow-up. In these series, urethral patency rates vary between 20-100% [552].

Summary of evidence

- Patency rate of cell-free tissue engineered grafts decreases with large stricture length and unhealthy urethral bed. 1b

Recommendation

- Do not use cell-free tissue engineered grafts in case of extensive spongiofibrosis, after failed previous urethroplasty or stricture length > 4 cm. Weak

9.4.2 Autologous tissue engineered oral mucosa grafts

These grafts contain a matrix seeded with autologous oral mucosa cells. Production requires a small oral mucosa biopsy (≤ 0.5 cm²) and the graft is further manufactured in the lab. The main advantage suggested is the reduction of oral donor site morbidity whereas the main disadvantages are costs and the strict time frame between manufacturing and implantation of the graft [552].
The clinical use of autologous tissue-engineered OMG was evaluated in a prospective, multicentre study including 99 patients [556]. Estimated twelve- and 24-months urethral patency rate was 67.3 and 58.2%, respectively. Oral adverse events were minimal. No comparative studies with acellular grafts or native OMGs are available nor are there any data about the cost-effectiveness [552].

### 9.5 Management of oral cavity after buccal mucosa harvesting

The post-operative morbidity of closure vs. non-closure of the buccal mucosa harvesting site has been evaluated by a number of prospective RCTs.

The results are summarised in Table 9.3. Based on these findings, no clear recommendation can be provided as to whether or not to close the harvesting site and the decision can be left to the treating physician.

Oral rinsing with chamomile [557] or chlorhexidine [545, 558] solution has been suggested in the first post-operative days without any evidence that this reduces pain or other oral complications.

### 10. PERI-OPERATIVE CARE OF URETHRAL SURGERY

#### 10.1 Urethral rest

After any form of urethral manipulation (urethral catheter, ISD, dilatation, DVIU), a period of urethral rest is necessary in order to allow tissue recovery and stricture “maturation” before considering urethroplasty. This improves the ability to identify the true extent of the fibrotic segments during subsequent surgery. If the patient develops incapacitating obstructive symptoms or urinary retention, a suprapubic catheter should be inserted. Terlecki et al., propose diagnostic evaluation after two months and urethroplasty after three months of urethral rest. These timings are based on the general principles of wound healing [561]. In their study, it has been shown that these periods allow for reliable stricture evaluation during urethrography which is, in turn, important to ensure selection of the most appropriate urethroplasty technique [561]. Utilising this strategy, similar outcomes were obtained compared to patients with stable previously unmanipulated strictures [561]. However, the optimal duration of urethral rest for all patients is not known and the degree of associated infection and inflammation should be taken into account as well, with longer periods of rest in those with greater degrees of infection and inflammation.
After any form of urethral manipulation, a minimum period of three months urethral rest is necessary to allow for tissue healing before performing urethroplasty.

### 10.2 Antibiotics

Post-operative wound infection and UTI are common post-operative complications and infection at the site of reconstruction may contribute to failure of urethroplasty. The vast majority of reconstructive urologists perform urine culture one to two weeks prior to surgery [562]. Urine culture is superior to urine-analysis which can be omitted in the pre-operative evaluation [562]. If infection or colonisation is present, a therapeutic course with antibiotics is recommended pre-operatively. In case of an indwelling catheter general principles would suggest at least an attempt to suppress the colonisation with pre-operative antibiotics [562]. These practices are in accordance with the strong recommendations of the EAU Guidelines on Urological Infections:

- “Screen for and treat asymptomatic bacteriuria prior to urological procedures breaching the mucosa.”
- “Treat catheter-associated asymptomatic bacteriuria prior to traumatic urinary tract interventions.”

An intra-operative prophylactic regimen with antibiotics (according to local antibiotic resistance profiles) is effective in reducing the rate of post-operative surgical site and UTIs [562]. Although most urologists continue with post-operative antibiotics upon and even beyond catheter removal, there is no evidence that such a prolonged administration would reduce the infective complication rate [562]. The EAU Guidelines on Urological Infections do not routinely recommend the use of antibiotic prophylaxis to prevent clinical UTI after urethral catheter removal. There is no evidence that this recommendation would not apply to catheter removal after urethral surgery.

### 10.3 Catheter management

After uncomplicated DVIU, there is no advantage in maintaining the catheter for a prolonged period and it should be removed within 72 hours [563].

After one-stage urethroplasty and closure of the urethral plate after staged urethroplasty, urinary extravasation at the site of reconstruction must be avoided [564]. For this purpose, urinary diversion by either transurethral catheter or suprapubic catheter with urethral stent can be used. With respect to the type of catheter material, a prospective randomised (but underpowered) trial comparing silicone vs. hydrogel coated latex transurethral catheters showed no significant difference in the time to stricture recurrence nor in the overall recurrence rate [564]. The size of the urethral catheter utilised usually varies between 14 Fr and 20 Fr [565, 566]. Systematic use of anticholinergic drugs has not shown a significant reduction in the rate of involuntary pericatheter voiding whilst catheterised [567].

After urethroplasty an indwelling catheter is commonly left in situ for two to three weeks [566, 568]. After three weeks of urethral catheterisation, an extravasation rate of 2.2-11.5% at urethrography has been reported after different types of urethroplasty [568-571]. However, success with early catheter removal under three weeks has also been reported. A study after EPA for non-complicated anterior strictures demonstrated no significant difference in extravasation (6.8% vs. 4.5%) and recurrence rates (4.9% vs. 5.2%) between catheter removal at one or two weeks respectively [572]. Peloaert et al., reported an extravasation rate of 3.5% vs. 8.3%, when the catheter was removed ≤ 10 days or > 10 days respectively after all types of urethroplasty (n=219) (p=0.158) [565]. Importantly, patients who had a duration of catheterisation of > 10 days had longer and more complex strictures [565].
Prior to catheter removal after urethroplasty, it is important to assess for urinary extravasation to avoid ensuing complications including peri-urethral inflammation, abscess formation and fistulation [568, 570]. Importantly, some authors have identified urinary extravasation as a predictive factor for stricture recurrence [565, 573]. Other series, however, could not confirm the prognostic significance of urinary extravasation but they included any form of extravasation (including minor leaks) [570, 571]. Grossgold et al., found that high-grade leaks (defined as length ≥ 1.03 cm and width ≥ 0.32 cm) were significantly associated with higher restricture rates. This study also found length of extravasation > 1.03 cm alone to be an independent predictor of restricture [573]. In cases of persistent and significant urinary extravasation, the catheter should be maintained or reinserted and the examination repeated after one week [568]. However, low-grade (“wisp-like”) extravasation does not appear to affect long-term restricture rate and the catheter can be removed in these cases without subsequent urethrogram [570, 573]. In case of any doubt about the significance of extravasation, it is safe to keep the catheter in for an additional week and ReDo the assessment.

The assessment of urinary extravasation is achieved by either pericatheter retrograde urethrography (pcRUG), classic RUG or VCUG [568]. Voiding cystourethrography (after catheter removal) is the most physiologic examination as it shows the urethra under normal intra-urethral pressures and using this test residual urethral narrowing is most accurately identified. This has been found to be a strong prognostic factor for failure in a series evaluating bulbar FGU [571]. In contrast, pcRUG is associated with supraphysiological intra-urethral pressures and a potentially higher chance of false positive results [568, 573]. Although there is no evidence that one imaging modality is superior to the other, pcRUG should be performed if there is a high-risk of leakage as it avoids the need for catheter reinsertion through a recently reconstructed urethra in case of a positive exam. High risk of leakage depends on the complexity of urethroplasty (e.g., stricture length > 10 cm, panurethral repair) [570, 573]. External clinical signs of impaired wound healing (e.g., abscess formation, wound dehiscence) are also associated with a high risk (71.4%) of leakage [565]. In cases of attempted VCUG where the patient is not able to void during fluoroscopy after catheter removal, RUG should be performed [573].

Although limited evidence for urethroplasty care in trans men exists, one study advised a three-week period of transurethral catheterisation with pcRUG upon catheter removal [514].

After perineostomy or the 1st stage of staged urethroplasty, the catheter can be removed without need for urethrography after three to five days [349, 570].

11. FOLLOW-UP

11.1 Rationale for follow-up after urethral surgery

The rationale for following-up patients after urethral stricture surgery is to detect and manage any complication or recurrence. As with any surgical procedure, following urethroplasty some patients will present with complications at short to medium follow-up: approximately 38% with bulbar urethroplasties [322] and up to 54% for all anterior urethroplasties [574]. Most of these complications (92%) would be classified as Clavien
grade 1 or 2 [322]. Even though urethroplasty techniques provide the highest chances for successful treatment of urethral strictures, some patients will experience recurrence [326]. For further details on particular outcomes in each urethral segment, please review the individual chapters of this Guideline.

### 11.2 Definition of success after urethroplasty surgery

The “traditional academic” definition of post-operative success after urethroplasty has been considered as “The lack of any post-operative intervention for restricture” [575]. This definition, despite being widely used [307, 322] is problematic as it ignores asymptomatic or even symptomatic recurrences in patients not willing to undergo further surgeries [575]. There is some variation as to what is considered intervention with some groups accepting endoscopic treatments as success, while considering failure only as the requirement for a ReDo urethroplasty [308].

A more objective definition of success is the “anatomic success”, defined as “Normal urethral lumen during RUG or cystoscopy, regardless of patient symptoms”. Using this definition, stricture recurrence or anatomical failure is considered by some groups as urethral narrowing found to be endoscopically impassable – without force – with a 16 Fr flexible endoscope [143, 576]. This definition is certainly stricter, with up to 35% of cystoscopic recurrences after bulbar urethroplasty remaining asymptomatic, and thus would have been considered as successful if a “lack of further intervention” definition was used [143]. Other groups consider cystoscopic recurrence as any stricture that is visible on post-operative cystoscopy, even the so-called “large calibre re-strictures” (> 17 Fr) [141]. Not all anatomic recurrent strictures would need further treatment [575]. It was suggested to intervene when the anatomic recurrence is associated with recurrence of symptoms, structure-related high post-void residuals or a stricture calibre of < 14 Fr even if these are asymptomatic [575].

Over the last ten years, the evaluation of urethral surgery outcomes has shifted towards a “patient-reported definition of success”. The aim of any urethral intervention is to allow patients to return to a normal state of voiding while maintaining QoL [577] or to minimise symptoms, reduce disability, and improve HRQoL by restoring normal urinary function [578]. Even if the surgeon reconstructed a wide and patent urethra, if patients experience pain, sexual dysfunction or perceive their urinary function as not improved, they will not rate their outcome as successful [575]. On a multivariate analysis including both patient-reported and clinical parameters, urine flowmetry parameters failed to demonstrate significant contribution to satisfaction [579]. Kessler et al., reported that only 78.3% of patients with clinical success described themselves as (very) satisfied. More dissatisfaction significantly appeared with penile curvature, penile shortening, worsening of erectile function and impairment of sexual life [580]. Conversely, 80% of patients defined as clinical failures considered themselves as (very) satisfied with their outcomes [580]. Regardless of anatomic success after urethroplasty, post-operative pain, sexual dysfunction and persistent LUTS were independent predictors of patient dissatisfaction [579]. Improvement in voiding function (i.e., statistical improvement on IPSS) alone does not predict patient satisfaction after urethroplasty [581]. On a multivariate analysis including both patient-reported and clinical parameters, after adjusting for disease recurrence and age, persistence in voiding symptoms (weak stream), genitourinary pain, and post-operative sexual function alterations were the greatest independent drivers of post-operative dissatisfaction [579]. In addition, penile shortening (OR: 2.26; 95% CI: 1.39-3.69) and chordee (OR: 2.26; 95% CI: 1.44-4.19) were independent predictors of patient dissatisfaction after urethroplasty [581] (Table 11.1).

*p < 0.05; ** p < 0.001.

SHIM = Sexual Health Inventory for Men; MSHQ = Male Sexual Health Questionnaire;
CLSS = Core Lower Urinary Tract Symptom Score; IPSS = International Prostate Symptoms Score.

Due to this evident discrepancy between surgeon’s assessment and patient assessment, PROMs have been developed for the follow-up after urethroplasty [158, 578].

A complete approach for urethral surgery outcomes would combine both anatomic, endoscopic, and patient-reported success [324, 575]. The Panel suggest using a functional definition of success in clinical practice, namely “lack of symptoms and/or need for further interventions”.

Collecting standardised documentation of the patient’s subjective assessment of their symptoms and objective anatomic outcomes would be limited for academic purposes, in order to allow comparison of surgical outcomes among reconstructive urologic surgeons and centres. Those objective and subjective outcomes measures should therefore be assessed and reported (simultaneously but separately) when evaluating urethroplasty results [575].

11.3 Follow-up tools after urethral surgery

11.3.1 Diagnostic tools for follow-up after urethral surgery

11.3.1.1 Calibration during follow-up after urethral surgery

The difference between calibration and urethral dilatation is usually subjective as soft strictures may be dilated during calibration [582]; therefore, urethral calibration should be used with caution for follow-up after urethroplasty. Dedicated calibration bougies should be used and not dilators.

11.3.1.2 Urethrocystoscopy during follow-up after urethral surgery

Urethrocystoscopy has been considered the most useful tool to confirm the presence or absence of a recurrent stricture [141, 583], as up to 35% of patients with re-strictures remain asymptomatic [143]. Also, the cystoscope could be a measure to calibrate the strictured lumen, bearing in mind the most commonly used endoscopes: 15.7 Fr (5 mm diameter) or 17.3 Fr (5.5 mm diameter) [583]. Urethrocystoscopy allows differentiation of recurrences as diaphragm/cross-bridging – responding to simple intervention, or significant urethral restrictures – requiring repeated interventions or ReDo surgeries [584]. Endoscopic assessment at three months after anterior urethroplasty can predict the risk for further re-intervention at one year. Compared to normal endoscopy, large calibre (> 17 Fr) restrictures have a HR of 3.1 (1.35-7.29) for repeat intervention while small calibre (< 17 Fr) restrictures have a 23.7 HR (12.44-45.15) adjusted for age, stricture length, location, and aetiology [141]. The main problem with using urethrocystoscopy for routine follow-up is the low compliance of patients as only 54% of patients underwent endoscopy at one year after urethroplasty, even when it was a part of a study protocol [143].

11.3.1.3 Retrograde urethrogram and voiding cystourethrogram during follow-up after urethral surgery

Retrograde urethrogram combined with VCUG are commonly used to confirm suspected recurrence [585, 586] or as part of a routine protocol to assess post-operative urethral patency [587, 588].
11.3.1.4 Urethral ultrasound – Sonourethrography during follow-up after urethral surgery

The use of SUG as a follow-up tool is not very common. It would be a reliable tool for diagnostic recurrent strictures [585].

11.3.2 Screening tools for follow-up after urethral surgery

These tools are used to assess whether there is suspicion of stricture recurrence and need for subsequent diagnostic evaluation (see section 5. Diagnostic evaluation).

11.3.2.1 Flow-rate analysis during follow-up after urethral surgery

Evaluating the $Q_{\text{max}}$ is the commonest follow-up tool. Different cut-off points from $Q_{\text{max}}$ 15 ml/s or 12 ml/s were suggested to consider the intervention as a failure or to trigger a confirmatory test for recurrence [587]. There is no clear threshold, and 19% of patients with $Q_{\text{max}} < 14$ ml/s would still have a patent urethra, allowing passage of 15 Fr cystoscope [144].

Flow rates may be affected by operator error, BPO/LUTS, bladder dysfunction, and variations in bladder capacity. Further limitations of uroflowmetry include the need for a minimum voided volume of 125-150 ml to reach a voided flow rate that reliably predicts an abnormality [582]. Even in controlled settings, the percentage of patients with adequate pre- and post-operative uroflowmetry analysis is only 31% [588]. Comparing both pre- and post-operative $Q_{\text{max}}$ levels was suggested, and a difference in $Q_{\text{max}}$ of 10 ml/s or less is found to be a reliable screen tool for recurrence (sensitivity 92%, specificity 78%). This measure also has strong reproducibility ($R=0.52$) [588]. Unfortunately, this improvement after urethroplasty is significantly different between age groups, with less than 10 ml/s average change in those over 65 years old, probably affected by BPO and/or bladder dysfunction [589]. Another parameter to consider is the shape of the voiding curve, recording it as flat (obstructed) or bell-shaped [590]. An obstructive voiding curve demonstrated 93% sensitivity to predict recurrent strictures, while a combination of urinary symptoms and obstructive voiding curve achieved 99% sensitivity and 99% NPV [590].

11.3.2.2 Post-void residual ultrasound measure during follow-up after urethral surgery

Post-void residual US measure is significantly increased in patients with recurrent strictures compared with those without recurrences [585]. Unfortunately, PVR measurement is affected by abdominal ascites, bladder diverticula and/or poor bladder function [582], with some studies reporting inconsistent correlation with obstruction in the presence of BPO. Also, US measures of PVR are user dependent, showing high interobserver variability. Combined with other tests – uroflowmetry, IPSS, and SUG – PVR achieves adequate predictive values [585], but currently there is no literature to support its solo use, to assess urethral stricture recurrence [591].

11.3.2.3 Symptom questionnaires during follow-up after urethral surgery

The IPSS questionnaire, despite being designed for BPO, showed significant improvement after successful urethroplasty and inverse significant correlation with $Q_{\text{max}}$ [581, 582]. The mean improvement of IPSS is around -11 points (range -19 to -5) [589].

</table>

N = number of patients; NR = not reported; IPSS = International Prostate Symptoms Score; IQR = interquartile range.

Combination of IPSS and $Q_{\text{max}}$ analysis was suggested to diagnose recurrences. Using an IPSS cut-off point of 10 points associated with $Q_{\text{max}} > 15$ ml/s would prevent further invasive studies in 34% of patients, while only 4.3% of strictures < 14 Fr would have been missed. Using an IPSS cut-off point of 15 points associated with $Q_{\text{max}} > 15$ ml/s would prevent further invasive studies in 37% of cases, while 6% of strictures < 14 Fr would have been missed [593].
The Visual Prostate Symptom Score (VPSS) was also used to diagnose recurrent urethral strictures, offering a significantly shorter time to completion compared with IPSS, especially in cases of illiteracy or limited education. Visual Prostate Symptom Score showed a good correlation with IPSS, $Q_{\text{max}}$ and urethral diameter. A combination of VPSS > 8 with $Q_{\text{max}}$ < 15 ml/s had a NPV of 89% and a PPV of 87% for recurrent urethral strictures [594].

Post-micturition dribble, assessed by the specific question of the USS-PROM questionnaire, was present in 73% of patients pre-operatively and 40% after anterior urethroplasty, while only 6.3% was de novo. Incidence was not predicted by stricture location nor urethroplasty type [148].

11.3.3 Quality of life assessment, including disease specific questionnaires during follow-up after urethral surgery

Urethral stricture affects QoL evaluated by EQ-5D-3L questionnaire. Pre-operative anxiety and depression was found in 29% of patients. De novo AD after urethroplasty is uncommon (10%) and has two predictors: decreased sexual function and poor reported image of overall health [595]. A more recommended approach is the assessment of the condition-related QoL [596]. The USS-PROM proved useful to assess outcomes in anterior urethroplasty patients [578]. Its use also received criticism, as some of the individual generic QoL questions do not improve after successful urethroplasty, as they are not condition-specific [597]. Currently, there is another version of PROM, being developed and validated by a North American collaborative group, including questions related to the sexual consequences of urethral stricture disease [159]. PROM questionnaires should be implemented in each visit to check for functional success, as they are able to show improvement over time.

The Core Lower Urinary Tract Symptom Score (CLSS) questionnaire was used to assess pre- and post-urethroplasty pain in the bladder, penis/urethra, and perineum/scrotum. Most of the parameters improved after urethroplasty, but up to 29% of patients reported worsening of perineal pain after surgery [598].

Sexual function should be evaluated by validated tools if not assessed in a PROM. The international index on erectile function (IIEF), SHIM, O’Leary Brief Male Sexual Function Inventory (BMFSI), SLQQ (Sexual Life Quality Questionnaire), Male Sexual Health Questionnaire (MSHQ) have all been used after urethroplasties for evaluation of erectile and ejaculatory functions. Other non-validated tools were suggested such as the Post-Urethroplasty Sexual Questionnaire (PUSQ) [599] or specific questionnaires for genital appearance (length, curvature) or sensitivity [600].

11.4 Ideal follow-up interval after urethral surgery

The optimal follow-up strategy must allow for an objective determination of anatomic and functional outcomes to assess surgical success whilst avoiding excessive invasive testing that leads to unnecessary cost, discomfort, anxiety, and risk [575].

After anterior urethroplasty, 21% of recurrences are clinically evident, and cystoscopically confirmed, after three months [601] and 96% after one year [584]. Early recurrences are more frequent in patients with LS and older age, in longer strictures and when skin grafts were used [601].
11.5 Length of follow-up after urethral surgery

The median time of recurrence after bulbular urethroplasty is approximately ten months [328]. In case series, between 55.4% [601] and 96% [584, 587] of all recurrences are detected during the first year of follow-up after urethral surgery. Twenty-three percent of bulbular stricture recurrences are detected during the second year of follow-up, and the percentage of recurrences decreases after the second year [326].

On the other hand, long-term follow-up studies highlighted the role of length of follow-up as a predictor for stricture recurrence after bulbular urethroplasty [326, 603]. Late recurrences—later than five years after urethroplasty—could be observed in up to 15% of cases [144, 326]. This should be considered mainly after augmentation urethroplasties, especially in case skin grafts were used [586]. Certainly, patients should be instructed to seek urological evaluation if they experience late recurrent symptoms [603].

11.6 Risk-stratified proposals during follow-up after urethral surgery

Cost of follow-up after urethroplasty is higher in the first year after the procedure [602]. In a literature review it ranged between 205 to 1,784 US Dollars, with higher costs associated to posterior urethral repairs [602]. As the risk of recurrence and side effects are related to the type of stricture and urethroplasty, a different follow-up schedule was proposed and shown to be cost-effective in the USA, potentially saving up to 85% of costs after five years [576]:

- Urethroplasties with a low risk of recurrence (EPA urethroplasty without history of radiotherapy, hypospadias, or LS features) could be safely followed up based on monitoring of symptoms, using self-administered IPSS questionnaire, every three months for one year, and annually thereafter.
- Urethroplasties with standard risk of recurrence (urethroplasty using grafts, flaps, and/or post-irradiation, hypospadias and/or LS patients) could combine IPSS questionnaire + flowmetry every three months for one year, and annually thereafter. Additionally, RUG at three and twelve months should be performed.

In this protocol, urethrocystoscopy is only performed if required [576]. Another suggested follow-up protocol includes urethrocystoscopy or RUG/VCUG at three months post-operatively, in order to rule out early failures, especially in case of graft use. If there is evidence of good anatomical outcome in these tests, flowmetry and questionnaire results at three months should be considered as the new baseline. Thereafter, follow-up could be safely and routinely performed with non-invasive tests (flowmetry – evaluating $Q_{max}$ and the shape of curve – and questionnaires). Any deterioration should be further investigated with a urethrocystoscopy [591].

A recently suggested protocol also included assessment of LUTS, sexual function (erectile and ejaculatory), and LUT pain, that need to be compared with pre-operative findings which should include a PROM questionnaire [575]. Cystoscopy and flowmetry should be performed between three to six months postoperatively, and flowmetry findings should be considered as the new baseline for longitudinal follow-up. Future significant decline (25-30%) in $Q_{max}$ or $Q_{max} - (average flow rate)$ should trigger new cystoscopy to rule out anatomic recurrence, even in patients who are symptom-free [575]. A routine cystoscopy at twelve to fifteen months should be performed at the surgeon’s discretion, based on risk assessment of three aspects: higher-risk patients, evidence of partial urethral narrowing at three-month assessment, low-volume surgeons [575].

11.7 Follow-up protocol proposal after urethroplasty

11.7.1 Surgeries with low risk of recurrence

- Anastomotic urethroplasties in the bulbular/bulbo)membranous segment with no history of radiotherapy, hypospadias, or balanitis xerotica obliterans (B XO)/LS features.
Table 11.3: Follow-up protocol for urethroplasty with low risk of recurrence

<table>
<thead>
<tr>

<td>+**</td>
<td>On indication</td>
<td>On indication</td>
</tr>
</tbody>
</table>

*Follow-up could be discontinued after two years, advising the patient to seek urological evaluation if symptoms worsen. Academic centres could increase the length of follow-up for research purposes.

**The Panel suggests performing an anatomic assessment at three months.

11.7.2 Surgical management options with standard risk of recurrence

- Anastomotic urethroplasties in the bulbar segment with prior history of radiotherapy, hypospadias, or BXO/LS features;
- Penile urethroplasties;
- Non-traumatic posterior urethroplasties;
- Graft or/and flap – substitution – urethroplasties.

Table 11.4: Follow-up protocol for urethroplasty with standard risk of recurrence

<td>+</td>
<td>On indication</td>
<td>On indication</td>
<td>On indication</td>
</tr>
</tbody>
</table>

* Follow-up could be discontinued after five years, advising the patient to seek urological evaluation if symptoms worsen. A longer follow-up period should be considered after penile and substitution urethroplasties. Academic centres could increase the length of follow-up for research purposes.

Please see Figure 11.1 for further guidance.
Figure 11.1: Follow-up after urethroplasty

Urethroplasty

3 months

Uroflowmetry
PROM – including sexual function
Urethrocystography / RUG-VCUG

Consider Flowmetry values, PROM and scores as new baseline values

Consider
1) Location of stricture
2) Urethroplasty technique
3) Prior radiotherapy
4) Hypospadias
5) BXO/LS

Low-risk of recurrence

Uroflowmetry
PROM – including sexual function

12 months after urethroplasty

Urethrocystography / RUG-VCUG
• If flowmetry $Q_{\text{max}} < 15 \text{ ml/s}$
• If flowmetry $Q_{\text{max}}$ descends 10 ml/s from new baseline (3 months value)
• If significant worsening on PROM values
• If clinically indicated

Uroflowmetry
PROM – including sexual function

Discharge patient, advising to seek urological evaluation if symptoms worsen

24 months after urethroplasty

Uroflowmetry
PROM – including sexual function

5 years after urethroplasty

Uroflowmetry
PROM – including sexual function

Urethrocystography / RUG-VCUG
• If flowmetry $Q_{\text{max}} < 15 \text{ ml/s}$
• If flowmetry $Q_{\text{max}}$ descends 10 ml/s from new baseline (3 months value)
• If significant worsening on PROM values
• If clinically indicated

BXO = balanitis xerotica obliterans; LS = lichen sclerosus; PROM = patient reported outcome measure; $Q_{\text{max}} = $ maximum flow rate; RUG = retrograde urethrography; VCUG = voiding cystourethrography.
